In the conversion of pig iron into steel by the Bessemer process there is a loss, which approximates 4 or 4.5 per cent of the total weight of the charge in iron and practically all of the manganese, which latter approximates ½ per cent, and making a total unavoidable loss of about 5 per cent of the weight of the charge in these two metals. For the open-hearth process some authorities give the amount of iron lost in open-hearth slag as 2.5 per cent of the weight of steel made, and the loss of manganese, 0.5 per cent.

It is an interesting fact that much of our iron ore contains the elements manganese and silicon in sufficient quality to meet the specifications of ordinary steel, and moreover, these elements are reduced in the blast furnace and are almost invariably present in the pig iron in sufficient quantity to meet

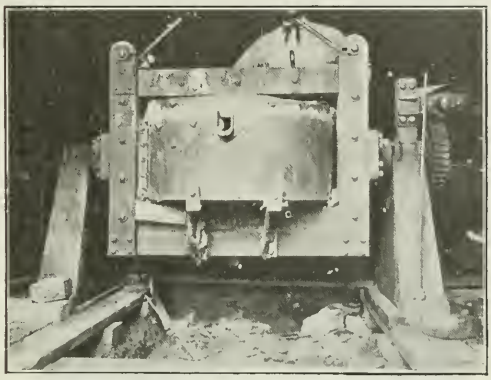

FIG. 2.—ELECTRIC CONVERTER.

requirements without any additions, were it possible to save them in the converter; but during the converter blow the silicon and manganese are practically all eliminated and then these alloying metals are put back again by charging into the steel some expensive alloy additions. It costs to reduce these elements in the blast furnace, and it costs to replace them again after they are oxidized. The value of the manganese so lost is quite important.

The object of Mr. Greene's paper is to point out how the electric furnace in combination with a control of chemical reactions by regulating the gaseous agents, provides a means of producing metal of higher grade and of doing it more efficiently and with far less loss than is possible in Bessemer or in open-hearth furnaces, and to describe a new process which takes advantage of a combined control of temperature and gaseous reagents to accomplish such a saving. The chief advantage of the electric furnace does not consist simply in its ability to produce extremely high temperatures; but rather in the fact that it provides a means of maintaining a charge at any given temperature, thereby enabling one to control the composition of the atmosphere at will.

In this connection Mr. Greene discussed the meaning of the term "neutral," as commonly applied to the atmosphere within furnaces in general, including electric furnaces. "Neutral" means inactive. But the atmosphere, if of proper composition, may react in such a way as to greatly aid a metallurgical process; for instance, the atmosphere in a steel-producing furnace might be reducing toward iron oxide and prevent the steel from oxidizing; or it might be oxidizing toward carbon or phosphorus, and thereby eliminate them. Now, it is a most interesting fact that we can have an atmosphere which is reducing with respect to iron oxide and nevertheless oxidizing toward carbon or toward phosphorus. For this reason it seems that the term "neutral" and also the term "non-oxidizing" is very indefinite, where there are different elements present, unless it is stated with respect to what the atmosphere is neutral or non-oxidizing.

In view of the fact that it is possible to have an atmosphere which simultaneously is reducing toward iron oxide and oxidizing toward carbon, the author sketches the following theoretical process for oxidizing carbon out of iron without oxidizing the metal itself. If molten pig iron be placed in a closed crucible,

made of magnesite for instance, and kept at a uniform high temperature, and the space above the iron in the closed crucible filled with carbon dioxide gas, the gas and iron will react and finally come to a state of equilibrium. The reaction might be represented as follows: $CO_2 + Fe = FeO + CO$. Under the equilibrium conditions which would be reached the ratio of the amounts of the two gases present would have a given value for the particular temperature.

If we then replace the mixture of these two gases by another mixture containing relatively more carbon monoxide and less carbon dioxide than the equilibrium mixture, and allow this new mixture to react with the iron and the iron oxide, some of the iron oxide would be reduced and the CO_2 component of the gas increased. This replacement could be made continuous by successive introductions of the new mixture. In this way reduction of iron oxide could be carried practically to completion, and moreover, this could be done by means of a gas containing an oxidizing agent for carbon.

This was the theory on which the American Electric Smelting & Engineering Company started in its experiments several years ago to develop a practical process for converting pig iron into

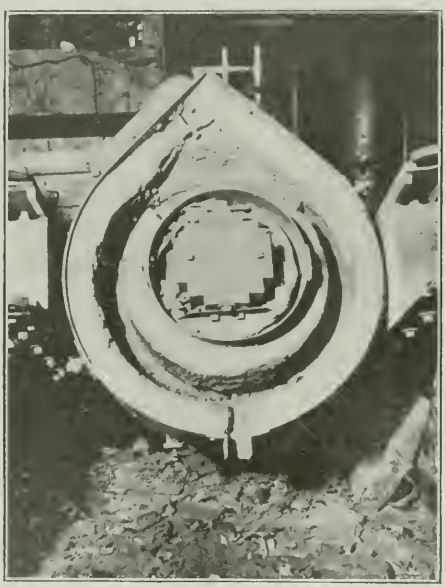

FIG. 3.—ELECTRIC INDUCTION-HEATED CONVERTER WITH COVER REMOVED.

steel and refining it without oxidizing the iron and other valuable constituent metals.

In the preliminary experiments it was found that there was a wide range of composition of mixtures of CO_2 and CO gases suitable to prevent oxidation.

It was found that producer gas might easily be made to serve the purpose, and that a producer gas containing as little as 4 per cent of carbon monoxide and as much as 15 per cent of carbon dioxide would, when blown into molten pig iron at a temperature of about 1450° C., eliminate the carbon with practically no oxidation of iron, manganese or silicon.

After the preliminary experiments which were made in small electrically heated crucibles, the process was carried out in an induction-heated vessel of 300 pounds' capacity.

This furnace had an enlarged portion at the back forming a pot, and tuyeres were put into this part in much the same way as they are put in a Tropenas converter.

The process consists of providing a bath of molten low phosphorus pig iron containing, for example, the usual proportion of manganese, silicon and carbon. The charge preferably contains sufficient manganese and silicon to slightly more than meet the specification for the particular steel to be made. The temperature of the bath is raised to something over 1425° C., and, while it is maintained by the electric heat, a gaseous mixture containing carbon monoxide and carbon dioxide is blown into the metal in much the same way as air is blown into a Tropenas converter.

This mixture may contain 12 to 18 per cent of CO_2 and 5 per cent or more of CO.

The rate of elimination is a little slower than with the Bessemer process for the same rate of blowing. A well-operated, side-blown converter requires from 25 to 35 minutes to make a blow, using about 1500 cu. ft. of gas per minute per ton of metal. In this small induction furnace, using about 50 cu. ft. of gas per minute per 200 lbs., or about one-third the rate of blowing in the side-blown Bessemer vessel just referred to, the carbon can be eliminated in something more than an hour and one-half, depending on how much carbon there is at the start. Thus, with only one-third as much gas blown per minute per unit weight of metal, the time is a little more than three times as long as for a similarly blown vessel using air. By increasing the rate of blowing the time can be very greatly cut down.

In this small furnace pig iron can be converted into steel with as small a loss of iron and manganese and silicon as 2.5 per cent, including losses of metal in charging and spills in handling the steel.

The most convincing evidence in Mr. Greene's opinion, that oxidation does not take place in this process may be found in connection with the loss of manganese. In converting a 13.4 per cent spiegel (containing 13.4 per cent manganese) into manganese steel they have done this without any additions of any kind and have produced a steel containing over 12.5 per cent manganese, and this was without the use of a slag to prevent vaporization. The carbon was reduced from over 4 per cent to 1.20 per cent.

In later tests, using a lime slag, the vaporization loss has been further diminished.

It is well known that the high percentage of carbon present in commercial ferro-manganese makes it practically impossible to obtain as much as 12 to 14 per cent of manganese in manganese steel without raising the carbon content above 0.9 or 1 per cent. No great difficulty is met with in producing very low-carbon manganese steel by the electric converter process, and the properties of low-carbon manganese steel are very interesting.

Mr. Greene finally considered the application of the process to the removal of phosphorus and sulphur and to the production of a high-grade steel from low-grade pig iron in one continuous process.

Mr. Greene states that in the electric converter he can oxidize phosphorus out of iron and hold it out by means of lime and do this with practically no oxidation of iron or manganese. He has done this at pig iron temperatures below 1350° C. without oxidizing carbon, and he has done it at high temperatures, above 1500° and up to 1900° after carbon has been oxidized. And beside these facts he found that the sulphur can be taken up and held in this same slag that holds the phosphorus, which action he attributes to the absence of oxide of iron in the slag.

He has converted a low-grade pig iron into a high-quality steel in one continuous operation in this way, taking out the carbon without oxidation of iron and manganese and then, with a lime slag on top of the metal, by continuing the blow of the gaseous mixture, the phosphorus has been oxidized and eliminated. The phosphorus was found combined with the lime as calcium-phosphate and practically all the sulphur was found in the slag as calcium-sulphide.

He has had such results as follows:

Analysis of charge.....	Phosphorus, .76%	Sulphur, .113%
Analysis after blow.....	" .026	" .040

and also

Analysis of charge.....	Phosphorus, .094	Sulphur, .040
Analysis after blow.....	" .008	" .017

He has carried out such a conversion of molten pig iron into refined molten steel as just outlined in less than thirty minutes, which indicates that the reaction takes place quite rapidly and that the problem of installing the process in large vessels of ten or more tons capacity is a mechanical one of getting the gas into the metal.

Mr. Greene then compared the electric converter process with the Bessemer converter, the open-hearth and the Bessemer converter electric furnace combination processes, and finally said a few words on the type of electric furnace used for his converter process. The induction furnace has shown important advantages. In the operation of this process in large induction-heated furnaces he believes that less than 30 kilowatt-hours per ton of steel will be required.

The substitution of a gas containing carbon monoxide and carbon dioxide for air is believed not to involve as great a change in present methods as at first it may appear to do. Such gas as is needed to carry out this process is available from cupolas or blast furnaces or may be made in a very simple gas producer. Blast furnace gas is preferably modified by mixture with stack gas, since the percentages of carbon monoxide in blast furnace gas is usually much higher than required. The process itself, at least in so far as the elimination of carbon is concerned, is a gas producer process, the off-coming gas being richer in CO and lower in CO_2 than when blown into the metal; and this fact opens the possibility of using the gas over and over by burning a part of it to maintain the desired composition.

The paper was briefly discussed by Dr. Richards and Mr. Hibbert.

The Pinch Phenomenon Employed for Electric Furnace Design.

A paper by Mr. Carl Hering, of Philadelphia, Pa., describes "a new type of electric furnace" in which use is made of the 'pinch phenomenon."

Let the circle, Fig. 1, represent the cross-section of a cylindrical conductor; the electromagnetic forces which constitute the pinch phenomenon tend to act radially as shown by the arrows. If now the conductor be made to be a vertical column of liquid as, for instance, the part marked "resistor" in Fig. 2, consisting of a hole in a non-conducting material closed at the bottom by the electrode and filled with the liquid, then these forces will act horizontally and perpendicularly to the axis along the whole length. They create a suction near the periphery and a pressure at the center.

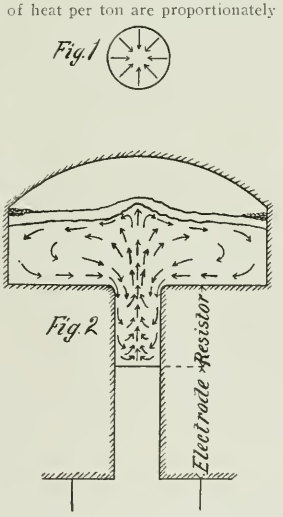
Moreover, by hydraulic action these radial forces in turn produce corresponding longitudinal forces at the center and at the periphery, and as these axial or vertical forces cannot expend themselves at the bottom they do so at the top, thereby producing a veritable fountain, as shown in Fig. 2, the liquid flowing up in the center and down at the periphery about as shown by the arrows; moreover, the direction of this hydraulic flow is independent of the direction of the electric current, hence is the same for direct or alternating currents.

This new phenomenon, which was colloquially named the "squirt phenomenon," is made by Mr. Hering the basis of a liquid resistor furnace. If such a column is made the resistor in which the heat is generated by passing the current through it by means of an electrode at the bottom, the heated liquid will be rapidly expelled and forced to the top against the blanket of slag, while the cooler liquid at the bottom will be sucked down into the hole near the circumference to be in turn heated and immediately expelled with considerable force. With energetic circulation through the resistors the fatal objections to the use of liquid resistors could be overcome.

In practice one would naturally use two holes, one for each electrode, as that reduces the depth of the hole to one-half. The proportions of the hole, that is, the ratio of the section to the length, are, of course, determined by the resistivity of the material, the amount of heat to be generated and the relation of the volts to the amperes; the actual dimensions are therefore still a matter of choice. The ejecting force, or "squirting force," increases with the square of the current and diminishes as the cross-section increases. It will be seen therefore that there is very fortunately some choice left as to the dimensions of these "flowing resistors."

In most materials there is apparently a very rapid rise of resistivity with the temperature, which is very favorable to the proportions of such resistors, as is also the apparently very rapid increase of the specific heat of iron at the higher temperatures.

The advantages of a furnace based on this principle are stated by Mr. Hering as follows: It is ideally simple and cheap, consisting merely of a crucible or hearth with two suitable holes in the bottom plugged with the electrodes. The heat is generated in the material itself, which is just where it is wanted; moreover, it is generated in the most rational place, namely, at the bottom and not on the top surface; it is conveyed and distributed mechanically, so to speak, throughout the melted mass, and this conveyance of heat is immensely more rapid than it would be by mere conduction or by the slow flow due to differences of density; hence a charge is treated and finished rapidly, whereby the output of the furnace per day is increased and the losses of heat per ton are proportionately reduced. As



FIGS. 1 AND 2.—PINCH AND SQUIRT PHENOMENA.

far as is known now there is no temperature limit except that of the failure of the refractory lining, as the pinch effect can no longer limit the temperature.

This very active agitation and circulation of the liquid mix the product rapidly with any of the refining ingredients which may be added and tend to make the product very homogeneous. Every particle of the liquid is in turn, and repeatedly, brought to the surface, where mechanically suspended impurities and gas bubbles are expelled and forced into the slag and where the metal is exposed to the chemical action of the slag. The temperature at the surface of contact of metal and slag, on which temperature the slag action depends, is maintained better when the heat flows up naturally from the hot metal to the cooler slag than when it is forced to flow down unnaturally from the hotter slag to the cooler metal.

Other advantages besides this lie in the fact that the electrodes are very cheap, are not consumed, and as they may be made of

metal they are far more economical in energy loss than carbon or graphite would be. No moving and adjusting of the electrodes are required. The interior of the furnace may be made as small as the quantity of material to be held requires, hence the thermal efficiency of the walls of such a furnace could be made to reach the practical maximum of all types of furnaces. Moreover, as the heat is rapidly distributed mechanically throughout the mass, the maximum temperature need be no higher than that required for the desired metallurgical or chemical action, hence the heat losses, which increase rapidly with the temperature, are correspondingly reduced; in this there is a great advantage over arc furnaces, in which the temperature is necessarily that of the vapor of carbon, hence immensely higher than what is needed.

The regulation is simple, rapid and in fact ideal. When the electrode is made of the same diameter and material as the resistor the furnace tends to become self-regulating as to temperature. When, for instance, the temperature becomes higher the electrode automatically becomes longer and the resistor therefore shorter, whereby less heat will be generated and the reverse when the temperature becomes lower. The place where the electrode ends and the resistor begins is, of course, that section across which no heat flows; the heat generated below this section flows out to the terminal and that generated above it flows into the furnace; it is this plane that automatically moves up or down.

The hottest liquid is that in the center of the resistors and is therefore not in direct contact with the refractory lining.

The friction of liquid against liquid, in the interior of the conductor, is far less than might be supposed, provided the liquid is in a very fluid state. The rapid flow is not along the walls of the hole, but in the center where it causes no wear.

The counter e.m.f. which must necessarily be generated by the movement produced is an advantage as it shortens the resistor.

By using a bath of some suitable metal in the bottom of the furnaces as the prime receiver of the heat, the furnace is adapted to be used to melt non-conductors like glass, or to heat granular ores, reduce and volatilize such metals as zinc and arsenic from their ores, etc. By dissolving carbon in the iron in one part of a bath and the oxide in another part, iron can be reduced from its ores and the CO gas produced can be burned to preheat the ore, whereby the total energy of the carbon may be utilized.

The power factor can, of course, be made very high, probably practical unity, and, unlike in the induction furnace, the frequency need not be abnormally low.

When badly proportioned the columns are apt to pinch off, causing rapid "makes and breaks"; this so greatly reduces the amount of heat which can be generated that there is danger of freezing. Such repeated breaking of the circuit should by all means be avoided. Several times a charge was left to freeze in the furnace over night and yet was readily started the next day from the cold state, thus showing that the resistors do not part in shrinking.

The larger the furnace the better and the less will be the difficulties, because the resistors then become shorter and thicker. There are, of course, many modifications which at once suggest themselves which will be tried in due course. It would be quite simple, for instance, to add gaseous fuel heat, or the heat of an arc, in the upper part; or to add the electrical parts to existing open-hearth or other furnaces and use the electric heat only for the final treatment.

The transformer is best attached directly to the bottom or side of the furnace, as the furnace currents are of course of low voltage, hence large in amperes. The flexible connections to a tilting furnace then consist merely of the two thin primary wires. The furnace is readily adapted to three-phase currents; the only change is that there will be three holes and electrodes instead of two. This is an advantage because for the same current in each electrode it shortens the resistors by one-third. A two-phase current may be readily transformed into one of three phases by means of a Scott transformer.

Under all conditions there should always be reached a stable state of temperature in the resistors, at which the heat generated in them is equal to that carried out of them mechanically; the best conditions must be determined by practice; fortunately there is a considerable range of latitude in the proportions which could be chosen.

Mr. Hering's paper is concluded by a list of some of the objectionable, troublesome or undesirable features of arc, induction and simple resistance furnaces with liquid resistors, and the claim is made that they would all be avoided entirely or at least lessened in his present type of furnace.

Mr. Hering's paper was discussed by Messrs. Hibbert, Clamer, Saunders, Richards, Hitchcock, Kemery, and Queneau. Mr. Hering stated that the tubes in which the squirt phenomenon is produced are made of alundum and Mr. Clamer stated that the wear and tear of the tubes is practically nil.

Iowa and Maine for Electrochemical Industries.

A paper by Mr. Frank P. H. Knight discussed the advantages of Keokuk, Ia., for electrochemical industries, due to the water-power development now going on. The initial installation will be 120,000 hp, which it is expected will be completed in two and one-half years. This will be increased later to 200,000 hp. The author also gave data on commercial advantages, natural resources, transportation facilities by rail and water, and factory sites.

A paper by Mr. C. Vey Holman, State geologist of Maine, discussed the advantages of Maine for electrochemical industries. He pointed out the geographical advantages and the possibilities of water-power developments; he estimated that 2,500,000 hp would be available. The author concluded with reference to the iron ores and other mineral resources of Maine.

After a vote of thanks to all who had made the convention successful, the meeting adjourned.

The next convention will be held in autumn at Toronto, Ontario, Canada.

In the following we give a complete alphabetical list of the names of members and guests in the last printed registry list. Where no city is stated, New York City is meant.

SYNOPSIS.

Gold and Silver.

Amalgamation Following Tube Milling.—It has been the generally accepted practice in South Africa that amalgamating plates in a tube mill plant should shake, as it was considered that the pulp was too concentrated to allow the gold particles to come in contact with the amalgamated surfaces of the plates. In the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa, for January, 1911, Mr. W. R. DOWLING gives some results obtained by stationary plates, showing that they are quite as efficient as the shaking plates.

The experimental work was carried on at the joint plant of the Knights Deep and Simmer East mines. Fifteen plates, each 10 ft. 5 in. long by 4 ft. 7 in. wide, of a three-tube mill plant were stopped shaking, and the fall of the plates increased from 10 to 18 per cent. Under these conditions amalgamation was most satisfactory. For the two months preceding the use of stationary plates the extraction by tube mills was 21.81 per cent of the screen assay value and 34.04 per cent of the tailing value. For the two months succeeding the extraction was 22.94 per cent of the screen assay and 34.02 per cent of the tailing assay.

With a view to reducing the number of plates if possible, it was decided to try a concentrating scheme. Two small cones and two stationary tables were erected. It was found that the gold released from the sand by tube milling could be concentrated in the underflow of the cones, and that the underflow with some diluting overflow could be handled by two plates. To test this scheme five and two plates took the pulp from one tube mill on alternate days. The result was a difference of 1.2 oz. of amalgam per day in favor of the two plates. After these results the entire plant was put on a basis of two plates per tube mill, and has been operating thus for some time with good results.

In adopting two instead of five plates it is important that the water ratio should be kept low, and it has been found that a moisture of 55 to 57 per cent, or a ratio of solid to liquid of about 1 to 1.27, is the irreducible minimum. Reduced to its simplest form amalgamation simply means bringing the amalgamable gold into contact with the amalgamated surface, and it is apparently accomplished by this arrangement.

Fine Grinding.—The all-sliming or one-product method of cyaniding gold and silver ores has been the subject of more or less varied criticism for some time. The latest and one of the most ardent champions of the system is Mr. H. S. DENNY, who contributes his views to the *Mining Magazine* (London) for March, 1911. Mr. Denny's wide experience in South Africa and Mexico will earn for him a respectful hearing.

Granting that in certain unusual cases the additional outlay for grinding machinery and operating cost will offset any advantages gained by fine grinding, Mr. Denny states most emphatically that as a generalization this belief is wrong. The most pertinent questions on the fine grinding process are its limiting factors and its efficiency. The former are involved in a comparison between the added cost of each extra unit of fine grinding and the added extraction, and are not easily determined. The author finds hope, however, in the recent work by Stadler on the efficiency of grinding machines, and believes that we may yet find a method of computing with some degree of accuracy the all-important figure of cost. As regards the added extraction, there is no doubt that if care is taken this point can be determined.

Discussing the economic considerations, the author assumes the treatment of a silicious ore containing 5 per cent pyritic material. Assume that this be ground to 60-mesh, and that 90 per cent of the pyritic content can be concentrated, carrying 70 per cent of the gold. If the ore assays 0.4 oz. per ton we have after concentration: 4.5 tons of concentrate carrying 28 oz., or 6.22 oz. per ton; 95.5 tons of pulp carrying 12 oz., or 0.125 oz. per ton.

If the pulp were then classified we probably would have, say, 65.5 tons of sand, assaying 0.15 oz. per ton, and 30 tons of slime, carrying 0.0725 oz. per ton.

Now, assuming that an extraction of 80 per cent could be made on each of the above products (concentrate and pulp) by agitating and pressing and without further grinding, the question naturally would arise as to application of finer grinding. It is quite clear that the concentrate is the portion demanding attention. An 80 per cent extraction of the 6.22 oz. would leave a residue of 1.24 oz., whereas an 80 per cent extraction on the original ore (80 per cent of 0.4 oz.) would leave a residue of only 0.08 oz., and it would at once seem possible to materially reduce that by a proper handling of the concentrated portion.

Fine grinding would be suggested as the remedy and might be accomplished as follows:

Regrinding all the pulp from the crushing plant that is coarser than 200 mesh.

Regrinding a hydraulically classified portion of the pulp.

Regrinding a carefully concentrated portion of the pulp.

Assuming that one of these methods was followed and that the extraction would be increased from 80 to 94 per cent, we would find that our concentrate is the portion yielding the greatest increase extraction, and is, therefore, the part to be

considered most carefully. The question would arise whether it might not be best to get a very clean concentrate and regrind that portion only. The main points in connection with this are:

What is the cost per ton of regrinding from 60 to 200 mesh?

If the sand is not reground would it be necessary to have a separate treatment plant for it, or could it be mixed with the concentrate?

If 50 per cent of the valuable content of the ore could be extracted by amalgamation, would that step be advisable, even though the ultimate recovery would not be increased?

As the concentrate contains the bulk of the value, would it not be well to make some provision for regrinding this product so as to insure reduction to absolute impalpability. Could this be done, and how?

Answering these questions seriatim, the author believes that:

The cost of regrinding from 60 to 200 mesh will not be far from the average figure of 75 cents per ton, although varying conditions may change this.

It would not be wise to try to treat the unground sand and the reground concentrates together. In filter pressing the mixture of coarse and fine would cause trouble. While it would be necessary to have separate treatment plants for sand and concentrate, the sand need not be ground so fine as the concentrate. A plant designed to handle and treat one product only would be much more simple in design, less costly in capital outlay, and cheaper to work than a plant consisting of three departments for as many products.

There is nothing to be gained by a recovery of 50 per cent by amalgamation, because the operation costs something and involves some loss, and because it is too easy to steal gold in amalgam form. The extra consumption of cyanide and zinc would be almost inappreciable if all the gold were recovered in the cyanide solution.

If a clean concentrate can be made there is little doubt that it would be advisable to recover it and grind it to impalpable pulp, which is possible in several ways.

The author quotes from a paper of A. Grothe presented before the Mexican Institute of Mining and Metallurgy, in which Mr. Grothe shows a flow sheet embodying the idea of regrinding concentrate and coarse sand in tube mills, keeping the concentrate in the circuit of tables and tube mill until it is ground fine enough to pass off from the tables with the slime.

The author concludes as follows: The day of the percolation method of treatment for sand and the decantation system for the treatment of slime has gone, except in special cases, and it is only due to the persistence of some of the metallurgical fraternity who have been wedded to these ideas that they are to-day included so freely in the treatment of simple gold ores. There can be no logical argument opposed to the principles of the one-product treatment now becoming almost universal, and the only points remaining for settlement are the methods and devices to be adopted in fine grinding, and the degree to which this principle is to be pushed in order to gain the best results.

Modern practice has so emphatically taken up the circulation of cyanide solution throughout the entire plant, followed by fine grinding and filter pressing, and the results have so abundantly demonstrated the value of this practice that there can no longer be any discussion as to its merits. The author predicts that the tendency in the future will be to crush in stages, classify, grind in stages, agitate and filter press on the one-product principle. He believes that the upshot will be cheaper plants, lower working costs and improved extractions.

Combination Treatment of Silver Ores.—As an example of the combination concentration-cyanide treatment of a Mexican silver ore, V. B. Sherrod contributes an experience to the *Mexican Mining Journal* for April, 1911. Before the present system of treatment was adopted a great deal of unsuccessful experimental work was done in an effort to dispense entirely with concentration. Extraction was fair but consumption was prohibitive. A thorough concentration was possible and successful metallurgically, but the grade of the concentrate was so low that marketing costs would have been excessive.

Finally a series of experiments conducted for another purpose showed how a combination could be effected, whereby the grade of the concentrate would be high, and the consumption of chemicals in cyanidation would not be much higher than when concentration was thorough. The following screen analysis of the lip sample from a battery crushing through 4-mesh screen illustrates the possibilities of concentrating a selected portion of the pulp, selection being made by screening, followed by hydraulic classification or not.

Screen Size	Per cent of Total Pulp	Kilos Silver	Per cent of Total Value
— 20	43.9	0.647	35.3
— 40	13.6	0.733	12.4
— 80	11.2	0.876	12.4
—150	6.6	0.850	7.0
—200	2.7	0.968	3.2
—200	22.0	1.086	29.1

A trial of the concentrates from the above samples showed that every particle of mineral liberated would easily pass a 60-mesh screen, but on account of the trouble and expense connected with fine wet screening it would be ore practicable to use coarser screens and handle a somewhat larger tonnage for the concentration. A Callow screen of 30-mesh slot-woven wire cloth, traveling at 60 feet per minute, gave the following results:

	Screen Size	Per cent of Total Pulp	Kilos Silver	Per cent of Total Value
Oversize.....	30	49.5	0.653	40.5
Undersize.....	30	50.5	0.945	59.5

The undersize from the above operation was classified into two grades of sand and one of slime, the latter being sent directly to the slime plant. By this scheme a very high grade of concentrate was obtained, and six tables were sufficient for a 300-ton plant. Conditions in the cyanide treatment were more normal, and the problem was solved successfully.

ASSAYING.

Notes on the Matte Assay.—Most assayers will be surprised to hear a method of fire assaying recommended which intentionally gives rise to the formation of a matte. Such, however, is the recommendation of Mr. L. J. Wilmoth, who communicates his method in the December *Journal* of the Chem. Met. and Mining Soc. of South Africa. He suggests its use for the assay of battery chips of iron and steel, and for copper drillings. He has even extended it to the assay of high-grade copper-bearing material with good results. The principal advantage derived from the formation of a matte is that it will take care of a large amount of base material.

The following charge was used with metallic copper: Drillings, 10 g; litharge, 1 AT.; sodium carbonate, 1.5 AT.; borax, 1 AT.; silica, 0.5 AT.; charcoal, 1.25 g; sulphur, 8 g; and a heavy iron nail. The average result from three assays was 16.417 per cent gold. The same sample assayed by the scorification method gave 10.31 per cent fine gold, and by the combination method, 10.49 per cent.

For copper matte carrying 25 per cent to 30 per cent copper and some lead the charge consisted of: Matte, 0.5 AT.; litharge, 1 AT.; sodium carbonate, 1 AT.; borax, 1 AT.; silica, 1 AT.; sulphur, 0.1 AT.; charcoal, 1.5 g; and a heavy iron nail. On pouring the charge the matte was easily detached from the lead button. On reassaying the matte it was found to contain no gold and only a little silver.

The author concludes that the application of the matte assay for copper-gold-bearing ores and products presents no difficulty and is of great advantage when the percentage of copper is high and the gold value low. The advantage is illustrated by the assay of 20 per cent copper matte. In this case a scorification gave 48.5 dwt. and a matte assay 53 dwt. per ton.

Recent Metallurgical Patents.

Iron and Steel.

Improved Construction.—With the object of providing a cheap, simple and efficient form of bosh, in which burning out is reduced to a minimum, Mr. FRANCIS J. ZIPPLER, of Avalon, Pa., has patented a form of construction shown in the accompanying cuts, Figs. 1 and 2. Fig. 1 shows the lower portion of a furnace embodying his form of invention, in which 1 represents

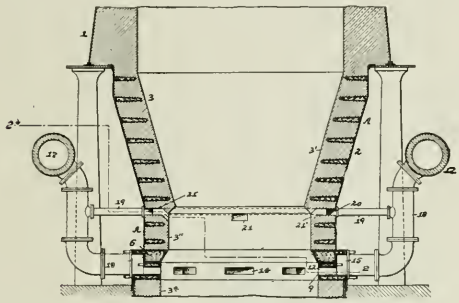

FIG. 1.—BOSH CONSTRUCTION.

the upper portion and 2 the bosh of a furnace. Fig. 2 represents a section along the line 2-2 of Fig. 1. The usual bustle pipe and tuyere supply pipes are designated by 17 and 18 respectively. Water jackets 6 and 9 form an annular air chamber 15, into which air from the pipes enters, being deflected into pockets 13 formed by the walls 12, so that it will pass around the same and into the tuyeres 14 of the furnace. At the same time a portion of the air blast will pass through the pipes 19, and thence into an annular space 20 in the wall portion 3", and enter the tuyeres 21. Owing to the tapering construction near the tuyeres, the lower or main blast is directed upward, and that from the auxiliary blast downward, through the charge. By the use of the annular air chambers, a large volume of air

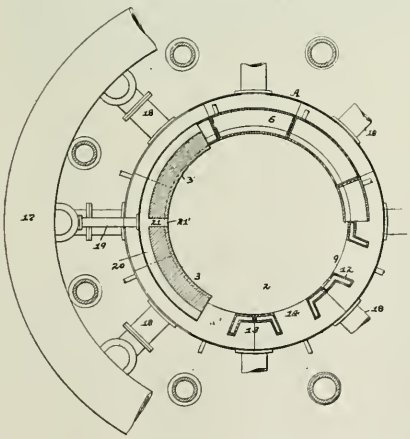

FIG. 2.—BOSH CONSTRUCTION.

is admitted and equalized before it passes through the tuyeres. By the use of the upper tuyeres in connection with the lower, the furnace is prevented from scaffolding, and will economize in fuel. The construction is further claimed to prevent the burning out of the bosh walls and the contained tuyeres. (986,792, Mar. 14, 1911.)

Conversion of Iron to Steel.—The type of apparatus in which iron is converted into steel by means of a surface blow is the subject of a patent granted to Mr. SELDEN S. DEEMER, of New Castle, Del. In this process as heretofore practised there has been inefficiency by reason of the sluggish movement of the molten bath, and the difficulty of introducing means of desulphurizing, dephosphorizing, decarbureting or recarbureting the metal. The inventor's proposed converter and process are designed to overcome these objections.

Fig. 3 is a side elevation of the converter, and Fig. 4 a section on line 3-3 of Fig. 3. The converter has the usual outer shell and lining, with the bottom of the hearth rounded to present as little resistance as possible to the circulation of the metal during the blow. Air for the surface blow is provided by a suitable engine, and conducted to the tuyere *B* by way of the connection d^1, c and wind box *C*. The trunnion *D* is hollow and provided with a slotted opening *d*, through which the air may flow when the converter is in proper operating position. The tuyere may be a series of small openings or a single long one in the form of a narrow slot.

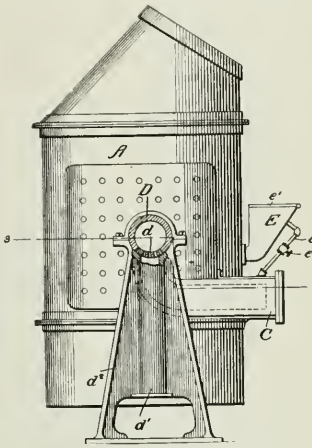

FIG. 3.—CONVERTER.

In order to provide for the suitable introduction of reagents at the proper time, a charging box *E*, divided by partitions and served by air from the main air chamber through pipes e^2, controlled by valves e^3, is placed just above the wind box as shown in the cut. The opening from the charging box into the converter is arranged to deliver the reagents onto the molten bath at a greater oblique angle than that of the surface blow.

In operation the converter is charged with molten low-grade metal, such as pig iron, to the proper depth; the charging box is filled with the proper reagents; the air blast is turned on and the surface blow continues, with rapid circulation of the metal, until the time arrives for the charging of the reagents. This is accomplished by opening the proper valve e^3. When the blow is completed the converter is tipped and discharged in the usual manner. (987,704, March 28, 1911.)

Agglomerating Fine Ore.—The preparation of fine and friable iron ores for smelting is the subject of an invention of Mr. HUGO DICKE, of Frankfort-on-the-Main, Germany, which he has assigned to Jacob E. Goldschmid, of the same place. The inventor claims that in previous devices for agglomerating fine ore the principal fault has been the method of firing. He states that by firing a revolving furnace with water gas entirely new results are obtained in the treatment of iron ore. Not only can all the good results heretofore accomplished be obtained in the water-gas flame, but, owing to its peculiar formation, oxidation or reduction and fusion can take place at will. The essential advantage of the water-gas flame is the possibility of controlling it and adapting it to the needs of the material under treatment.

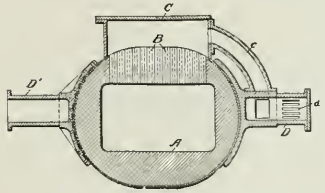

FIG. 4.—SECTION OF CONVERTER.

In the practice of the invention it has been ascertained that what is called a neutral water gas flame, viz., one in which the proportions of gas and air are in chemical equivalents, iron ores of the formula Fe_2O_3 can be reduced to Fe_3O_4, and that this will continue, even though the flame be slightly oxidizing.

The working of the furnace can be so regulated as to produce three zones of action; one in which drying and preliminary heating occur; another where oxidation and fusion are in progress, and a third where volatilization of noxious elements such as sulphur and arsenic may be removed. The inventor states that the furnace and water-gas flame may be used with equal advantage on ores of iron, copper, etc., the removal of small quantities of zinc, sulphur, arsenic, etc., being greatly facilitated in case of the latter. (986,271, March 7, 1911.)

Still another method of preparing fine materials for furnacing is that recently patented by Mr. George W. Coggeshall, of Dedham, Mass. The process does not relate especially to iron ores, but is applicable to the preparation of mixtures of fine material preliminary to some subsequent operation in a furnace. The principal idea involved is to add a suitable binding agent, such as water or a solution of sugar, glue or the like, to an excess of the dry mixture, thus getting the full benefit of the binding agent without using an excess of it: then screening the unbound material from the nodules formed by the binder, and treating the nodules in any way desired. The operation can be carried on in an ordinary rotary drier, the upper part of which is screened to permit the discharge of the fine unbound material. The nodules pass over the screen to the lower part of the tube, which may be heated to bring about the desired reaction between the constituents of the nodules.

Specifically, the inventor applies his operation to the formation of potassium titanate, which is formed from dry, finely ground titanium oxide and anhydrous potassium carbonate. The mixture is subjected to the action of drops of water which agglomerate it into nodules, which are later heated to perfect the reaction. This takes place at a dull red heat and is almost quantitative in as short a time as 17 minutes. (987,554, March 21, 1911.)

A Blazing Tuyere has been devised by Mr. Charles A. Case, of New York, for the purpose of firing a furnace with liquid or gaseous fuel admitted through the tuyere with an air blast, and igniting the fuel electrically as it passes through the tuyere. The air jet passing through the tuyere has a tubular core of low-pressure air, surrounded by a zone of high-pressure air. The oil or gas used as fuel enters with the low-pressure air and passes an arc which ignites it. Combustion is supported by the low-pressure air core, while the high-pressure zone protects the shell of the tuyere from burning and supplies oxygen for the reduction of the ores in the furnace. (985,394, Feb. 28, 1911.)

Gold and Silver.

Treatment of Telluride Ores.—In view of the speculation which has been rife regarding the process used by the Portland Gold Mining Company at its mill at Victor, Col., the following patent specifications will be interesting. They form the basis of a patent granted to Mr. Thomas B. Crowe, superintendent of the Victor mill and one of the staff engaged in experimental work prior to the adoption of the process now used. It is not to be inferred that the following is a statement of the process now being used at Victor, although it may contain some of the essential details.

The two main points in the patent are that an alkaline hypochlorite is a solvent for tellurium, and that, in order to apply this reaction profitably to telluride ores, it is necessary to remove from the ore all possible reducing agents, such as sulphides of the base metals. Another essential is that the natural acidity of the ore be *just* neutralized, instead of having an excess of lime, for example, as is customary in ordinary cyanidation.

The inventor mentions the use of an alkaline persulphate with potassium cyanide for the similar purpose of dissolving tellurium and gold in telluride ores, but states that he has found the required quantities so large as to be economically prohibitive. He further states, however, that he has discovered that cyanogen iodide will serve as a suitable and efficient solvent if the natural acidity of the ores is just neutralized as stated above. The advantage in the use of cyanogen iodide is that it is at once a solvent for both gold and tellurium thus being a simpler reagent than a combination of, say, potassium cyanide and an alkaline persulphate. The claims granted in the patent, however, refer only to the use of an alkaline hypochlorite and alkaline cyanide, and not to the use of cyanogen iodide. The removal of sulphides by concentration and the neutral state of the ore are referred to as necessary conditions. (987,964, March 28, 1911.)

Vacuum Filters.—A continuous vacuum filter has been devised by Mr. George Johnston, of Chihuahua, Mexico. As to its type, it consists of a number of filtering frames of

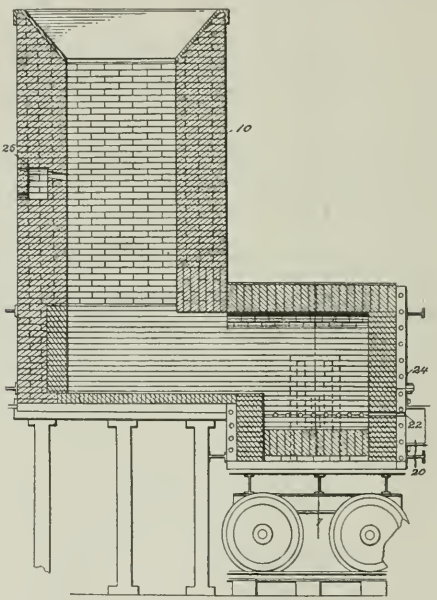

FIG. 5—VACUUM FILTER.

the usual construction arranged singly or in groups around an axis. The axis and frame are made to revolve so that the filter frames are successively immersed in the pulp to be filtered and raised out of the pulp for the purpose of washing and discharging the cake. The filter is in reality a modification of the drum filter idea, in which the filter surface is made of a number of frames, instead of the periphery of a drum. Or, in other words, it is a modification of the ordinary leaf filter idea, in which the leaves are subjected to continuous instead of intermittent operation.

The apparatus is arranged in such a manner that when the filter leaves are immersed in solution they are also in connection, through suitable valves, with a vacuum pump, and that as they revolve out of the solution they are brought to a position convenient for washing and dumping the cake. If used for the filtration of gold cyanide solutions it would appear that the filter is not complete in itself for there is no provision for displacing the solution held in the pulp, and this operation would have to be performed in a second filter treating the discharged cake from the first. (988,107, March 28.)

Copper.

Continuous Matte Smelter.—A novel idea in copper smelting furnaces has been patented by Messrs. REDICK R. MOORE, of Garfield, and JOHN H. KEES, of Salt Lake City, Utah. The furnace has for its object the continuous production of a matte of lead, copper, nickel, cobalt and the precious metals, without the need of previous roasting and without the addition of carbonaceous fuel.

As shown in Fig. 5, the furnace consists of a stack 10 and a converting chamber 14 connected by a passage 13. The converting chamber is suitably mounted on wheels to facilitate its removal for repairs, etc.

The underlying object is to utilize the heat escaping from the converting chamber to smelt the ores in the stack, causing them to melt and run into the converting chamber, where they are converted into a matte by a suitable blast applied through tuyeres 22. The air blast is supplied through a flue 20 surrounding the converter. The latter is water jacketed in the usual manner, shown conventionally at 24.

In operation the stack 10 is charged with the ores to be reduced, and a quantity of molten matte from any source is placed in the converter. Vapor of S and SO_2 are both present with nitrogen in the upper part of the furnaces treating pyritic ores and the sulphur will condense on the cool charge if it be high enough above the source of heat. As the charge continually travels downward the condensed sulphur will be again vaporized, resulting in a zone where the charge is permeated with sulphur vapor. This may be removed by a condensing arrangement, 25, which is a pocket opening in the stack wall.

When the air blast is turned on heated air will be forced through the matte, oxidizing iron, sulphur, etc., forming ferrous sulphide which will unite with the silica and other constituents of the charge in the stack to form a molten slag and produce sulphurous gas which with the nitrogen of the air will give up its heat to the cooler charge in the stack (thus melting down more sulphide to be converted into matte in the lower chamber, and supply fuel for further smelting. (985,105, Feb. 28.)

Treatment of Low-Grade Ores.—The recovery of copper from the so-called porphyry copper ores of the West is usually accomplished by concentration and smelting. The ores contain an average of 2 per cent copper and they are treated on a huge scale. Mr. GEORG SCHNEIDER, of Lauenstein, Germany, proposes a chemical method of treatment which he believes would result in greater percentage recovery of copper.

His experiments have shown him that such ores are amenable to treatment consisting of a roast with 10 per cent salt at a low red heat, and subsequent lixiviation with 5 per cent HCl solution for eight hours. His tests showed that ore containing 2.34 per cent copper would yield 2.22 per cent metal. He finds that these results are due to the presence of silica in the ore, which acts in a way to decompose the alkaline chloride used, liberating chlorine for the chlorination of the copper sulphides. It is claimed that this process would be cheaper and more efficient than the present method of concentrating and smelting, and that ores of as low a grade as 1 per cent copper could be treated at a profit. Any silver in the ore would be extracted as chloride in the presence of iron and alkali chlorides and gold would have to be extracted by the ordinary chlorination process. (986,508, March 14, 1911.)

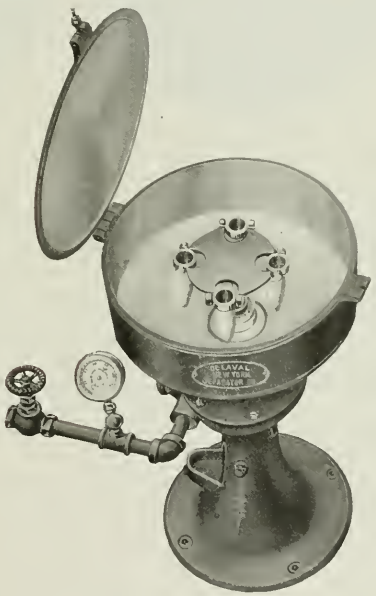
Nickel.

Sulphide ores of nickel, cobalt, iron, copper, arsenic, zinc and molybdenum, but particularly nickel, may be treated according to a process recently patented by Mr. JAMES A. MCLARTY, of Toronto, Canada. His object is to oxidize the sulphide ore without resorting to the usual roasting process. Preferably he first concentrates the ore in the usual manner, after which it is treated in a magnetic concentrator to remove iron and nickel sulphides. These are then oxidized by heating in a closed vessel with steam at 125 lb. pressure. The reaction which follows forms oxides of the metals and H_2S gas. The nickel oxide thus formed is not magnetic and may be removed from the iron oxide which is magnetic by again passing the pulp through a magnetic separator. (987,156, March 21, 1911.)

Centrifuge Tester.

In our March issue, page 147, a machine for the separation of liquids and solids by centrifugal force was described, which has recently been developed by the De Laval Separator Company, 165 Broadway, New York City. In this development work, which extended over ten years, the engineers of this company had to carry out a large number of tests with mixtures of materials of all kinds to see what kind of a separation could be made with them by centrifugal force.

For these tests they developed a small centrifugal tester, which has proven exceedingly convenient and handy for such work. It is operated by direct steam, the steam acting on a turbine wheel mounted on a flexible shaft, and the driving mechanism being very similar to that of the well-known De Laval cream separator. On the basis of many years' practical experience with the latter it has been possible to give to the



CENTRIFUGE TESTER.

small centrifuge tester a very rigid and compact construction.

When the tester revolves the test tube pockets take a horizontal position, as is indicated by a dotted line for the right-hand pocket in the adjoining illustration. There is, of course, nothing new about this. But the feature of the De Laval tester is the exceedingly high speed which can be obtained without difficulty and the wide speed limits within which it can be operated. This tester can be driven up to a speed of 4000 revolutions per minute, which is believed to be much higher than the maximum speed obtained in former machines of this kind. In this way a pressure of 168 pounds per square inch can be obtained for water, the corresponding pressures for other materials being easily determinable from this figure with the aid of their specific gravities.

As the speed can be lowered down to about 100 revolutions per minute, it is evident that any suitable pressure within wide limits can be obtained and that with this tester it is easy to determine quickly the possibilities of separation by centrifugal force in any given case.

A New Type of Synchroscope.

In the alternating-current power plants, which are now the rule rather than the exception in our large metallurgical and chemical works, the parallel connection of alternators is still at times a troublesome problem. At present there are only two types of synchronizing device in general use, namely, the synchronizing lamp or voltmeter and the rotating synchroscope. The first method is crude and consumes much time. It is entirely unsuited to use on large systems. The second device is unreliable and is generally used with synchronizing lamps to guard against a fatal error. At best the rotating synchroscope, even when combined with a lamp, is an extremely unsatisfactory device, since it requires the operator to divide his attention between the lamps and the instrument.

FIG. 1.—FRONT VIEW OF SYNCHROSCOPE.

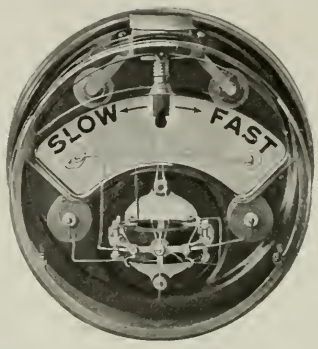


FIG. 2.—PHANTOM VIEW SHOWING LAMP AND POINTER.

There has recently been placed on the market an entirely new type of synchroscope, which has all the characteristics of an ideal rotating synchroscope and at the same time its indications are infallible and accurate.

In construction the instrument is quite similar to the new Weston type switchboard single-phase wattmeter; that is, it is a Weston electrodynamometer instrument. The pointer is mounted behind a translucent glass and stands normally in the middle of the scale. Behind the pointer is installed a small synchronizing lamp, which casts the shadow of the pointer on the scale. The pointer is only visible by the light from this lamp.

The connections of the instrument are shown in Fig. 3. The movable coil is connected in series with a condenser across the incoming machine, while the fixed coil is connected in series with a slightly inductive resistor across the line. The lamp is connected in the secondary circuit of a special three-legged transformer with two primaries, one across each source. The lamp transformer, condenser and resistor are mounted on one base and installed in an auxiliary box.

The mode of operation may be easily comprehended by thinking of the instrument first as a correctly designed wattmeter. It is well known that a good wattmeter will show no deflection when the current and e.m.f. are in exact time quadrature; therefore, in the present instance, if the constants of the circuits are properly chosen the currents in the coils will be in quadrature when the e.m.fs. of the two sources are in phase coincidence or in phase opposition. That is, the pointer stands at rest in the middle of the scale under these conditions, and since the lamp is dark when the e.m.fs. are in phase opposition, it will be seen in this position only when the machines to be synchronized are in exact phase coincidence with each other.

For every value of phase displacement between the e.m.fs. a corresponding torque will be developed and the pointer will be deflected to one side or the other, depending upon whether one of the waves is lagging or leading with respect to the other. That is, a good wattmeter connected in this way will indicate the phase displacement between two e.m.fs.

When the frequencies of the two e.m.fs. differ, the phase displacement between the two will vary continuously through complete cycles of 360 time degrees and the currents in the coils of the instrument will alternately lag and lead with respect to each other, and the pointer will swing back and forth over the scale.

Such an instrument would indicate a difference in frequency, but would give no information as to which one of the machines is fast or slow. Here is where the lamp comes in. One complete swing corresponds to a phase displacement from quadrature plus or minus to quadrature minus or plus, and this period also coincides with the period of incandescence or darkness in the lamp; therefore, the pointer will be seen only during every other swing, and will appear to rotate smoothly and silently in one direction. The direction of apparent rotation indicates whether the incoming machine is fast or slow and the speed of rotation is a measure of the amount by which the frequencies differ.

Just what takes place inside the instrument is best demonstrated by a diagram such as Fig. 4. At the top of the diagram are shown two waves, which differ in frequency. These two waves may be chosen to represent the currents in the primaries of the lamp transformer, then the resultant (shown dotted) may be considered as the current active in the lamp. Assuming that when the resultant current remains inside the shaded band the lamp filament will not be incandescent, the period of light and darkness is roughly determined by considering the points where the current crosses the band as transition points between light and darkness, which may be found from diagram.

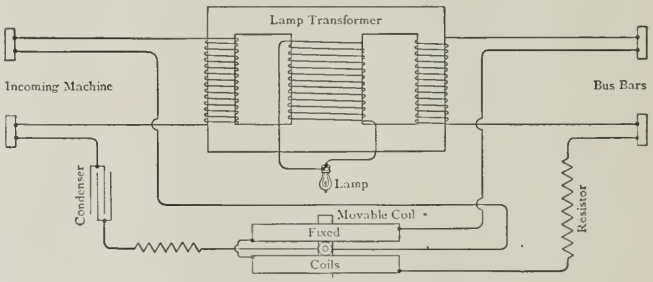

FIG. 3.—CIRCUIT DIAGRAM.

Assuming the fast wave to belong to the incoming machine, the currents in the coils of the instrument may be represented by plotting the slow wave exactly as it is shown at the top and plotting the fast wave 90 time degrees ahead of its original position to allow for the effect of the condenser. This has been done in the middle set of waves. The product of these current waves gives the torque active in the instrument, which is shown by the curve bounding the shaded areas. The sloping straight lines indicate the general trend of the average torque. They show that when the incoming machine is fast the pointer travels from left to right during the time the lamp is lighted.

The bottom set of waves is constructed in the same way as the middle set and shows that when the incoming machine is slow the pointer reverses the direction of apparent rotation.

The accuracy of this instrument is quite remarkable, es-

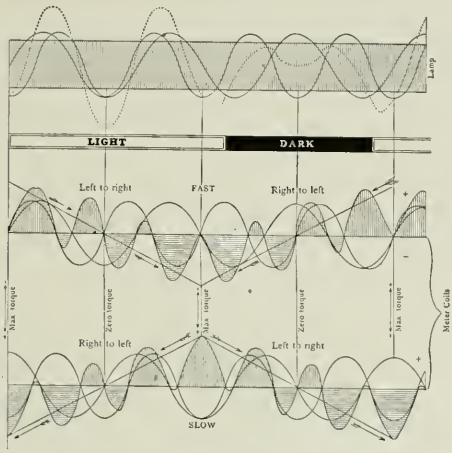

FIG. 4.—PERFORMANCE DIAGRAM.

pecially as regards its freedom from errors due to fluctuations in voltage or frequency. For example a 60-cycle, 110-volt synchroscope, when subjected to frequencies varying from 40 to 80 cycles per second and e.m.fs. varying from 95 to 130 volts, indicated true synchronism to within 1 deg. of phase coinci-

dence. This new type of synchroscope has been placed on the market by the Weston Electrical Instrument Company, of Newark, N. J.

The application of these principles to the operation of a synchromizing device is the invention of Mr. B. P. Romaine.

Personal

Mr. Lucien I. Blake, consulting engineer of the Submarine Signal Co., Boston, and inventor of the Blake machine for electrostatic separation of ores, intends to spend the coming year in Europe, traveling in the interests of the Submarine Signal Company and to inspect various ore treatment plants. Mr. Blake has made his home in Denver for the past few years, where certain problems in ore dressing have attracted his attention.

Mr. Warren F. Bleecker, of Denver, is spending some weeks in New York preparing for the erection of a mill in the San Juan district of Colorado, for the treatment of vanadium ores.

Mr. D. W. Brunton has returned to Denver after spending a few weeks at Hot Springs, Ark., where he was obliged to go for his health.

Prof. Bucherer, of Germany, during his recent brief stay in this country, attended the smoker at the New York meeting of the American Electrochemical Society. While he is now professor of theoretical physics at the University of Bonn and, by fundamental experiments, has largely contributed to the modern theory of relativity, Professor Bucherer was years ago among the pioneers of industrial electrochemistry, being connected for a year with Mr. Alfred H. Cowles in his early electrochemical development work.

Mr. J. J. Fitzgerald, of Florence, Colo., is acting as mill superintendent for the Frontenac Consolidated Mines, Ltd., at Black Hawk, Colo.

Mr. Mark R. Lamb, who recently returned from a South American trip, has been appointed manager of the South American branch of the Allis-Chalmers Company, with offices in Santiago, Chili.

Mr. Victor G. Hills, of Denver, has been appointed consulting engineer of the Scheelite Mines, Ltd., in Nova Scotia.

Mr. Frank Klepetko has been in Peru making an examination of the Ferrobamba copper property.

Dr. Karl Georg Frank, the American representative of the Siemens & Halske Company, has sailed for Germany and is expected back in about two months.

Chief Engineer Maleyka, Mr. Werner von Siemens, and **Dr. Puppe,** all of the Siemens & Halske Company, of Germany, are in this country to study American practice in the use of electric power in large metallurgical plants, especially electric driving of rolling mills.

Prof. Robert H. Richards will spend some time in the West this spring, visiting Montana and other Western States.

Mr. Jesse Scobey has acquired an interest in the ore-testing plant of Henry E. Wood, Denver, and will be in charge of the works in the future. Mr. Scobey's superintendence of this work will insure fair and accurate tests on ore sent to the plant.

Mr. George F. Waddell, mill superintendent of the Nevada Consolidated Copper Company, McGill, Nev., is making a professional trip among the Western copper concentrators to inspect the methods of slime treatment, with a view to making some improvements at McGill.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

317,246, May 5, 1885, to Edward P. Thompson, of Elizabeth, N. J., and E. P. Roberts and G. H. Pierce, of Cheyenne, Wyom., assignees.

Gold. Electro-deposits from a solution of its chloride The cell is a circular vessel, containing concentric annular cathodes of corrugated sheet copper. Between them is an anode consisting of depending electric-light carbons arranged in a circle. Steam is admitted to the electrolyte, heating and agitating it. The gold-plated cathodes are then removed to another cell containing a solution of sulphuric acid or copper sulphate and a current is passed from them to an intermediate cathode of copper. The copper of the former cathodes, now anodes, is thus dissolved and redeposited, leaving the gold.

332,705, Dec. 22, 1885, to Henry H. Eames, of Philadelphia, Pa.

Gold, silver, etc. Electrolytically chlorinates prior to amalgamation or lixiviation. The cell is a cylindrical iron vessel

lined with wood and having a steam-tight iron cover with manhole, safety valve and gage. The electrodes are opposed copper plates, secured to the inside of the tank and extending from top to bottom. A shaft passes up through the bottom of the cell, carrying a water-sealed depending cone with vertical stirrers. The electrolyte is a solution of sodium chloride, sulphuric acid, or iron or copper sulphate, into which the pulverized ore is charged. Steam is used at a pressure of from 20 lb. to 25 lb.

333,815, Jan. 5, 1886, to Michel Body, of Liege, Belgium.

Gold, silver, copper, nickel cobalt. The ore is subjected to preliminary treatment by exposing a heap of it wetted, to the atmosphere. Spent electrolytic liquor is preferably used for wetting. Or a sodium chloride solution, or calcium or magnesium chloride lyes, may be used. Or the pulverized ore can be roasted. The ore is then electrolytically dissolved at the anode of a cell containing a solution of a ferric salt and sodium chloride. The ores are thus dissolved by the action of the ferric salts, simultaneously converted into ferrous salts; the dissolved metal is deposited at the cathode, and the evolved chlorine re-oxidizes the ferrous salts, any excess assisting in dissolving the ores. The electrolytic cell is a rectangular vessel of Portland cement, painted inside and out with an impermeable coating. The inner portion of this floor is elevated and supports a carbon-plate anode. The four sides of the vessel are lined with carbon. A central compartment is provided by vertical inner walls, between the lower ends of which and the elevated portion of the floor are diaphragms of felt. The ore is placed in this central compartment, which contains a revolving stirrer, resting on the carbon anode, and the inner and outer compartments are filled with a solution preferably consisting of water, 100 parts; sodium chloride, 20; iron persulphate, 5; and surphuric acid, 5. The solution is introduced into the central compartment and flows upward and over its walls into the four outer compartments, escaping from their bottoms. The metal is precipitated on copper cathodes, depending into the outer compartments.

BOOK REVIEWS.

Engineering Chemistry.—A manual of Quantitative Chemical Analysis for the Use of Students, Chemists and Engineers. By **Thomas B. Stillman**, M.Sc.,Ph.D. Late Professor of Engineering Chemistry in the Stevens Institute of Technology. Fourth edition; 8vo, 744 pages, 174 illustrations, price $5.00. Easton, Pa.: Chemical Publishing Company.

The excellences of this work are well known to all students of chemistry. This edition has been brought up to date in all departments. The chapters on coal, alloys, lubricating oils, and paints have been amplified by the addition of specifications for the purchase of these materials. The subject of pyrometry has been revised by Messrs. E. A. Uehling and W. H. Bristol. A chapter on "Foundry Chemistry" has been contributed by H. E. Fields, one on "Official Methods of Sampling Iron Ore" by Chief Chemist J. M. Camp, of the U. S. Steel Corporation, and one on "Acetylene" by R. E. Brückner. The new edition is, therefore, a considerable improvement on the valuable and much appreciated earlier edition, and will prove an acceptable addition to chemical engineering literature.

Iron and Steel: A pocket encyclopedia, including allied industries and sciences. By **Hugh P. Tiemann**, B.S., A.M. 354 pages, 43 illus. Price, $3 net. New York: McGraw-Hill Book Company.

This little book is a combination of a dictionary, a cyclopedia and a handbook. It is alphabetically arranged, giving under each heading a concise definition and description (sometimes illustrated) of the apparatus or process in question. Cross references are numerous. With respect to the subject matter included the book is absolutely up to date.

That there should be a large demand for such a book is admirably brought out in an introduction written by Prof. Henry M. Howe, of Columbia University, from which we quote the following:

"The jargon of the millman, like that of the philosopher, is a deplorable necessity. It is a collection of invaluable special tools for special men doing certain work. When the dentist and the obstetrician regard the unfathomable mysteries of each other's 'kits,' each has the consolation that he need not attempt the fathoming. But, alas, you and I cannot thus escape each other's jargon, for the metallographist must needs learn from the millman and the millman from the metallographist, and each has become the slave of his own tools, his own jargon. He talks and perhaps thinks in terms of it, if indeed we think in any language, which I doubt. At least, if he thinks in any language it is in his jargon. Life is too short, patience too flimsy, to permit our forcing our thoughts into others' minds by means of any tools other than our own jargon. The author gives me an admirable case in point.

"Foreman: 'How does this steel work?'

"Heater: 'If you don't wash it, it won't clean.'

"This is 'shorthand' for: 'The iron oxide or scale which forms on the surface of this steel adheres so firmly that, unless it is heated so highly that it melts, some of it will cleave to the metal during the operation of rolling and hence will deface the finished plates into which the steel is to be rolled.' The heater's words are not English; they are jargon, and it is proper that they should be. If he persisted in translating them into English as I have done, and in talking English in general, he would simply justify the dismissal which would surely come. The guild has evolved its jargon for its own use. To replace it with the king's English would be as unwise as to replace it with French or modern Greek, or to replace 'shorthand' with 'longhand' in the reporting of debate.

"When the metallographist and millman meet it is as the meeting of French and Greek. The millman scolds the metallographist; yes, and I have had to endure with my scanty patience many such scoldings for deliberately inventing jargon, useful for the metallographic guild, but a stumbling block to the millman. Of course, it is not I, but the nature of things that ought to be scolded; but then it is pleasanter and less transparently foolish to scold me, especially if I have previously earned your gratitude by disentangling some of your fallacies and sophisms.

"Now, here comes the gallant author to the aid of fumbling metallographist and irritated millman. With infinite pains, ingenuity and skill he blesses both where they had banned each other, and enables the brothers to dwell together in harmony, unfurling to each the jargon of the other by means of a tri-lingual dictionary, translating the jargons of both into the common language, English."

The book has even a wider scope. While it forms, as Professor Howe points out, an admirable conecting link between millman and metallographist in the steel industry, it should appeal with equal force to the large number of chemists, electrochemists, mechanical engineers and others who, while not primarily active in the iron and steel field, are necessarily interested in its development and are often puzzled by the jargons of the steel millman or metallographist, however familiar may be the conceptions expressed under other names. In all such cases this little book will prove an easy and effective key.

If a suggestion may be made for future editions—which should surely be numerous—it is the addition of references to existing literature; not a complete bibliography, but in each case a reference to one or two of the principal publications on the subject. The increase in volume would hardly be prohibitive, while such references would often be very handy, even for the experienced steel man. As it is, this little volume is certainly excellent.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. IX. New York, June, 1911 No. 6.

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

Western Office, 1510 Court Place, Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

J. W. Richards, Ph.D., President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.
Telephone Call: 4700 Bryant.

E. F. Roeber, Ph.D., Editor.
H. C. Parmelee, Western Editor.

Yearly subscription price for United States, Mexico and United States dependencies, $2.00; for all other countries, $2.50 (European exchange, 10 shillings, 10 marks, 12.50 francs).

Copyright, 1911, by the Electrochemical Publishing Company.

Entered as Second-Class Matter at the Post Office at New York, N. Y., under the Act of Congress, March 3, 1879

New York, June, 1911.

The Foundry Convention at Pittsburgh.

The sixteenth annual convention of the American Foundrymen's Association, held late last month in Pittsburgh jointly with the newer bodies, the American Brass Founders' Association and the Associated Foundry Foremen, illustrated the enormous progress which has been made in the art of iron and steel founding in the past 15 years. According to the viewpoint one may attribute the remarkable growth of the American Foundrymen's Association to the progress in the art, or may attribute a large part of the progress in the art to the association movement. It is really a case of action and reaction. They have grown together, and in observing such results it is immaterial what have been the precise causes, for whatever they may be they are at work and are producing better and better results every year. Certain it is that the free exchange of information which the association movement has brought about has been of inestimable benefit to all connected with the foundry industry.

Not the least important, and perhaps the most important, feature of the foundry convention at Pittsburgh was the colossal exhibit of machinery and materials. Papers can be published and read at any time; they pass through the mails and can be distributed readily. Not so with the machinery which visiting foundrymen were able to see in actual operation.

Two Causes of Mill Failures.

In the domain of ore treatment the history of large companies is seldom marred by those financial and technical failures that characterize lesser concerns. Expressed in common phraseology, the principal reason for this is that the large companies "go at it right." In other words, they provide adequate capital and employ the best technical skill available. And these two points form the basis of a fundamental lesson.

On the financial side there is a critical period in the early history of a mill, which many small companies do not anticipate and which they are not able to weather—a sort of peak load of financial stress which bears them down to disaster. And the strange feature of it to them is that this period comes when they think they have provided ample funds and should commence to make money. Given a new mill, free from debt and ready to run, it is difficult for them to realize that their troubles have just begun and that very substantial sums frequently must be spent in making alterations and tests before real operations can begin. Thus, while many small companies are able to build and pay for their plants, they have not sufficient money to tide over the critical period of alteration and adaptation which ensues. It is almost safe to say that a small company should have a reserve equal to one-third or one-half the cost of its mill for use in making the plant a real success. Large companies have these experiences to a certain degree, but they are not heard of as failures, because money is available to make them ultimate successes.

In the second instance we may lay down certain axiomatic facts for the guidance of the small concern. First, it is poor economy to "save" the professional fee of a competent metallurgist or engineer when the sum thus involved bears only a small ratio to the total expenditure. Second, excellent business men in other lines do not necessarily make good managers of metallurgical plants, and it is likewise a mistake to put in charge of operations a man whose chief qualifications are that he is a nephew of one of the directors and unemployed. Those who have had experience in such matters know that it pays to be guided by specialists and that many mistakes and perhaps ultimate failure are avoided by employing an engineer who can make a complete study of the situation before a stroke of construction work is done. The whole matter sums up to this: that if adequate financial reserve cannot be supplied and competent professional advice afforded, the venture had better be abandoned before it ends in almost certain failure.

Experiment and Practice.

A principle in testing metallurgical processes on a small or laboratory scale is that the conditions of the experiment shall comply, as far as possible, with those which will be encountered in actual practice. In every point that the conditions of the test depart far from those of practice there is a possibility of failure, or at least of disappointment, under commercial operation.

In the cyanide process, extraction usually is relative to the degree of fineness to which the ore is ground; the finer the subdivision the better the extraction. But in commercial operation we strike an equilibrium between the cost of grinding and the value of the gold extracted, beyond which it is not profitable to go. At that point finer grinding ceases, and we arrive at the best possible commercial conditions. We have reason to believe that in laboratory experimental work this condition in grinding is neglected to a degree, or rather that the laboratory conditions are not made comparable to commercial conditions, with the result that commercial operation does not come up to the expectations indicated by the tests.

One reason for this is inherent in the different means used for grinding in laboratory and mill. Laboratory grinders usually will produce a greater proportion of undersize of any given mesh than will the commercial machines used in the mill. Hence, if the laboratory tests indicate a suitable extraction when all of the ore is put through a 30-mesh screen, for obvious reasons that standard of excellence scarcely will be attained in practice. By the time a laboratory sample is ground on a bucking board or in a disk grinder so that the whole sample will pass a 30-mesh screen, it probably will contain a greater proportion of, say, the minus 150-mesh size than will be discharged by a Chilean mill fitted with 30-mesh screen. Further, if the ore is of such a nature that the best value is contained in the fine pulp or slime the laboratory test will show a better cyanide extraction than can be obtained in practice, owing to the prohibitive cost of regrinding to equal the laboratory conditions. We believe that a closer control of this tendency toward excessively fine grinding in the laboratory will result in a closer comparison between experimental and practical results.

Reduction Works as Public Utility Corporations.

Scarcely a biennial session of Western legislatures passes without a spasmodic effort being made to "regulate" the companies engaged in treating custom ore. Some of the proposed legislation has been well meant, but futile, while more of it has been inspired by political motives and without regard to the welfare of metallurgy. Hitherto smelting companies have maintained an active opposition to this sort of activity, at the expense of time and money, and have anticipated the necessity of combating adverse legislation with each recurring biennial period.

The latest attempt to control ore reduction is the passage of a bill by the Colorado Legislature submitting to the people a constitutional amendment which, if adopted, declares all smelters, mills, reduction plants, and ore-treatment works of all kinds to be public-utility corporations, and, as such, amenable to legislative regulation and control as regards the tariff charged for their work. Aside from being poorly drawn as to exact wording and meaning, and leaving out of consideration the fact that the people of Colorado will scarcely adopt the amendment, the bill possesses certain potential features which are undesirable.

If the amendment should be adopted, future Legislatures would be empowered to regulate ore-treatment rates. In the smelting business particularly this is a technical matter, owing to the necessity of having the proper variety and quantity of ores to make suitable smelting mixtures. In chlorination and cyanidation it is frequently necessary to discriminate in favor of clean ores and against those containing an undesirable element or substance. In all ore treatment the gross value of an ore affects treatment rates and recoveries.

Considering these things it will be apparent how difficult it would be to regulate rates for ore treatment, save through the medium of a board of experts who would have to be as competent technically and as well-informed commercially as the custom companies themselves. In other words, in order to act competently such a board would have to be in possession of all the professional and business knowledge of the companies, and this is obviously impossible. Further it would be incumbent on such a board to reconcile the differences of mining companies in different districts, producing ores of diverse metallurgical character and justly subject them to discriminating rates of treatment. If it is not clear now that the entire procedure would result in a hopeless tangle, the fact will be appreciated when the attempt is made to put the law into effect.

The mere adoption of the amendment, however, would be a menace to metallurgical progress even though future Legislatures did not use their powers and try to regulate rates. New companies contemplating entering Colorado would hesitate about engaging in an industry over which hung a possibility of disturbance and interference.

Perhaps those against whom the bill was directed realized the futility of the whole scheme, for no obstacle was placed in the way of the bill's passage. Should its provisions finally come into full effect, it is difficult to say what would be the action of the principal smelting companies. Instances have been known where companies have seized on a suitable pretext to quit business altogether and abandon plants, and as the smelting industry in Colorado is in none too good condition it might be fur-

ther hampered by the abandonment of plants. Granting that metallurgical companies need regulation in Colorado, the cause will hardly be improved by the present effort.

Efficiencies in Electrochemistry

We believe it was Mr. James Swinburne who once remarked that efficiency is a byword of politicians and that when engineers use the term they should speak of efficiencies rather than efficiency. It may not be out of place to give here a concise sketch of the almost bewildering variety of efficiencies with which we have to deal even in such a restricted field as electrochemistry. The subject is of timely interest in view of the discussion, or, rather, repeated discussions, at the recent convention of the American Electrochemical Society, where besides various shades of intermediate opinions two extreme views found expression—one to the effect that a manager of a works does not know what he is doing except he can state the efficiency of operation in per cents, the other to the effect that in most cases of practice efficiency is so vaguely defined that it means nothing and that the term should not be used at all.

In any case, when we speak of an efficiency we compare a figure obtained in practice with a theoretical figure corresponding to ideal conditions. In electrolytic processes we may compare the quantity of material reduced at the cathode or oxidized at the anode in practice with the quantity which should be reduced or oxidized according to Faraday's law under ideal conditions. Faraday's law is always exactly fulfilled. "Under ideal conditions" means, therefore, such conditions that only the one desired reaction and nothing else occurs at the cathode or anode. For instance, according to Faraday's law, every 1000 ampere hours deposit from the solution of a bivalent copper salt 1.2 kilogram of copper if this is the only cathodic reaction. If in practice we get only 0.9 kilogram of copper, we say the cathodic amperehour efficiency is 75 per cent. This means that the balance of 25 per cent. of ampere hours are consumed to produce some other reaction that is not wanted and are therefore wasted. The figure of amperehour efficiency has therefore a distinct well-defined practical meaning; it states to what degree the one reaction which we desire to obtain really goes on. But even here we should distinguish between two efficiencies, the anodic and cathodic amperehour efficiencies, since there is no reason why both should have the same value.

However, of more direct practical bearing is the watthour efficiency, since not the amperehours, but the watthours, are paid for. In this case we, therefore, should give the energy given out in practice by a galvanic cell or the energy consumed in practice by an electrolytic cell in per cents of the energy given out or required according to theory under ideal conditions. A galvanic cell works "under ideal conditions" when the whole available energy is changed into electrical energy (that is, if there is no local action, if the Joulean heat developed is negligible, etc.). But what is the "whole available energy"? In practice it is customary to use simply the reaction heat. This is absolutely wrong in principle. The available energy is the "free energy of reaction," not the reaction heat, to be correct in principle. This subject was discussed at some length in an editorial on page 2 of our Vol. II in connection with a paper by Prof. Lorenz (Vol. II, p. 15); hence there is no necessity to discuss it here further than by pointing out one example. This is the rather rare case that an endothermic process may be used for the generation of electrical energy in a battery. In one example referred to in Prof. Lorenz's paper a cell, according to Thomson's rule, should require the expenditure of 0.14 volt to be impressed from the outside, while in reality it gives out spontaneously an e.m.f. of 0.32 volt; when the reaction goes on at constant temperature heat is supplied from the surroundings to the system, and this heat is partly used up in supplying the heat of the chemical reaction and partly changed into electrical energy. It would clearly be foolish to define watthour efficiency in such a case on the basis of taking the heat of the reaction as available energy. This whole question is intimately connected with the question of Thomson's rule versus the Gibbs-Helmholtz equation. The latter is the correct one in principle. Nevertheless the former is mostly used and is, in the majority of cases, a good enough approximation for practical purposes. In an analogous way we may continue to use the old watthour efficiency, employing the reaction heat as basis of calculation, if we always remember that it is only an approximation and that in some cases it may lead into unsurmountable difficulties.

However, industrial electrochemistry is a much broader field than the restricted one which we have discussed so far. It includes all electric-furnace processes, whether they involve any chemical reaction or not. Further, industrial processes are in general not constant-temperature processes, as has been silently assumed in the preceding paragraphs. It is, therefore, important, as Dr. J. W. Richards pointed out at the meeting of the American Electrochemical Society, to distinguish two things: First, the process involving a temperature change, like the melting of a cold charge; and, second, the process of keeping a molten charge at a constant temperature. In the first place an exact definition of efficiency is possible; to calculate it numerically, it is necessary to know or to assume specific heats, latent heats of fusion and perhaps vaporization, and also to take into account any chemical reactions which occur.

On the other hand, in the second case—where a molten charge is kept at a constant temperature—it seems impossible to give in an analogous way a useful definition of efficiency, simply because the ideal condition in this case is that there is no energy required (assuming that the charge is allowed to "rest" and that no chemical reaction takes place). Hence, on the basis of comparison with an ideal furnace, all real furnaces are alike in having zero efficiency in this respect. What is possible, however, is to compare real furnaces among themselves by stating, for instance, that different furnaces, otherwise alike, require so and so many kw-hours per ton of charge to maintain their temperature constant. As Mr. Lidbury pointed out at the meeting, such comparative figures are all that is needed and there is no need of speaking of efficiency at all. What such a figure represents is strictly specific power consumption, not efficiency. But if people want to call it an efficiency we do not see how they can be prevented. The jargon of the engineer cares very little for the rules of the philologist and logician. This much, however, must be insisted upon: That when an efficiency figure is given it should be accompanied by an exact definition of what is meant and by a statement of the assumptions made and of the figures used in the calculation.

American Institute of Chemical Engineers.

The summer meeting of the American Institute of Chemical Engineers will be held at Chicago from June 21 to 24. All the sessions will be held at the Congress Hotel.

Dr. Frerichs will present his presidential address on methods of attacking chemical industrial problems. Dr. S. P. Sadtler will present the report of the committee on chemical engineering education.

The program of papers is as follows:

Wednesday, June 21, 11 a. m.:

Report of committee on chemical engineering education. By Dr. Sam. P. Sadtler, chairman.

The four-year chemical engineering course. By. Prof. J. H. James.

Wednesday, 8 p. m.:

Presidential address by Dr. Frerichs.

Friday, 9:30 a. m.:

Industrial chemical calculations. By. Prof. J. W. Richards.

Rapid determination of tin in food products. By Dr. Edw. Gudeman.

Distillation on the continuous system. By. Chas. L. Campbell.

A new system of lead and silver lining for chemical apparatus. By Chas. L. Campbell.

The Institute and the United States patent system. By Dr. Wm. M. Grosvenor.

Friday, 7:30 p. m.

Manufacture of gelatine. By Ludwig A. Thiele.

The practical value of calorific tests on anthracite coal. By S. F. Peckham.

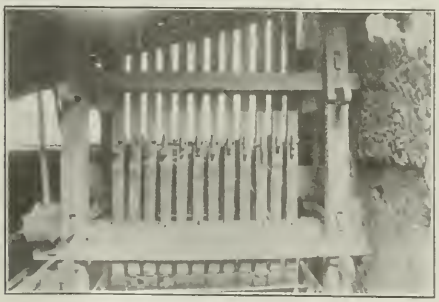
Two methods of testing asphalt. By. S. F. Peckham.

A large number of interesting excursions has been arranged for the afternoons of Wednesday and Friday, and for the whole days of Thursday and Saturday. These include the plant of Swift & Company at Union Stock Yards, the Corn Products Refining Company at Argo, Ill., the laboratories of Dearborn Drug & Chemical Works, the By-Products Coke Corporation at South Deering, the Carter White Lead Company at West Pullman, the Indiana Steel Company at Gary, Ind., the Universal Portland Cement Company at Buffington, Ind., the Illinois Steel Company at South Chicago, and the Standard Oil Refinery at Whitney, Ind.

Dr. J. C. Olsen, Polytechnic Institute, Brooklyn, is the secretary of the Institute.

Old Mexican Stamp Mill.

The accompanying illustration is interesting as showing the primitive practice of the Mexicans in stamp milling gold ore.



OLD STAMP MILL AT TEZICAPAN, GUERRERO, MEXICO.

The photograph was taken at Tezicapan, Guerrero, Mexico, by Mr. George J. Hough, and shows twelve stamps of wooden stems and iron heads. The stems are about five inches square, and the heads of cast iron are about the same dimensions in cross section and twelve inches long. One of the stamps in the illustration is shown detached from the stem, into which it was the practice to insert it with wedges. The cam shaft was a large, round timber with spikes or stems driven into it. As the shaft revolved these stems engaged the keys on the stamp stems and raised the stamps a short distance. Perforated cowhide was used as a screen, and portions of hide tanned with the hair on were to be found in a good state of preservation near the mill.

The Western Metallurgical Field.

Metallurgical Education.

Diversity of opinion exists as to the best methods of teaching metallurgical processes to students in our schools of mining and metallurgy, particularly with reference to the equipment and apparatus used. On the one hand we find a tendency to favor work on a large scale with standard size apparatus and machinery; and on the other a preference for small operations with well-designed models of the standard machines. The first idea is finding expression at home and abroad in the Imperial College of Science and Technology, South Kensington, London, and at the Colorado School of Mines, Golden. At each of these schools there is being installed a metallurgical laboratory and testing plant which compares in size and equipment with many mills built for commercial operation. The machines are standard size and the operations are conducted with tons of ore instead of pounds. The sponsors of this method of teaching are enthusiastic in their belief that it is the best for students, as it gives them opportunity to handle standard machines in a commercial way. They believe that the student can become familiar with principles by applying them in practice.

The other method has been far more extensive, for obvious reasons of expense of installation and cost of securing quantities of ore to work on, and perhaps those who advocate the new method regard the old as less efficient. Nevertheless, there is much to be said in favor of small operations for purposes of instruction. It has been the method pursued at the Massachusetts Institute of Technology, and as this school has acquired a reputation for the way in which its teaching work is done it may be well to consider the reasons which underlie the methods used there. The following is taken from recent correspondence on the subject:

The question of large versus small machines for teaching students in the laboratory is largely a question of the ability of the machines themselves. If the machines are well adapted and perfectly made the small machine can teach jigging and table work and small plant work just as well as the large machine. At the Institute of Technology the only large-size machine used is the vanner, and this has a width of 4 ft. instead of 6 ft., as is now common.

The question of size of machine seems to be partly a personal matter with the teacher, who may prefer large-size machines to small ones, and partly a question of locality. If ores can be had and given to the school by miners the large-size machines might be preferable, but where ores have to be brought a long way the small machine serves perfectly.

There are two other questions which come up in connection with settling this matter. One is the feeling of the profession of the neighborhood of the school, as to whether they are of the opinion that it is necessary to have large machines. If the public opinion says that the school must have large-size machines, then it must be so or the school will lose caste. The other is the question of testing ores for mines. If a school is located in a mining district it is pretty certain to have ores sent to it with the idea that the results of the tests shall be given to the owners of the ore, either for a small fee or as a return for the favor done in sending the ore, so that the mine may profit by the test, while the school profits by having the ore to work on.

It is the opinion at the Institute that if small machines are carefully designed there, they will do work that will rank with the very best large-scale machines ever made. It is further believed that the students working on small-size machines can do their preliminary illustrative work when they are learning what the machines are, at the same time they are listening to the lectures, and that this can be done just as well on small machines as on large. Finally, students can do just as careful testing work for their theses on small machines, and possibly better work, than they can on large.

The argument may be summed up by saying that if public opinion, which controls matters in the school, favors large machines, and if it will not ruin the treasury to buy these machines and pay for large quantities of ore to run them, then it may be best to buy them. If, on the other hand, public opinion in regard to this matter prefers leaving the selection to the teachers in charge, and if the cost of ore is a serious item, then the small machines would be selected by those in charge at the Institute.

On the score of ore tests, it is believed that it is a matter of extreme value to a mining company to have a lot of ore tested carefully on small-scale machines which have been carefully designed and properly run. From the results so obtained the company can get figures which will serve as a standard of perfection for them to try to attain on their large-scale operations; and if they attain the perfection which it is believed can be shown on well-designed small machines, they can feel satisfied that they have done the best that can be done according to the plan followed.

The Bureau of Mines and Metal Mining.

For various logical reasons the first work of the national Bureau of Mines has been in connection with the coal-mining interests. At the last session of Congress an effort was made to secure an appropriation for work in connection with metal mining, and $50,000 was set aside for such work as should be decided upon. It appears probable that this sum will be expended on the establishment of a western laboratory for investigations in metallurgy. Report has it that the laboratory will be located at San Francisco, and that its first work will be in the nature of conservation in metallurgical processes. Such problems as the prevention of smoke and fume loss, perfection of processes to minimize tailings losses, investigation of promising new fields of metallurgy and electrometallurgy, etc., probably will occupy the attention of this first laboratory. Prof. Frederick G. Cottrell, of the University of California, has been mentioned as the chief of the new laboratory, and judging from his former success as an investigator in metallurgical and chemical engineering the choice would be a good one.

Press comments are confused as to the function of a government laboratory, and some notion exists that it will be a free assay office and general information bureau. Certainly this is a trivial view to take of the matter. The mining industry has hitherto expended vast sums in overcoming obstacles in ore treatment and in investigating matters which promised uncertain returns. The effect has been good but of limited usefulness; because, being privately obtained, the information also was privately held. Again, many companies have duplicated work along certain lines, because each had to gain its own information or drop behind. Finally, much of the progress has been made by large companies, and is applicable only to large-scale operations and of little value to a small operator.

Thus the industry has progressed because some companies were rich enough to spend sums in investigation which is denied the larger part of the operators. It is believed that government laboratories can undertake many lines of investigation which will obviate some of the objections just raised and which will result in a general dissemination of information that will benefit the entire metallurgical industry.

Missouri Zinc Fields.

The unsettled state of affairs in Mexico has had the effect of sending more buyers into the zinc districts of Missouri, resulting in improvement in market conditions owing to greater competition. Additional interest in this district arises from the large operations of the American Zinc, Lead and Smelting Co., which is one of the largest factors in the field. Several weeks ago this company acquired under lease and bond 640 acres of land in the sheet-ground district near Webb City.

Following the policy of mining and milling its own ores, the company plans to erect a mill of over a thousand tons daily capacity, which will be the largest in the district. It is said that the mill will be patterned after the one owned by the same company at Plattsville, Wis., where the Huff electrostatic separators are in use. Among the other reported activities of this company is the erection of a new zinc smelter at Collinsville, Ill.

International Smelter, Utah.

The Tooele plant of the International Smelting & Refining Co., originally built and started as a copper smelter, is to be enlarged by the addition of two lead furnaces of a combined daily capacity of 500 tons. This is a part of the original plan of the company, although it was not known when the mining situation would warrant the starting of a new lead smelter in Utah. The company has been buying lead ores for some time, and a large tonnage is now on hand, which will provide at least six months' supply when the furnaces are ready.

This places the International company in competition with the American Smelting & Refining Co. and the U. S. Smelting Co., as regards lead ores as well as copper. The former operates a lead plant at Murray and a copper plant at Garfield, while the latter has both lead and copper smelters at Midvale. Apparently the general ore situation in Utah is improving, and with active competition on the part of three large corporations there should ensue a period of prosperity for the entire industry. In this respect Utah has an advantage over Colorado, which, in the height of its mining activity, had only one company bidding for smelting ores.

The Non-Ferrous Metal Market.

Dullness has characterized the market for all non-ferrous metals since our last report. Business has been so low in some cases that quotations are but nominal, and such business as has been transacted has been at shaded prices.

Copper.—Consumers are pursuing a policy of buying for immediate needs only, and the general belief is that most of them are not as well covered as good business policy would dictate. With a rise in prices there will undoubtedly be heavy purchases, especially if the upward tendency should appear permanent. Lake copper is quoted at 12⅛ cents to 12⅜ cents and electrolytic at 11.9 cents to 12 cents.

Lead.—The market is very dull and there has been a lower tendency in prices. The St. Louis market quotes lead at 4.22½ cents to 4.25 cents, and New York at 4.37½ cents to 4.40 cents.

Spelter.—Business has been negotiated at figures below the quotations, and the market has shown a tendency to go lower. Even though the supplies of spelter are required for work in this country, manufacturers show no disposition to buy heavily at present prices. St. Louis spelter is quoted at 5.20 cents to 5.22½ cents, and New York at 5.35 cents to 5.37½ cents.

Tin.—The market has been unusually quiet, and consumers can provide for their needs at figures below the import basis. The quotation for May tin in New York was nominally 42 cents.

Other Metals.—Aluminium prices are unchanged at 20½ cents to 21 cents per pound for No. 1 ingots. Antimony has moved slowly, and the prices range from 8 cents to 9.6 cents for various grades. Quicksilver has been steady at $46.50 per flask of 75 lb. in New York and $46 in San Francisco.

The Iron and Steel Market.

As this report is written the price structure in the finished rule a day or a week hence. On May 24 the Republic Iron & Steel Company began openly to sell steel bars at 1.25 cents, Pittsburgh, the recognized market having been 1.40 cents. It formally announced its abandonment of the policy of co-operation with other manufacturers in the matter of steel bar prices, directing attention to the impracticability of maintaining the 1.40-cent basis on soft steel bars when iron bars and hard steel bars rolled from old rails were being sold at prices so much lower, and intimating that there had been irregularities on the part of some other producers of soft steel bars.

Iron bars have sold as low as 1.20 cents, Chicago, while the 1.40-cent price on steel bars has meant 1.58 cents, Chicago. Bars rolled from old rails have sold at from 1.20 cents to 1.25 cents at various mills in the central West, and it has been quite obvious that the 1.40-cent, Pittsburgh, price on soft steel bars has been out of line.

Ultimately the break in the steel bar price is likely to lead to a general revision of prices of semi-finished and finished steel, but the readjustment may perhaps proceed slowly. In some respects the condition resembles that in February, 1909, when a general and rapid decline commenced, and in other respects the condition is quite different. In the previous instance there was a definite understanding among a number of producers that the entire steel market, outside of steel rails, should be opened; in the present instance the move is taken by a single independent steel interest, which does not make a full line of product. It is one of the heaviest producers of steel bars and is also prominent as a seller of billets and sheet bars, as well as of railroad spikes, but plates, shapes and wire products it does not make, while it has only lately commenced the manufacture of pipe.

The last week in April and the first three weeks in May constituted the dullest period in the booking of orders for finished steel products which the trade has seen for a very long time. The market seemed to be seized with an almost complete paralysis, the meager tonnage booked being far below any reasonable estimate of the minimum current requirements of the country. From this situation an improvement could not but result, and before the first break in steel prices there were signs of a slight improvement. The Pennsylvania Railroad System, which on April 1 issued general orders to discontinue shipments of rails and track supplies, rescinded the orders and began receiving material again. Several other roads which had issued somewhat similar orders began to take increased shipments, and some new buying began to appear.

By common consent the iron and steel trade has concluded that the second half of this year will be a large one from a tonnage standpoint, although at no time have prospects been that even fairly high prices would be realized. With a long period of liquidation in stocks after the unhealthy boom of the late months of 1909 the country has found itself bare of material in the hands of mills, jobbers and manufacturing consumers. Financial conditions are good and the country has had four years of growth since the last period when the capacity was fully employed.

Pig Iron.

The Southern pig-iron market dropped 50 cents a ton early in May as to deliveries in the second half, and fairly large sales were made for delivery to the end of the year on the basis of $10.50, Birmingham. There are predictions that this figure will prove the turning point after the long decline, which began in October, 1909, after the sharp rise just preceding. In the East basic iron sold down to $14.50, delivered Philadelphia district. In the Central West basic iron declined on practically each sale made, until $14, delivered Pittsburgh, or $13.10, valley, was done without much difficulty. Foundry iron has remained nominally at $13.75, valley, but buyers have no confidence in the market and pursue a strictly waiting policy. The Bessemer iron is held nominally at $15, valley, but a few odd lots have been sold by brokers at concessions of from 15 cents to 25 cents.

Production.

Production of pig iron and finished steel has declined steadily since about April 1. Pig iron is being made at the rate of between 21,000,000 tons and 22,000,000 tons a year, against a rate of 26,000,000 tons on April 1. In March finished steel was being made at the rate of about 75 per cent of total capacity, but at the close of May steel works operations do not average over about 50 per cent, and the decrease may continue through June. The almost universal expectation, however, is that the turning point will be reached by midsummer.

CORRESPONDENCE.

Generating Electricity from Heat.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The writer desires to point out a new possibility for converting heat into electricity by way of the primary battery.

It is generally known that some metals like copper and silver are decomposed by hot sulphuric acid with evolution of sulphurous acid. The latter is, however, the result of a secondary reaction and due to the reduction of the hot sulphuric acid by nascent hydrogen.

$$Cu + H_2SO_4 = CuSO_4 + H_2 \quad (1)$$

$$H_2 + H_2SO_4 = 2\,H_2O + SO_2 \quad (2)$$

Hence there is no material difference between the reactions of copper and zinc with sulphuric acid. The greater affinity of zinc for the acid sufficiently accounts for the fact that here the hydrogen is liberated at ordinary temperature, while in the case of copper a stronger acid and a higher temperature are required. By amalgamating the surface of a piece of zinc the evolution of hydrogen is much diminished; in other words, its chemical action on sulphuric acid is weaker, yet the faculty of the zinc to send its ions into solution is even greater when alloyed with mercury.

By raising the temperature of sulphuric acid in which a piece of copper is immersed we increase its tendency to pass into the ionic state, and it is probable that the electric pressure will rise more or less proportionately with the increment of temperature up to the moment when the SO_2 gas is liberated, it being then a maximum.

For the present it will be sufficient to indicate that there exists an e.m.f. between copper and sulphuric acid at a temperature somewhat below that at which SO_2 would be set free. To make this e.m.f. available for practical purposes we must avail ourselves of another electrode which is surrounded by a suitable depolarizer and the latter should be prevented from freely intermixing with the sulphuric acid. By fulfilling these requirements we create a modification of the Daniell battery.

Using like Daniell a solution of sulphate of copper as depolarizer in which a copper cathode is immersed, and using instead of the zinc an electrode of copper surrounded by hot sulphuric acid, we have as an interesting feature a battery with electrodes of the same material.

Since the hot electrode will always dissolve while the cold one will receive the deposition of metal from the hot one it is evident that the migration of the ions will gradually cause an accumulation of $CuSO_4$ about the dissolving copper anode and of free H_2SO_4 about the copper cathode upon which copper is deposited.

These conditions bring about a decline of the available voltage of the cell and in order to restore it to the original intensity it is now necessary to heat the compartment which before was kept cool and vice versa. An interchange of the hot and cold solutions by convection currents must be prevented, of course.

Since the cycle of reactions is complete the sole agent for the electric energy produced by this cell is the inequality of temperature prevailing at its electrodes.

Waterbury, Conn. R. V. Heuser.

Comparative Grinding Experiments with a Chilean Mill and a High-Speed Roll at the Detroit Copper Company's Concentrator, Morenci, Ariz.

BY RUDOLF GAHL, PH.D.

Several interesting articles have been published recently describing experiments carried out to establish the most economical method of crushing and grinding ore. Most of these experiments, as for instance those undertaken by Mr. Caldecott, deal particularly with the reduction of ores preliminary to cyanide treatment. Very few experimental data are available referring to the reduction of ore preliminary to concentration.

Some tests were made several years ago at this plant by Mr. Frank Probert, with the idea of determining whether Chilean mills or high-speed rolls are more suitable for grinding in concentrating plants, and his results were published.*

More recently the installation of Chilean mills by the Utah Copper Company has been made the subject of very severe criticism. In this connection the following experiments may be of interest which are essentially a very careful repetition of Mr. Probert's tests and were carried out in the course of the past year.

The Chilean mill used in these tests was a 5-ft. Monadnock mill made by the Trent E. & M. Company running at a speed of 36 r.p.m. The rolls made by the Gates Iron Works have a width of 15 in., a diameter of 36 in., and are operated at 140 r.p.m. The product of the rolls was in the first test screened by a shaking screen operated by a Wilfley motion, in the later tests by a trommel. The oversize was fed to an elevator and returned to the rolls. Operated in this manner the rolls made only one product, viz., the undersize of the screen, which could be compared to the product as discharged by the Chilean mill.

This undersize was carefully sampled for a number of days. Of a composite sample representing an average of the days over which the sampling was extended a careful screen analysis was made.

Test No. 1.—Feed: Tailings from jigs working on a trommel product, passing through 7 mm and remaining on 5 mm trommels.

Screens: 2½ mm round hole screens on Chilean mill, and on shaking screen screening roll discharge.

Average load: 109 tons per machine per day.

Oversize from shaking screen: 9.3 per cent of feed.

The results of screening the mill discharge and the roll screen undersize are tabulated in Table No. 1 and represented graphically in Fig. 1. The conclusions to be drawn from these figures are that when the same screen cloth is used on a Chilean mill and on the screen which screens the roll discharge the rolls produce very much less slime than the mills.

TABLE I.

	Rolls.	Mills.
0–20	23.10	11.00
20–30	16.00	7.00
30–100	23.40	21.20
100–200	6.60	9.30
200–∞	30.90	51.50
	100.00	100.00

The object of the following test was to determine whether the same difference in the sliming of the rolls and mills exists also when a finer material is reground.

Test No. 2.—Feed: Tailings from jigs working on a trommel product, passing through 5 mm and remaining on 2½ mm trommels.

Screens: 2½ mm round hole screens on Chilean mill, and of shaking screen, screening roll discharge.

Average load: 65.7 tons per machine per day.

Oversize from shaking screen: 6.0 per cent of feed.

Eng. & Min. Jour., Vol. LXXIX, 1905, p. 1089.

The results of screening the mill discharge and the roll screen undersize are tabulated in Table 2 and represented graphically in Fig. 2. (p. 294). The same conclusion may be drawn from these figures as those from test No. 1, that when the same screen is used for rolls and mills the rolls produce very much less slime than the mills.

The same result has been obtained by other experimenters and the conclusion been drawn that, inasmuch as the size of the maximum grains was the same for both machines, and the quantity of the undesirable slime so much smaller for the rolls, they were better suited for this class of work. In drawing this conclusion it has been taken for granted that the economic

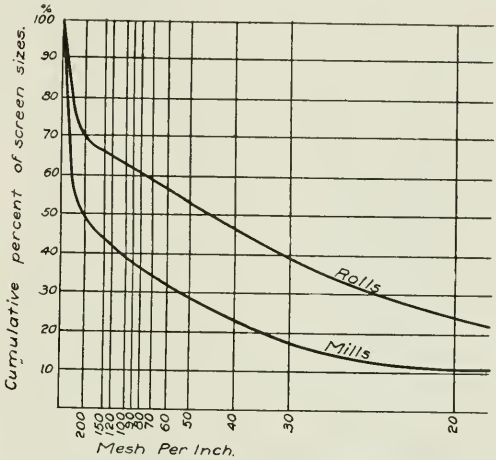


FIG. 1.—GRAPHICAL REPRESENTATION OF SCREENING RESULTS OF TABLE I.

mineral has been liberated equally well by the rolls as by the mills.

In order to determine whether this assumption is justified the different screen sizes were concentrated on a small experimental Wilfley table, with the exception of the material passing through 200 mesh. The amount of concentrates that could be expected to be saved from this slime was determined by panning. The results are also represented in Table 3 (p. 294).

It will be noticed that while a large amount of copper is lost by the mill in the form of slime, the sand tailings originating from the rolls contain more copper than the corresponding material from the mill. This accounts for the fact that actually more copper could be saved from the mill product than from the roll product.

The object of the following test was to make the same comparison as had been made in the preceding test for 2½-mm screens, with finer screens on the machines.

Test No. 3.—Feed: Tailings from jigs working on a trommel product, passing through 5-mm and remaining on 2¼-mm trommels.

Screens: One-mm round-hole screens on Chilean mill; 14-mesh No. 19 wire (opening, 0.79 mm) on trommel screening roll discharge.

Average Load: 48.8 tons per machine per day.

Oversize from Trommel: 21.8 per cent of feed. (This is equivalent to the statement that 68.6 per cent of the roll discharge is constantly returned. The high percentage of oversize returned is partly due to the fact that owing to the heavy load of fresh feed and returning oversize the trommel was heavily overloaded and its screening action very imperfect, which is shown by a screen analysis of the oversize tabulated in table 3.)

The results of screening the mill discharge and the roll

screen undersize are tabulated in Table 4 and represented graphically in Fig. 3.

The result is practically a standoff between rolls and mills, the rolls losing more copper in the sands and the mills more copper in the slimes.

It appears, therefore, that the same saving of copper can be obtained by grinding in Chilean mills as by grinding in rolls, and that in a much simpler way mechanically. Reliable comparative operating costs are not available, but it seems reasonable to assume that on account of their simplicity the larger sizes of mills should be cheaper in operation than rolls, counting in the auxiliary screening and elevating machines. Elevating can, of course, be avoided by sending the oversize to other grinding machines.

TABLE III.

Trommel.	Oversize.
0–10	16.0
10–20	24.2
20–30	34.9
30–50	14.2
50–100	7.2
100–200	0.8
200–∞	2.7
	100.0

The conclusion drawn from the previous tests, that the same saving in copper can be obtained from ore ground in Chilean mills as from ore ground in high-speed rolls, holds true, however, only for the case that the grinding in these machines is final and is not followed by regrinding of any part of the pulp. Where the coarse part of the pulp is reground rolls are evidently preferable, as their product contains considerable amounts of copper mineral in the sands from which it can be set free by regrinding.

It was tried in the following test to decide if this point of superiority is really due to the characteristic grinding action of the rolls or more to the fact that the ore is not ground in one step to the desired fineness, but in stages, grinding alternating with screening. If the latter is the case, the same object should be attainable by Chilean mills using a coarse screen (or possibly no screen at all) on the mill itself, and a finer screen not connected with the mill, in addition, which would make the separation between oversize (to be returned) and undersize (to go to the concentrating machines).

Test No. 4.—Feed: Tailings from jigs working on a trommel product passing through 5 mm and remaining on 2½ mm.

Screens: 3 mm (slotted) on Chilean mill. The Chilean mill product passed to a trommel with 14-mesh No. 19 wire (opening, .79 mm), the oversize of which was returned to mill.

Average Load: 70.3 tons per machine per day.

Oversize from Trommel: 58.7 per cent of feed. (This is equivalent to the statement that 37 per cent of the mill discharge is constantly returned.)

The results of screening the mill discharge are tabulated in

Table 5, and represented graphically in Fig. 3, together with the results of test No. 3.

The curve representing this mode of operating a mill in Table No. 7 (corresponding to the return of 40.6 per cent of mill discharge) approximates the curve obtained for the rolls when the product was screened on the same screen (with an oversize return of 68.5 per cent of the roll discharge). It seems to be safe to assume that for the same percentage of oversize the curve for the mill will reach the curve for the rolls.

It follows, therefore, that the rolls have not any inherent advantage over mills for grinding fine. It has to be considered, however, that to effect this reduction of sliming the mode of operating the mills becomes just as complicated as that of rolls, involving machinery for screening and elevating. (Elevating can be avoided by sending the oversize to other machines.) Under these conditions it is doubtful which class of machines can be operated at the lowest cost (the cost figures of this plant seem to point in favor of high-speed rolls), and the only serious objection to using them for this purpose would be the difficulty of keeping the faces true, which I understand has been found a serious drawback wherever fine grinding in rolls was attempted.

Regarding the point that the sliming of the mills can be reduced to the same amount as the sliming of the rolls, provided the mills make an oversize product of equal quantity, I want to add that this naturally only holds true for the conditions under which the test was made, that is, for reducing the maximum grains to about 1 mm. For coarser grinding the rolls, as hardly anybody doubts, are superior. In fact, some experiments along this line showed that the work of rolls operating in conjunction with a 2½-mm screen could, as far as minimum sliming is concerned, not be equaled by mills.

TABLE V.

Trommel.	Undersize
0–20	0.32
20–30	5.24
30–50	13.28
50–100	22.91
100–200	8.23
200–∞	50.02
	100.00

A fact which should be considered in judging the figures obtained in these tests is that in actual practice the results will be slightly different as the results of the concentration tests are based on the assumption that the concentration following the grinding is perfect. As a matter of fact the slime tailings from concentrators mostly show considerable amounts of free mineral on panning, while the coarser sizes are nearly free from such material.

This is an additional reason why the formation of slime should be avoided as far as possible by either replacing Chilean mills by high-speed rolls or by operating the Chilean mills in the manner suggested above, namely, grinding in stages. It has been reported that the Utah Copper Company is departing from the old method of running Chilean mills by using rather coarse screens on the mills and regrinding the coarser sizes of sands, which, judging from above tests, seems a commendable step.

The question whether high-speed rolls or Chilean mills with stage grinding are more economical can only be decided by tests on a practical scale extended over a long time. The experience of the Miami mill, where Mr. Burch is installing high-speed rolls of his own design in one section, to be compared with the Chilean mills of the other sections, may render such a decision possible.

Morenci, Ariz.

Duralumin

In a recent lecture of Mr. L. M. COHN before the Verein zur Beförderunz des Gewerbefleisses in Berlin, reported in *Electrotechn. Zeit.*, April 27, some interesting data on aluminium alloys are given, made by the Dürener Metallwerke in Düren i. Rh., Germany, and sold under the trade name "duralumin." These are alloys of aluminium with about 0.5 per cent magnesium, 3.5 to 5.5 copper, and 0.5 to 0.8 manganese. These additions are claimed to increase very materially the breaking strength, ductility, hardness and chemical resistivity of the metal.

The specific gravity of the different brands of duralumin varies between 2.75 and 2.84. The melting point is 650° C. The electric conductivity is "less than that of pure aluminium." The hardness of soft sheets, 7 mm thick, is 98 to 125, hence three times greater than that of pure aluminium and twice that of soft brass for cartridges. By rolling the hardness can be increased to 170. "The modulus of elasticity for alloy 681 A is 700,000 kg per square centimeter, the shearing strength 30 kg per square millimeter, the breaking strength about 50 kg per square millimeter, the elongation for a sheet, 2 mm, which is about 4 per cent." Since above 150° C. the strength rapidly decreases, duralumin should not be used above this temperature.

Special advantages of duralumin are its light weight and resistivity against chemical influences. But it should not be used in contact with copper or brass, but rivets of iron, or preferably duralumin, should be employed. Various kinds of vessels and fixtures are now made from this new alloy. For the airship just finished for the British army duralumin has been used throughout as material of construction.

Recent Progress in Calorimetry.

Details of Apparatus and Method.

By Walter P. White.

Last April, in an article in these columns describing recent progress in calorimetry, it was shown that most errors in the past have been due to uncertainty in the conditions attending a determination; that these uncertainties can be avoided by preventing evaporation, adjusting and regulating the speed of stirring and removing the calorimeter from the influence of all bodies of unknown or uncertain temperature; that the various lag effects can easily be made negligible; and that the preponderant *unavoidable* error is then in the temperature measurement.

The advantage which may be sought from the new methods will differ in different cases. For instance, one worker will wish chiefly to diminish his accidental errors—that is, to make his own results agree better among themselves—another may find it more important to reduce the systematic errors which produce discrepancies between the results of different observers; still others, satisfied with the accuracy they are now getting, may yet welcome an increase in the speed or convenience of their methods. Of these three advantages, the avoidance of accidental irregularities has presented the greatest difficulties and is most important. It will be further discussed presently. The securing of concordant results among different observers is often at present a great desideratum in commercial work. Its lack is sometimes acutely felt even where the accidental errors are satisfactorily small. It is, however, an easier problem than the other. It will be treated first.

Systematic variations between different observers may be due to four causes. (1) Error in some auxiliary process or observation (for instance, with the bomb calorimeter, incomplete combustion, impure oxygen, inaccurate weighing, etc.). (2) Error in the value taken for the heat capacity ("water equivalent") of the calorimeter. (3) Error in the thermometer calibration. (4) Various errors due to lag which, as already pointed out, produce the effect of an error in the value of the heat capacity. The simplest and by far the surest way to eliminate all these errors, it is generally recognized, is to make a direct calibration of the calorimeter under actual working conditions, using some standard substance of known thermal properties. A familiar instance is the calibration of bomb calorimeters by determining with them the heats of combustion of sugar or benzoic acid, whose true values are pretty well known. Results obtained with these calorimeters thus become definite, and comparable with those of others, and their absolute accuracy will increase with every increase in our knowledge of the standard values.

With this method of procedure, of course, it is essential that there be no change either during the calibration or afterward in the errors whose effect it is sought to eliminate. Changes in auxiliary processes, though important, do not fall within the plan of the present paper; changes in the water equivalent, though also important, do not seem to call for discussion here, and the same may be said of errors in the thermometer calibration. But errors due to lag are not so well understood, and should perhaps be discussed briefly.

The lags most likely to produce actual error are those due to bodies of uncertain temperature, such as covers not touching the water of either calorimeter or jacket, shields and other large masses within the jacket, or the jacket itself if it consists merely of shields and contains no water. These lags will be constant, and will, therefore, not be productive of appreciable error in a calibrated calorimeter as long as the conditions affecting them do not change too greatly. But the one who, therefore, counts on ignoring them, of course, does so at his own risk, and must, to avoid error, not only be able to keep the essential conditions always constant, but must also be sure that he fully understands what *all* the essential conditions are.

It should not be supposed, however, that the errors, if any occur, would be large. These lags only alter the cooling correction by a fraction of itself; the cooling correction is only about 2 per cent of the total heat quantity, and no change of conditions is likely to alter the lags consistently by more than a rather small fraction of themselves. Hence, while these lags might cause considerable discrepancies between the results of calorimeters whose water equivalents were merely computed, they are not likely to cause in calorimeters directly calibrated any systematic errors greater than 1 part or 2 parts per mille. Present data do not seem sufficient for a more definite statement, since most of those who have given any particular attention to these lags have preferred to eliminate them rather than to bother with them.

The preceding suggests one general consideration. In many cases the presence of large lag effects is doubtless due to a legitimate attempt at simplicity of apparatus, but it also often results from an effort to increase accuracy by diminishing the magnitude of the cooling correction. This, of course, results from the mistaken notion that the cooling is the main source of error. But appreciable error rarely or never arises from the main part of the cooling correction; it comes from the smaller but variable subsidiary effects; hence a very large decrease in the total value of the cooling constant is a positive disadvantage *provided*, that it is accompanied by even a slight increase in the variations and conversely. The failure to appreciate this fact has frequently led to an unfortunate design or procedure. For instance, calorimeters have been considerably used in which the jacket consists of two fiber pails. If the space between these pails were to be filled with water, slightly stirred, the cooling correction would increase, but the errors would decrease because the environing temperature would become more constant. Similarly, where metallic shields are used inside a water jacket. Again, the substitution of Dewar flasks for metallic calorimeters has seemed to many persons an enormous improvement on account of the accompanying decrease in the cooling rate. (It is perhaps not everywhere known that use as a calorimeter was the original object of the Dewar flask, which antedates liquid air.) Of course, such a decrease is, other things being equal, a desirable thing, though less important than many appear to have supposed; the rate is, to judge from two recently reported cases, about one-fifth the usual one, but this is a very long way from giving anything like five-fold accuracy. On the other hand, in the Dewar flask, where there is a continuous glass connection between the calorimeter proper (inside) and the jacket (outside), the lag effects and the water equivalent are hard to determine and vary as the water level changes. Hence, while these flasks, if used with proper precautions, often have great advantages, they are not likely to prove particularly valuable in cases where it is supposed that their small cooling factor is alone enough to secure accuracy without special precautions.

Another case where the advantages of reducing the cooling correction have been overestimated is the case of adiabatic methods. In these methods the jacket is heated so as always to be at the same temperature as the calorimeter; there is thus (theoretically) no direct heat flow at all from the calorimeter (though a correction for the effects of stirring and evaporation is, in general, still necessary). This total absence of direct cooling is generally supposed to increase accuracy. Of course, it does nothing of the sort (in determinations of ordinary length). In fact, Professor Richards, who has been a leading exponent of the method, did not expect to gain accuracy from this source as much as from the elimination of certain lag effects. But it is now known that the errors from these effects are negligible or non-existent, though this was not known at the time when the method was introduced. There is now no good reason to suppose that adiabatic methods have any advantage in accuracy in determinations of ordinary length. They may often have decided advantages in convenience.

The value of a small cooling correction has also loomed large to those experimenters who have suggested that the calorim-

eter should be of such a shape as to have the minimum surface. As a matter of fact, differences of shape, unless extravagant, have but slight influence on the cooling rate, and hence have an altogether insignificant effect on the accuracy. The shape of the calorimeter should be chosen with reference to facility in stirring, and, of course, to convenience in construction or manipulation.

Passing now to consider the *accidental errors*, which set the present limits to calorimetric accuracy, the principal conditions for good work are: Constancy of conditions and sufficient thermometric sensitiveness. The means of securing these are in detail much as follows:

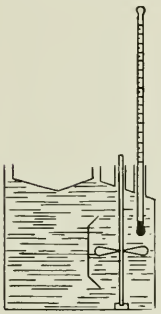

FIG. 1.—THIN SECTION OF CALORIMETER WITH FLOATING COVER IN CONTACT WITH WATER.

The Calorimeter.—To avoid lag errors projections should be avoided as far as possible, especially those of poor heat-conducting material. For the same reason, if there is any cover, it should be in direct contact with the water. Unless the calorimeter is to be always operated at a temperature lower than the jacket, the control of evaporation will require also a rather tight cover. A cover for the jacket alone will not answer at all. The simplest cover to manipulate is a floating cup, about 1 mm narrower than the calorimeter opening. The evaporation with such a cover will seldom reach 1 mg per minute, which means 0.6 calory heat loss a minute. If the cooling correction is (as usual) of the type which eliminates the effect of a *constant* evaporation, and if there are 2 or 3 liters of air space inside the jacket, the error due to evaporation then will seldom be as much as 0.2 mille for an ordintry determination, involving 6000 calories and lasting not over 10 minutes. Or, the edge of the cover can be made to rest in a narrow groove, and the joint sealed with 300 mg or so of oil, when evaporation is, of course, practically nil. Other fastenings are also possible, since absolute tightness is not needed. With such, since the water must touch the cover, the amount of water must be properly regulated. This is easily and quickly done by sucking the water out, down to a certain level. A tube shaped like the letter "J" is probably best for this purpose, and gives levels constant to one-tenth or two-tenths of a millimeter. Such a tube, stuck through a large cork which rests on the calorimeter rim, when in use, makes as good an adjuster as any.

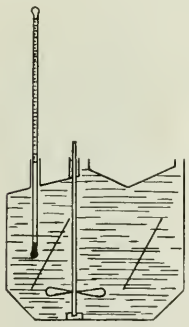

FIG. 2.—THIN SECTION OF CALORIMETER WITH FLOATING COVER. THE INCLINED TUBE GIVES CENTRAL STIRRING WITHOUT ENCUMBERING THE OPENING.

The stirrer shaft and thermometer can run through the movable cover, but are more conveniently inserted through a fixed cover, or half deck, as shown in Fig. 1. The stirrer, unless there is strong reason to the contrary, should be a propeller, because that is more efficient and causes less evaporation than an up-and-down stirrer. The effectiveness of propellers is usually promoted by inclosing them in side tubes, as in the figure. Such tubes should not be too small. Suppose, for instance, two calorimeters, in one of which the side tube is two-thirds as wide as the main calorimeter, while in the other it is one-third as wide. For any given effectiveness, then, the speed of the water in the narrow side tube is four times as great as in the other, and, since the heat is about proportional to the cube of the speed of flow, the heating is possibly 64 times as great. But friction is greater for the same speed in a narrow tube, so that the heating may be 100 times as great or more and is certainly far greater than in the wider tube. The disadvantage of throttling the stream of water is thus evident. Throttling is at a minimum if the stirrer is in a central tube. An arrangement by which this construction can be secured without having the stirrer shaft interfere with the calorimeter opening is shown in Fig. 2. This arrangement has proved very successful in reducing the heat of stirring.

The jacket, for the best results, should contain water, whose temperature should be kept uniform by stirring, and should be measured. The water should surround the calorimeter completely, so that the whole surrounding temperature is definite. The water, therefore, should be *above* the calorimeter, as well as below and at the sides. Several satisfactory methods of accomplishing this have been used. One of the best is as follows: The calorimeter chamber is a vessel open at the top and sunk in a larger vessel; the space between the two, partly open at the top, contains the water; the cover is a flat box, air-tight except for two large tubular openings which project downward and reach below the surface of the water in the lower vessel. The cover is filled with water, which is made to stay there by atmospheric pressure; the stirrer is directly under one of the tubular openings, and so produces circulation in the cover as well as in the lower vessel. (Fig. 3.) The opening of the chamber may be provided for in either of two ways: (1) The cover, tubes and all, is moved directly aside; this method agrees best with a design having a square outer ves-

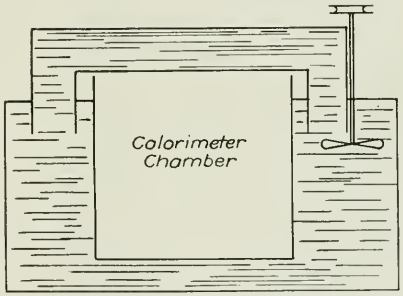

FIG. 3.—THIN SECTION OF CALORIMETER JACKET WHICH SURROUNDS THE CALORIMETER COMPLETELY WITH A SINGLE STIRRED BODY OF WATER AND IS READILY OPENED AT ANY TIME.

sel and two half covers, one of which transmits the thermometer, stirrer, etc.; this half can be kept stationary while the other is moved to expose the calorimeter opening. Both are moved apart to remove or insert the calorimeter. (2) In the other method the two tubular openings are near each other and the single cover swings around one of them as an axis in exposing the chamber and calorimeter; the thermometer passes through either a hole in the cover or a notch in its edge; partitions guide the circulation.

The upper bearing for the stirrer should be on the jacket, or, at any rate, not on the calorimeter itself. If the calorimeter is always below the temperature of the jacket the jacket may almost as well be left open at the top, since there is comparatively little tendency for heat to pass downward across an air space at ordinary temperatures. Of course, such a jacket is not to be unreservedly condemned, even where the calorimeter is sometimes warmer than it, if the highest accuracy is not required. A good deal will depend on how constant the room temperature is. There should be no difficulty in determining by actual observation how great is the direct influence of room temperature upon the calorimeter. A few hours' observation of the cooling rates, with different relations between jacket and room temperature, is all that is required. The error likely to result

through the use of an open jacket can then be readily estimated for any given variation in room temperature.

The necessity of measuring the jacket temperature can also be avoided if certain cooling correction methods (e.g., the Pfaundler) are used, and if that temperature is also kept practically constant. It can easily be shown that variations in the jacket temperature arising from the temperature change in the calorimeter will be less than 0.1 per mille if the jacket has ten times the heat capacity of the calorimeter. Changes in the jacket arising from the room temperature are more serious. If the difference between room and jacket is equal to the calorimetric interval the resulting error will often reach, and may exceed, 1 per mille. Here, also, the probable magnitude of the error for a given difference of room and jacket can readily be found experimentally—in this case by a little observation of the cooling rate of the jacket.

Summary.—Systematic errors in calorimetry can usually be eliminated by a direct calibration, except for certain lag errors, which can be avoided by proper construction and procedure. Accidental errors can be greatly reduced by various features, described above, in the design of calorimeter and jacket. Temperature measurement and the calculation of temperature corrections will be treated in a third paper.

Carnegie Institution of Washington,
Washington, D. C.

Positive Rays and Chemical Analysis

The discourse on "A New Method of Chemical Analysis" which Sir J. J. Thomson delivered at the Royal Institution in London on April 7 showed that a line of research, of which Professor Thomson gave a preliminary account before the Sheffield meeting of the British Association, has led to most remarkable results. The following account of the lecture is taken from London *Engineering* of April 14:

There is nothing chemical in the new method of analysis. But the study of the positive rays (Kanalstrahlen) tells the experimenter not only what gases he is actually dealing with in the apparent residual gas of his vacuum tubes, but in what state—atomic, molecular, or molecular aggregations—they are, all deduced from measurements of deflection of the rays, which measurements give a clue as to the atomic weight (or equivalent). This is the strength, and possibly also the weakness, of the new method, which bears some resemblance to spectroscopy.

The new method identifies the elements by their masses. It informs the experimenter that some substance having a certain e/m (ratio of electric charge to mass) is present, and as the experimenter knows with some degree of certainty what substances he starts with, the method affords a valuable help to the chemist, especially as it is wonderfully sensitive and records the presence and mass of elements or radicles which are far too evanescent to be isolated.

Sir Joseph said, in introducing his subject, that he approached a chemical problem with some trepidation, since chemists were fighting men. But his weapons were bullets traveling at 1000 miles per second. The positive rays were positively electrified particles attracted to the negative electrode. When that electrode was perforated (by Goldstein's Kanal) the particles would pass through the cathode in streams which, in neon, had a beautiful orange-red color, as was shown. The particles were deflected both by the magnetic and the electric field, and the research depended upon the measurement of these deflections.

There are several arrangements of the bulbs possible, and these bulbs are sometimes very large. In one of the new arrangements (Fig. 1) the tubular cathode is continued backward in a fine tube, terminating at two electrodes, between which an electric field is established. A magnetic field is also provided so that after passing through the two fields the particles strike the flat screen of willemite, closing the tube.

With the magnetic field alone in action, the original light spot O (Fig. 2) of the undeflected particles is shifted to N; the deflection ON being equal to Ae/mv, where A was a constant depending on the intensity of the field and the size of the tube, while m was the mass of the particle, e its charge, and v its velocity. The electric field similarly deflected the particle to OM, at right angles to ON, and $OM = Be/mv^2$, where B was another constant.

When both fields were excited the particles would be shifted to P, and it could easily be shown that the ratio of m to e should vary as the ratio of OM to ON^2. If, now, all the particles were of the same kind and had the same speed, the position of P would merely depend on m/e, and a number of spots P—as many as there were different kinds of particles—would be seen. But the particles of the same kind did not move all at the same speeds, and each spot was drawn out into a curve, which was a parabola if m were constant.

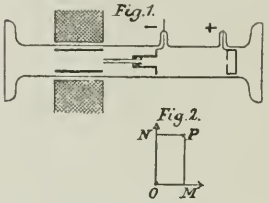

FIG. 1 AND 2.—ARRANGEMENT OF DISCHARGE TUBE.

The lecturer and his assistants had at first made the measurements directly on the screen while the experiment lasted. But that was very laborious, and they had substituted a photographic plate for the screen so that each particle photographed itself. They had placed the photographic plate first outside and then inside the bulb (as has also been done in similar researches conducted by Koenigsberger and others), and with the aid of a slide shutter, due to Sir Joseph's assistant, Mr. F. W. Aston, the exposure was made at the proper moment and several photographs were taken on the same plate.

In each case the first photograph was taken with the magnetic field producing a deflection upward, the second with the reversed field giving a deflection downward. Thus they obtained full parabolas (not only one branch), and they could ascertain the zero from which to measure with more definiteness. In the slide used the photographic plate was suspended by a silk thread wound round a plug worked in a glass-ground joint.

FIG. 3.—PHOTOGRAPHIC PICTURE OBTAINED.

Fig. 3 illustrates the beautiful curves obtained with a tube containing nitrogen isolated from the atmosphere. The central light spot indicates the original position of the undeflected ray. There were many faint and bright curves, sometimes beady; their number suggested the presence of many substances, constituents or impurities; the argon curve was present, for instance, while absent on another photograph taken with nitrogen prepared from ammonium nitrate. Most of the curves were on the right side of the photograph, in which direction the positive particles were deflected. But there were also some faint curves on the left-hand side, showing that some negatively-charged particles had found their way through the cathode.

The uppermost curve always corresponded to the hydrogen atom, and this was present on all plates from discharges through all substances. Traces of oxygen, carbon and mercury were also found on almost all the plates, no matter what substance they were experimenting with. The other substances followed in the order of their atomic or equivalent weights.

Thus, taking the ratio of m to e as unity in the case of

hydrogen, it is possible to calculate from measurement of the curves the relative value of this ratio for the other particles impressing themselves on the plate. We reproduce below figures deduced from the measurements of the parabolas of Fig. 3, showing the discharge through atmospheric nitrogen; the enumeration starts from the top of the diagram.

Positive Side.	Negative Side.
1.00 H +	1.0 H —
1.99 H_2 ++	11.2 C —
6.80 N ++	15.2 O —
11.40 C ++	
13.95 N +	
28.1 N_2 +	
39.0 A +	
101.0 Hg ++	
198.0 Hg +	

The + and — indicated, the lecturer explained, the simple or double charge carried by the particle. The H = 1 corresponded to the hydrogen atom carrying a single charge; the second, $H_2 = 1.99$ (instead of 2) to the hydrogen molecule; 11.40 C + to a carbon atom (C = 12); the 6.80 N ++ to a nitrogen atom carrying two charges (N = 14); the 13.95 N + to the nitrogen atom; the 28.1 N_2 + to the nitrogen molecule; the 39.0 A + to the argon atom (A = 40); and the two last curves, 101 Hg ++ and 198 Hg + to mercury (Hg = 200), carrying one and two charges respectively. The agreement between the deduced values and those assumed by chemists (figures added in brackets) was very close. The hydrogen, carbon, and oxygen found on the negative side are all in the atomic state.

Comparing the new method with spectroscopy, Sir Joseph pointed out that the spectroscopist, observing a new line, was not always certain whether he was not looking at a line of an old known substance produced under special thermal or electrical conditions. In his new method the particles wrote their names on the plate. The method was also exceedingly sensitive. He had traced the presence of helium in this way, when it could not otherwise be detected, requiring only a few particles of the substance confined in a vessel at a pressure of 0.03 mm. of mercury. The accuracy of the measurement was not dependent upon the weight of the substance present.

Although these researches had only been going on for a few months, he realized an accuracy of 1 per cent with 0.01 milligram of substance. No chemist would undertake a determination of atomic or molecular weights under similar circumstances. Another great advantage was that the purity of this substance—the great difficulty of the chemist—was of no consequence. The method sifted the particles, merely giving an additional curve for each constituent. It is further noteworthy that the atom or particle recorded itself within a millionth of a second of its production; thus substances were detected of which the free existence had not, so far, been proved by other means.

The lecturer then exhibited slides of the curves obtained with other gases—chemically-prepared nitrogen, carbon monoxide, carbon dioxide, methane, chloroform, carbon oxychloride, etc., and he reproduced also the tables of the measurements. A few characteristic features may be pointed out. The chemically-prepared nitrogen did not give the argon line, as it should not. A faint mercury curve 65.5 Hg +++ was frequently observed, but somewhat uncertain. The carbon compounds showed 6.0 C ++ in addition to the 12.02 C +.

In the experiments with methane, CH_4 (marsh gas), a veil in the neighborhood of the carbon line had finally been resolved into four curves, 11.95 C +, 12.9 CH +, 14.05 CH_2 +, 14.9 CH_3 +; these were familiar groups to the chemist, but had never been obtained in the free state.

They hoped to study the transformation products of radioactivity substances in the novel way. In the case of chloroform, $CHCl_3$ and some other compounds, two obscure faint lines were observed, 1.5 and 3, the 1.5 also on the negative side; the 3 might possibly be C ++++. The lecturer did not comment on the fact that none of his photographs exhibited any helium curves.

Passing to general conclusions, Sir J. J. Thomson remarked that, leaving accidental impurities out of consideration, this analysis always demonstrated the presence of the respective substance in several states or systems, atomic, molecular, or complex aggregations, carrying one or several positive and sometimes also negatives charges.

Oxygen, for instance, was found in nine modifications, comprising ozone, O_3 × (the suggestion is not new to chemists), O —, and uncharged atoms and molecules. In view of this variety, it did not appear surprising that substances gave many kinds of spectra under different conditions; the various systems might give rise to different spectra.

On the negative side were found the atoms of hydrogen, carbon, oxygen, and chlorine, but never in the molecular condition; the last two would naturally be expected on the negative side, and the association of hydrogen (though a highly electropositive element) with negative charge was no longer a novelty.

As regards these curves on the negative side, it would appear that negative particles were carried through the cathode and that they were picked up by neutral particles and held by attraction. Only the atoms, not the molecules, seemed to be able to do this, and the phenomena illustrated the different behavior of atoms and molecules. Apparently the atom, not the molecule, was capable of exerting momentarily a very powerful attraction. The explanation was probably that the atom had more freedom of motion than the molecule. When magnetism acted on a sphere of a magnetic substance, the electricity within that sphere was free to move and to readjust itself in accordance with the magnetic induction, and a strong attraction resulted. On a sphere of sulphur the freedom was limited and the attraction was weak.

In illustration of this view, about half a dozen compass needles had been mounted, each on its vertical pivot, on a piece of cardboard, which was held suspended by strings in front of an electromagnet. When the electromagnet was excited, the whole system on the cardboard was attracted toward the electromagnet; but when the needles were taken off their pivots and placed on the board, on which they could no longer move freely, hardly any attraction was observed. Similarly, Sir Joseph remarked, there were stiff and freely-moving atomic and molecular systems. It depended upon the numbers of corpuscles in the atom; one corpuscle more than a critical number would (as he had explained on other occasions) impart to the atomic system one freedom of motion, one bond or one valency; two free corpuscles would correspond to two bonds and two valencies. When the atoms joined one another to form molecules, the bonds were linked, the system became rigid, and it failed to attract bodies outside. These researches, Professor Thomson concluded, might help forward the solution of the problems of chemical combination.

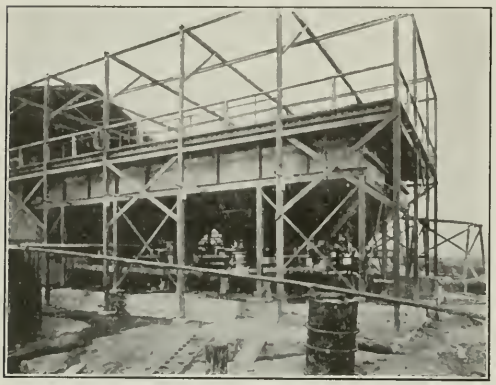
Chemical Analysis in British National Physical Laboratory.—Last year's report of the (British) National Physical Laboratory contains an account of some researches on chemical analysis (London *Eng'ing*, April 21). The small boats of fire-clay wanted for combustion tests were formerly molded and then pressed. The clay is now forced through a die and delivered as a U-shaped strip, which is pinched off at suitable lengths—a more rapid and neater process. The new electric oven for carrying on spontaneous-combustion experiments is a cubical box with asbestos walls, containing a copper box, 18-in. cube, in which the material is placed; a temperature of 500° C. can be kept constant within 1°. There is a free air space of 3 in. around the box. When materials like cotton wool or charcoal are examined a rise of the thermo-couples inside the material above those outside would indicate chemical changes which might lead to combustion.

The Butters Filter Plant at the Crown Mines, Ltd.

The February issue of the *Journal* of the Chemical, Metallurgical & Mining Society of South Africa contains an interesting account of the visit of the members of the society to the Crown Mines, Ltd.

The present metallurgical equipment is 675 stamps with 20 tube mills, and sand and slime plants, made up as follows:

A.	Crown Deep	300	stamps and	10	tube	mills.
B.	Langlaate Deep....	200	" "	6	"	"
C.	Crown Reef	120	" "	3	"	"
D.	Bonanza	55	" "	1	"	"



VIEW OF BUTTERS FILTER PLANT, FROM BENEATH.

With the present plant they have a capacity of 165,000 tons per month.

A fifth mill is being erected of more modern type, which, when completed, will increase the total crushing capacity to well over 200,000 tons per month. Special features are the tandem classifications and the tube milling at A plant; further, the installation of a 300-leaf Butters vacuum filter slime plant at C plant, which is unique not only on account of its being the first vacuum filter plant erected on the South African gold fields, but also because it occupies the site of the first slime plant designed and erected on the Rand by Mr. J. R. Williams.

The following is a description, by Mr. C. G. Patterson, of the Butters vacuum filter plant as installed and worked on the Crown Reef section of the Crown Mines:

The plant consists of two stock vats equipped (temporarily) with air agitation to keep the slime in suspension. After the values have been dissolved in Brown agitators the pulp at a dilution of 2 to 1 is transferred to the stock-pulp vats, from where it is fed to the filters as required.

There is one wash solution vat. All precipitated solution is delivered to this vat to be used subsequently for a wash in the filters. There are two Butters filter boxes, each fitted with 150 Butters vacuum filter leaves and one 14 x 14 Goulds vacuum pump. Each filter box is an independent filtering unit. One 10-in. Robeson-Davidson slime pump handles pulp and solution to and from the filter boxes and the stock vats, serving the boxes alternately.

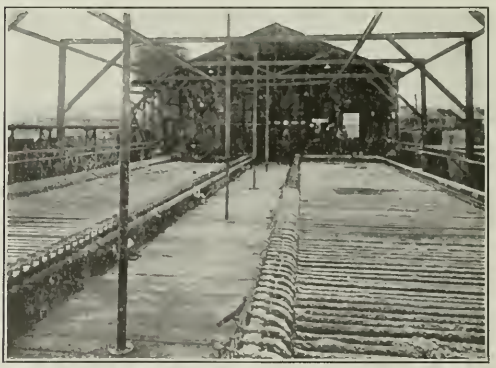
The piping is arranged round the pump in a loop, having four valves interposed so as to reverse the direction of flow through the pipes. The pump is set in either the emptying or filling position instantly, by means of one pilot valve introducing hydraulic pressure into the cylinders of the four valves simultaneously.

The motor for the 10-in. pump, and also valves in the pump systems, are operated from the switchboard. The style of plant is called the "pumping system" and the process of filtration is performed as follows:

Forming the Cake.—The filter box is filled with pulp to a point over the top of the filter leaves and a valve opened connecting the vacuum pump directly with the filters. Clear cyanide solution is drawn from within the filter leaves and delivered to the clarifying vat for precipitation, the slime remaining as a cake on the outside of the filters. The filters are kept submerged by refilling the box at intervals, and jets of air are introduced at the points of each hopper to keep the slime in suspension. When a cake 1 in. to 1½ in. thick has been formed, the surplus pulp is pumped back to the stock pulp vat and the box is then filled with solution to wash the cake. During the time of forming and washing the cake the vacuum is maintained at the highest possible point, but when the cake is exposed to air during the transfer of pulp and wash solution, the vacuum is reduced to 5 in. to prevent the cake cracking.

Washing.—The cake being formed by atmospheric pressure, the resistance and permeability are equal over the whole surface of the leaf, thus producing an ideal condition for the recovery of the valuable moisture contained therein, which equals 30 per cent to 35 per cent. Sufficient wash solution (about 2 tons per ton of slime) is drawn through the cake by the vacuum pump to effect a complete displacement of the original moisture. A portion of this solution goes to the clarifying vats for precipitation; the flow is then diverted to a stock vat to be used in making up new charges in the Brown treatment vats.

Discharging.—When the wash is complete the vacuum is disconnected and a reverse flow of solution (by gravity from the vat on the roof) is introduced to the interior of the filters, causing the cakes to drop. The surplus solution is then pumped from the filter box through decanters and returned to the wash solution vat. The mass of thick sludge remaining in the box is diluted with water and agitated with air for a few minutes to make a homogeneous pulp of 1 to 1, which is then pumped to the residue dam by a second 10-in. R. & D. pump, the delivery pipe of which is fitted with an automatic sampler.



VIEW OF BUTTERS FILTER PLANT, ON OPERATING PLATFORM.

Cycle of Operations.—

Filling box with pulp and forming cake, 45 minutes.
Transferring and washing, 70 minutes.
Discharging, 20 minutes.
Total time of cycle, 2 hours 15 minutes.
Tons treated per cycle, 1¼-in. cake = 50 tons each box.

Acid Treatment.—Five leaves are removed from each filter box every day, thoroughly washed with a spray of water and air, and then immersed in a vat of 2 per cent hydrochloric acid solution for the purpose of dissolving the calcium carbonate and keeping the leaves soft, pliable and in good working condi-

tion. The HCl solution is passed through the leaves in reverse directions alternately by means of an automatic arrangement that requires no power or attention. The leaves are removed from the acid bath after four to six hours' treatment, again washed with the spray and returned to the filter box.

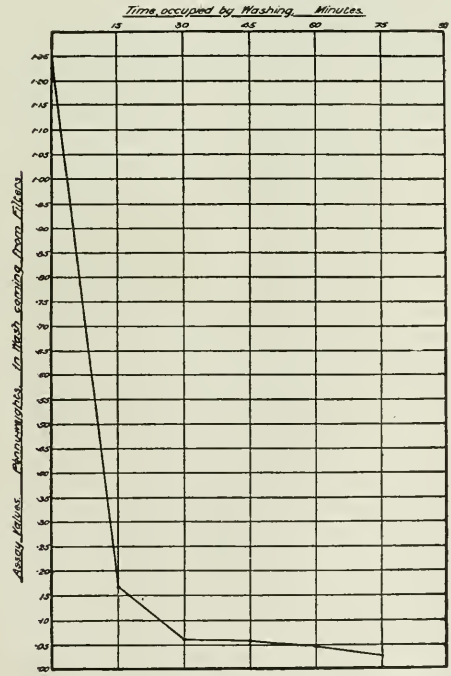
FLOW PLAN—
900 TONS PER DAY, BUTTERS VACUUM FILTER.

Space will not permit of a complete analysis of the six months' test work, as conditions were not normal, owing to insufficient slimes to work the plant to full capacity and to the



WASHING CURVE CHARGE NO. 24, 18, 8, 10.

treatment of deleterious accumulated slime in combination with the current slime the major portion of the time.

In January a special test was made on current slime only, treated first by the Adair-Usher process, the residues from which were delivered to the filter for the purpose of determining what further recovery of dissolved values was possible by filtration. In this test, as also in the former operations with accumulated slime, the efficiency of the filter was fully demonstrated, assays of the residues showing consistently during the whole period over 99 per cent recovery of dissolved values.

There is some dissolving of gold, incidentally effected, during the process of filtration; however, the Butters filter is essentially a slime-washing machine, purely mechanical in its functions, and might be termed a process of forced decantation.

The plant was designed to treat 500 tons per day. Subsequent operations proved that, owing to the exceptional adaptability of Rand slime to filtration, it has a capacity of 900 tons per day.

The plant was put in commission on Aug. 12, 1910, and after a most exacting test over a period of six months has been formally taken over by the Crown Mines, Ltd., as a part of their permanent plant.

Electrolytic Iron.

Last year's report of the British National Physical Laboratory gives an account of an investigation made with electrolytic iron.

According to London *Engineering* of April 21 the experiments have so far been made on electrolytic iron obtained under a German patent, from a mixture of iron and calcium chlorides, by electrolysis at 110° C. with a current of 23 amp per square centimeter; a high current density is essential for the process.

The report does not give analysis of this iron, whose purity is perhaps doubtful. Amberg found nitrogen in iron deposited from chloride among other impurities.

The cathode is a hexagonal prism which yields six slabs of iron 3 in. x 1 in., ⅛ in. thick; these slabs are rolled in the cold and annealed in vacuo to get rid of hydrogen. The thin strips can be bent between the fingers and long crystals 1 in. long, of iron, as thick as the strip, may then split off; these crystals of pure iron are tough and ductile, while the metal is brittle along their boundaries.

Humfrey has heated long strips to high temperatures (say, 1000° C) at one end and to 500° C. at the other, the strip being enclosed in an evacuated porcelain tube; the strip is afterwards etched by admitting gaseous hydrochloric acid or bromide, and it then shows changes, corresponding to a wide range of temperature. The method is an amplification of one introduced by Baykoff.

The Methods of the United States Steel Corporation for the Technical Sampling and Analysis of Gases.

Copyright, 1911, by J. M. Camp, Chairman Chemists' Committee.

This paper is descriptive of the methods selected by the chemists of the U. S. Steel Corporation, acting through the Chemists' Committee, for the technical sampling and analysis of gases. With the increased significance attached to the economic control of those industrial processes involving the combustion of fuels, and with the application of keen scientific research to the various problems involved, it becomes readily apparent that accurate knowledge of the composition of the gases encountered is a matter of prime importance. This fact is exemplified by the rapid increase in the use of internal combustion engines, using blast furnace or producer gas as a fuel, and by the increasing necessity of greater watchfulness upon the efficiency of boilers, stoves and furnaces. The need is obvious for the use by the laboratories of the United States Steel Corporation of a standard system of sampling and analysis of gases, in order that comparable results may be obtained with the maximum degree of accuracy, consistent with the minimum of time requisite for execution.

This description was consummated through a review of the practices specially written for this purpose, of all the laboratories of the Corporation engaged in the sampling and analysis of gases. The apparatus shown for the analysis is to be considered only as a type of the permissible form. The essential points are the exclusive use of capillary tubes, the permanency of connection of the auxiliary gases, compactness, and the applicability of the apparatus to the accompanying description. This form of apparatus and the methods as here described, are to take precendence over all others employed for the analysis of gases throughout the laboratories of the Corporation.

It is the desire of the Chemists' Committee here to acknowledge their grateful appreciation of the services of Mr. D. A. Barkley and Mr. R. J. Wysor, assistants in the Duquesne laboratory, in the preparation of this paper.

In the preparation of the accompanying standard methods for the sampling and analysis of gases, there has been an unwavering purpose to eliminate, so far as possible, tedious analytical procedures, or the use of cumbersome and antiquated forms of apparatus. It has been desired to adopt methods, inherently correct in principle, in conjunction with simplified apparatus, which will insure the requisite expediency, at times so necessary in commercial work, without an appreciable sacrifice in accuracy of results. While no notable originality is claimed in general for the substance of this paper, it is believed that the application of well-known methods, coupled with certain novel features in execution, and in the forms of apparatus used, will be presented. A sense of vagueness or lack of definiteness with reference to practical descriptions, it is believed, pervades the bulk of literature concerned with this subject. No apology is offered for the unabridged nature of the descriptions and explanations appearing in this pamphlet. The delineation of the methods has been made in considerable detail so as to be clearly intelligible to amateurs as well as to those better versed in the subject. The goal simultaneously attained by accuracy and speed of execution, and so much desired in chemical methods, has been striven for, with what success the future will demonstrate.

Sampling.

The impossibility is recognized within the compass of this pamphlet of detailing a method for sampling gases, that would be applicable to all the works of the Corporation and the various metallurgical operations therein. It is preferred, rather, to make this description general in its scope, leaving to each individual operator the solution of the details to meet his own particular conditions. In the sampling of gas two kinds of samples are recognized, the regular and the irregular. The former comprises all samples taken over a continuous division of this time. The results so obtained will constitute the regular or official analysis and they only will enter into comparison with like results from other works. Under the head of the irregular samples will be included all those samples taken for a shorter period of time than the minimum above given, and will represent momentary conditions of the particular operation in question, and are for the works' guidance only. All analytical reports shall show the duration of the time of sampling in order that the status of the results may be seen at a glance.

In sampling blast furnace or producer gas, which are considered homogenous as regards cross section of the main, the gas is withdrawn through a petcock on a pipe screwed into the shell of the main and extending in beyond the brickwork lining. In the absence of lining the gas may be withdrawn through a petcock on the shell, or when the main is inaccessible, on a pipe leading from the main and through which a constant current of gas passes.

In sampling flue gas it is necessary that the gas be withdrawn through a perforated pipe, which enters with air-tight connection and extends entirely across the flue. The pipe is closed at the anterior end and provided at the outer end by an aspirating device, operated by air, water, or steam (see sketch). The perforations in this pipe should be an equal distance apart, and, to obtain an equal flow through each opening, their combined area should be less than the cross sectional area of the pipe, three-fourths being considered a safe figure. The gas sample is withdrawn from the sampling pipe through a petcock situated between the flue and the aspirating device. This pipe may also be used in sampling blast furnace or producer gas; however, in place of the aspirator, the gas is allowed to escape under its own pressure.

An apparatus for withdrawing an accumulative sample is shown in the accompanying photograph. This appliance is one of many that may be used and has the advantage of simplicity of construction and operation. In obtaining a sample, the petcock, permanently attached to the main, flue or intermediary pipe before mentioned, is connected by a rubber tube with one hole of the doubly perforated stopper in the two gallon aspirator bottle. This bottle is full of water which has been saturated with the gas to be sampled and which may also contain one per cent of sulphuric acid. The lower opening of this bottle is connected by a rubber tube with a similar opening of another bottle placed on a lower level, the rate of flow of water from the upper to the lower being controlled by a screw compressor. The petcock being open, the screw compressor is released and the gas rapidly displaces the water in the upper bottle. On closing the petcock, reversing the bottles, and opening the pinchcock on the rubber tube leading from the second hole in the rubber stopper, the gas is rapidly expelled into the air until the rubber tube constituting the exit is full of water. The pinchcock is closed, the bottles reversed, and the upper one filled with gas, the rate of inflow of gas being so controlled by the compressor that the bottle is filled in the designated time, one-half to twenty-four hours.

A portion for analysis is transferred from the bottle to the small sample tube (No. 2, Analytical Apparatus). This tube, made of suitable material, is two inches in diameter, eight inches long, has conically shaped ends terminated by petcocks and a capacity of about 300 cc. This sample tube being filled with water, including the upper petcock, to exclude all air, is attached to the rubber tubing constituting the exit from the gas bottle, which is also full of water. The position of the aspirator bottles is reversed, placing the gas under pressure, the pinchcock is opened, the upper then the lower cocks on the sample tube are opened and the gas is allowed to displace the water in the tube and flush through for a short time to saturate the moisture adhering to the sides. The lower, then the upper cock on the tube is then closed, leaving the gas under slight pressure. The sample is delivered to the laboratory and analyzed as soon as possible to minimize the loss of carbon dioxide.

When so desired, a gasometer may be used for withdrawing a larger sample of such size that calorimetric determinations may also be made on it. If rough gas is to be sampled continuously, it is first passed through a suitable apparatus for removing the dust. The water in the gasometer is used continuously and as long as practicable. A small sample for analysis is forced through a petcock on the holder and suitable rubber tubing connection into the sample tube in the manner previously described.

Analysis.

The Apparatus.—1. The apparatus shown in the accompanying Fig. 3 has been designed with particular reference to its adaptation to the methods subsequently described. The distinguishing features in its design are the capillary tube of 1 mm bore, the accessibility of the auxiliary gases, oxygen and hydrogen, and the central location of the burette in the apparatus, thus decreasing the error due to the capillary space. Drawings of this apparatus, which have been copyrighted, have been supplied to Messrs. Eimer & Amend of New York, the authorized makers, who are prepared to supply it in whole or in part.

The general disposition of the apparatus is obvious. On the extreme left end of the capillary the rubber tubing connection leading to the Kipp apparatus (No. 9) is placed, while the connection to the oxygen supply (No. 7) is made on the end of the first stopcock. To the first capillary stem is attached the explosion pipette (No. 8), the platinum leads within which are partly covered with glass to prevent the spark from short-circuiting; next in order the pipette containing potassium hydrate solution (No. 4) is placed, followed by the burette (No. 3). To the right of the burette are situated the pipettes containing stick phosphorus and fuming sulphuric acid (No. 6 and No. 5, respectively).

The stem of each pipette is ground so as just to clear the corresponding stem of the capillary with which it is connected. The stem of the burette must not be altered, but is to be precisely adjusted to the stem of the capillary tube by regulating the height of the support at the bottom. The calculated volume of the capillary tube is aprpoximately 0.2 cc, but since one-half is kept filled with water, the capacity of the burette and capillary is 100.1 cc. Since the majority of readings are made in the lower part of the burette, the first 75 cc are graduated in tenths, and by interpolation twentieths may be read. The remaining 25 cc are graduated in fifths, and may be read in tenths. The numerations are from the bottom upward. The burette is surrounded by a water jacket, thereby maintaining practically a constant internal temperature throughout an analysis.

The pipettes have two compartments, and to the open side a thin rubber bulb is attached. This protects the reagent from the atmosphere. The pipettes will conveniently hold 100 cc of gas and 260 cc of the reagent, with the exception of the one for phosphorus. This pipette was designed for the use of stick phosphorus, and when moderately filled with this reagent will hold 100 cc of gas, and sufficient water to form a seal. Thus the gas is exposed to the maximum surface area of the phosphorus, facilitating the removal of oxygen. In filling, the phosphorus is introduced through an opening at the lower end of the pipette. The stem rises into the base of the pipette for a distance of about ¼ in., thus preventing the sticks from obstructing the orifice.

2. A ½ pint Kipp apparatus for generating hydrogen from C. P. stick zinc and dilute hydrochloric acid.

3. An aspirator bottle containing oxygen and nitrogen in predetermined proportion.

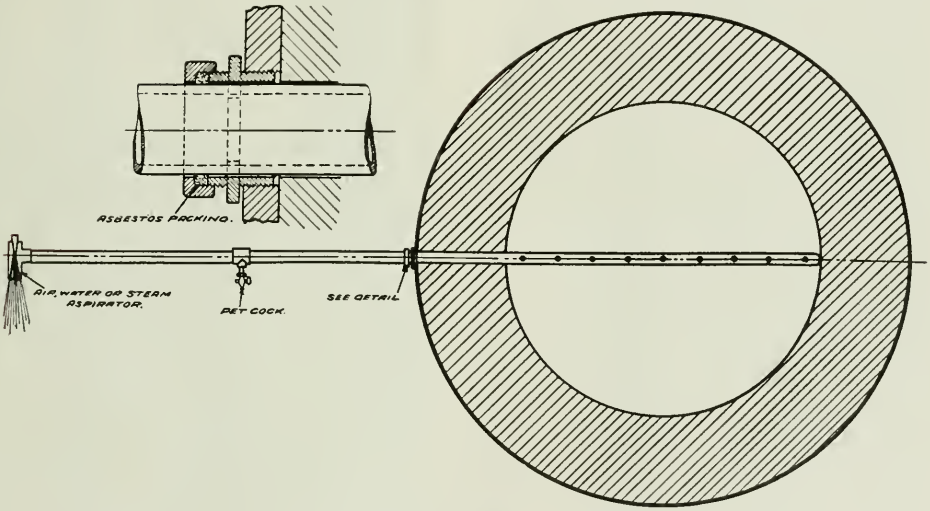


FIG. 1.—SAMPLING TUBE FOR FLUE GASES.

An induction coil of sufficient size to give a ⅛-in. spark. The current required for this coil is derived either from dry cells, a storage batter, or from direct-current lighting circuit with a suitable rheostat connection.

Reagents.—1. Potassium Hydrate. The pipette used for this reagent is filled with 260 cc of a solution of approximately 1.27 specific gravity. The absorbing power is in excess of 40 cc of carbon dioxide per cc of solution.

2. Stick Phosphorus. This reagent is prepared in sticks of about 4 mm or 5 mm diameter, and of suitable length for the absorption pipette, by melting the phosphorus under water in a test tube immersed in a vessel of water at a temperature of about 50° C. A glass tube of the proper internal diameter is inserted in the molten phosphorus, and a column of phosphorus is drawn into the tube by means of suction to the desired height, when the tube is withdrawn and immediately dipped into a beaker of cold water. The solidified phosphorus is then pushed out with a glass rod into the reagent pipette filled with water. When in use the water in the pipette is renewed occasionally to remove the oxides of phosphorus in solution. The need for this is apparent when the fumes in the pipette are

slowly or incompletely absorbed in one or two minutes. The chamber of the pipette containing the phosphorus is inclosed with a piece of black paper to protect it from the action of light.

3. Fuming Sulphuric Acid. Two hundred and sixty cubic centimeters are required. The acid should contain at least 20 per cent of sulphur trioxide in excess. It will become discolored owing to its action upon the rubber tubing, but this does not appear to interfere with its efficiency. This action tends to harden the tubing, after which it apparently ceases.

4. Dilute Hydrochloric Acid. A mixture of hydrochloric acid —100 cc, and distilled water—400 cc, is poured into the Kipp apparatus, the middle chamber of which is well filled with C. P. stick zinc.

5. Saturated Water. This is used to fill the burette, the explosion pipette, and the leveling bottles. Care should be taken not to contaminate this water with any of the reagent solutions, as the longer it is used, the less will be the liability of error due to the absorption of gas. It is obtained by causing the gas to bubble through distilled water contained in a bottle for a reasonable period of time. The water is filtered, 1 per cent of sulphuric acid is added, and the mixture well shaken.

Auxiliary Gases.—1. Hydrogen. This is generated in the middle chamber of the Kipp apparatus by the action of dilute hydrochloric acid upon C. P. stick zinc. The apparatus should be flushed several times with freshly generated hydrogen to remove all traces of air, and the rubber tubing connected to the left end of the main capillary tube.

2. Oxygen and Nitrogen Mixture. This mixture should contain from 35 per cent to 45 per cent oxygen and from 55 per cent to 65 per cent nitrogen. The container, a ½-gal. aspirator bottle, is assumed to have a volume in round numbers of 2000 cc. By calculation it has been found that a mixture of one-third oxygen, obtained from the oxygen tank, and containing between 95 per cent and 100 per cent oxygen, and two-thirds air will approximate 46 per cent oxygen and 54 per cent nitrogen in composition.

Suitable connections are made between two aspirator bottles, one being filled with water, the other containing enough to form a seal, and the rubber tubing connecting the two bottles is closed with a pinchcock. The volume of water in the former above the lower outlet is determined, and two-thirds of this amount is returned to the bottle, a mark being made on the side even with the water level; the bottle is then filled with water. A connection is made with the oxygen supply, the pinchcock between the two bottles released, and the oxygen is allowed to pass slowly into the bottle until the water reaches the indicated mark, the overflow passing into the second aspirator bottle. At this point the rubber tubing leading to the oxygen supply is disconnected, the second aspirator bottle is immediately lowered, and the air drawn in the upper bottle until the water level is even with the outlet. The end of the rubber tubing on the upper bottle is closed with a pinchcock, and the gases thoroughly mixed by agitation. The bottles are placed on their shelves, and the tubing connected to the stem of the three-way cock on the left of the gas analyzing apparatus.

Methods of Analysis.—1. Percentage of oxygen in oxygen and nitrogen mixture.

In the application of the following methods it has been found that a mixture of oxygen and nitrogen, in the proportion given before, is the most practical for use in the combustion of the component gases, but it is necessary to know the exact percentage of oxygen in this mixture in order that the amount of oxygen added for the explosions may be known. The object in introducing this mixture instead of oxygen alone is that a larger volume of the former can be added, and only a normal excess of oxygen will be present after the first explosion, thereby keeping the explosion ratio as high as practicable and reducing the flame temperature, thus minimizing errors due to the combustion of nitrogen. The explosion ratio is the proportion of the inert to the total gases entering into the combination. The oxidation of nitrogen cannot be entirely avoided since oxides of nitrogen are formed in all explosions in amounts varying chiefly with the temperature attained. The design of the explosion pipette, owing to its eudometric shape, is an aid in avoiding the combustion of nitrogen in that the flame movement is slower, and necessarily the production of heat is lower, than in the spherical form of pipette. Experiments have been made on the gases discussed in this paper, and approximately quantitative determinations made of the oxides of nitrogen formed in the combustions. It has been found that with this mixture, and the explosive ratios as high as practicable, the errors due to oxides of nitrogen are negligible. With pure oxygen, even though the explosive ratio is the same, the formation of oxides of nitrogen is markedly increased.

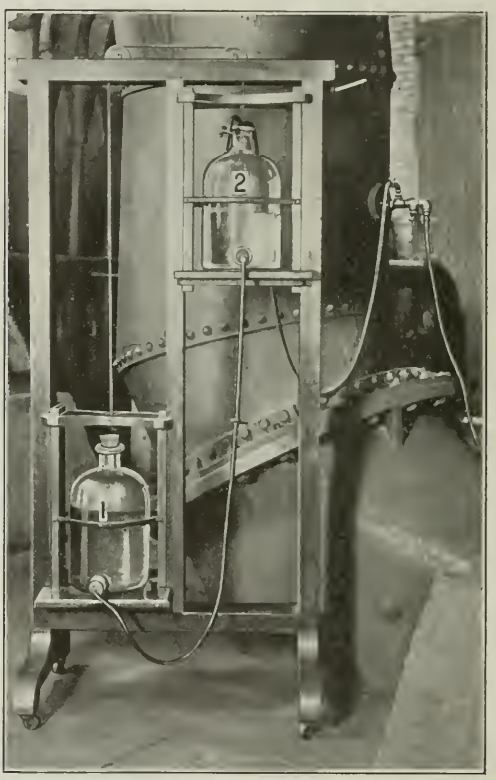

FIG. 2.—APPARATUS FOR THE SAMPLING OF GASES.

With the data of an analysis at hand, the explosion ratio for the first explosion is found by dividing the gas residue after Contraction II, by the sum of Contraction I and Contraction II, and the ratio for the second explosion by dividing the residue after Contraction III, by Contraction III. In the analysis of furnace, producer and flue gases, the most practical ratios of inert to the combining gases are those lying between 1.5 to 1 and 3 to 1; with producer gas the ratio obtained in the first explosion should approach as near as possible to the latter ratio, since the amount of heat liberated in the combustion of methane is relatively great.

Before beginning the analysis, it is advisable each day to agitate the bottle containing the oxygen and nitrogen mixture, and to flush out the connecting rubber tubing by lowering the leveling bottle (*L*), drawing in about 25 cc each of hydrogen

and oxygen and nitrogen mixture, and discarding through the three-way cock at the right. The solutions in the reagent pipettes are drawn flush with the main capillary tube, care being exercised that there are no unfilled spaces in the capillaries of the pipettes. The left half of the capillary is filled with water drawn over from the explosion pipette, the levelling bottle is now raised and any portion of the solutions that may have been drawn into the main capillary are expelled through the stem of the three-way cock at the right, to which is attached a piece of rubber tubing discharging into a suitable waste receptacle. While the levelling bottle is still raised the three-way cock is closed and in this manner the capillary tube is left filled with water. After the gas has been passed on the left side for absorption or explosion, or after the addition of each of the auxiliary gases, the capillary tube may be filled with water from the explosion pipette before a reading is taken, thereby avoiding the error due to the capillary space of 0.1 cc. The leveling bottle is placed at the base of the apparatus, and approximately 75 cc of hydrogen and 25 cc of oxygen and nitrogen mixture are added in succession, each being accurately measured by bringing the water in the leveling bottle to the same level as that in the burette. From a half to one minute should be allowed for the burette to drain before a reading is taken. The leveling bottle is raised and the cock leading to the explosion pipette (8) is opened, and the gas passed over and back two or three times to insure a thorough mixture, as an imperfect mixture may prevent the desired explosion.

The electric circuit is then closed causing the explosion. The bottle (Y), which receives the overflow from the explosion pipette, and the location of which on the lower shelf is never changed, the gases thereby being kept under partial vacuum, is connected to the latter by a piece of strong rubber tubing about 1 ft. long, partly constricted by a screw compressor near the bottle. The degree of the constriction is determined by increasing it until no bubbles appear in the pipette after an explosion. All the conditions of this arrangement tend to diminish the force of the resultant explosion.

After the explosion, the gas is immediately drawn back into the burette until the water from the pipette fills the left half of the capillary tube. The cock in the pipette is then closed, and after an interval of one minute for allowing the gas to cool, a reading is made. This less the previous reading represents the contraction due to the formation and condensation of water and is known as Contraction I. The oxygen that entered into the explosion is equal to one-third of the contraction, since

$2H_2 + O_2 = 2H_2O$. 2 volumes + 1 volume = liquid (disappearing).

$$\text{Percentage of oxygen in the mixture} = \frac{\text{oxygen and nitrogen mixture added}}{\text{oxygen found}} \times 100.$$

Example Data

	Burette Readings.	
	100.0	
Add hydrogen.....	74.6	Hydrogen added.
Add oxygen and nitrogen	25.4	
Mixture	25.2	Mixture added.
	.2	
Explosion	33.6	Contraction.
	33.8	
	11.2	⅓ Contraction or Oxygen found.

Calculations.

$$\frac{\text{oxygen found}}{\text{oxygen and nitrogen mixture added}} \times 100 = 44.4 \text{ per cent oxygen.}$$

Explosion ratio, 1.97.

Two or more determinations are made, which should agree within 0.1 per cent or 0.2 per cent. If there is question as to the accuracy of the results obtained, they may be proven by using air as a standard, and subjecting it to conditions similar to those just described. It being known that there is 20.9 per cent of oxygen in air, it follows that if the oxygen factor as previously obtained is correct, the determined amount of oxygen in the sample of air should equal the theoretical.

The residue of gases from the previous analysis is rejected and about 60 cc of air are drawn into the burette and the burette is allowed to drain. The leveling bottle is placed on top of the apparatus, the tube leading from it is pinched tightly, and the three-way cock opened, the pressure of the gas being thus released. The remaining portion is slowly forced out by releasing the pressure on the tube until the meniscus just reaches the 50-cc mark in the burette, and the three-way cock is closed. When the leveling bottle is applied

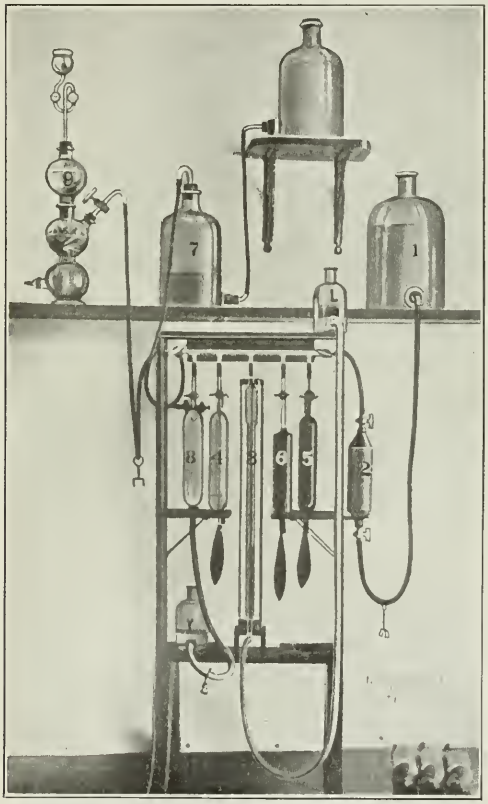

FIG. 3.—APPARATUS FOR THE ANALYSIS OF GASES.

there should be exactly 50 cc of air in the burette and to this approximately 20 cc of oxygen and nitrogen mixture, and a like amount of hydrogen, are added, a reading being taken in each case. The gases are mixed, exploded, drawn back into the burette and, after allowing one minute to drain and cool, Contraction I is noted. Hydrogen is then added until the volume of the mixture approaches 100 cc. The gases are again mixed and exploded, drawn back into the burette, and Contraction II is noted. It follows from the reaction previously stated that

$$\text{Total oxygen} = \frac{\text{Contraction I} + \text{Contraction II}}{3}$$

Oxygen in sample of 50 cc of air = total oxygen − oxygen added.

The result should approximate 10.45 and if so, proves the factor to be correct.

Example—Burette Readings.

100.0	
Add Air.....	50.0 Air added.
50.0	
Add Oxygen and Nitrogen Mixture...	20.0 O and N Mixture added (44.4%O_2). 8.88 Oxygen added.
30.0	
Add Hydrogen.....	19.6 Hydrogen added.
10.4	
Explosion	29.4 Contraction I.
39.8	
Add Hydrogen.....	38.8 Hydrogen added.
1.0	
Explosion	28.6 Contraction II.
29.6	

Calculations.

$$\text{Total Oxygen} = \frac{\text{Contraction I} + \text{Contraction II}}{3} = 19.33$$

Oxygen in sample of 50 cc of air = total oxygen — oxygen added = 10.45 cc.

Oxygen found in 100 cc of air = 20.90 cc.

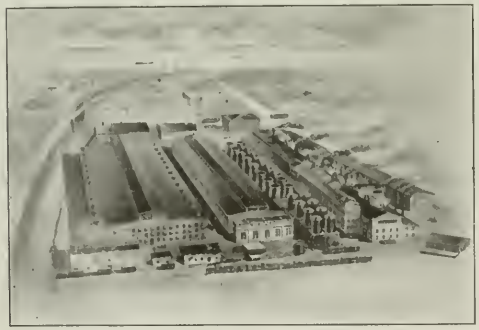
Explosion ratios: I, 2.05; II, 2.46.

The percentage of oxygen may also be found from the same data; the oxygen in the mixture is the difference between the total oxygen found and that contained in the air used, the percentage is found by dividing the oxygen in the mixture by the volume of mixture used and multiplying the quotient by 100.

(To be concluded in the next issue.)

Hooker Electrochemical Co. Works.

We are glad to show in the accompanying illustration the plant of the Hooker Electrochemical Company at Niagara Falls, N. Y., for the production of caustic soda and chloride of lime by the Townsend electrolytic cell, which they purchased in the early stages of its development and have since perfected and successfully operated. It is a splendid example of concrete steel construction and is the result of the gradual expansion of the business since 1905. The company now ranks among the foremost producers of heavy chemicals in this country. In 1910 a portion of the plant was seriously damaged by fire, but was quickly replaced by construction of the most permanent character, and full operation was resumed early



NIAGARA WORKS OF HOOKER ELECTROCHEMICAL CO.

last fall. During the shutdown the company fulfilled its contracts for the delivery of material, waiving the rights secured to it by fire clauses in its contracts. This action is indicative of the broad business policy which the Hooker company has pursued since its inception.

The Townsend cell, which is comparatively simple and inexpensive both in construction and operation, has been successfully used in the mining industry to produce chlorine for the chlorination of ores, and is recommended and licensed by the Hooker company for this purpose.

Evaporators and Vacuum Pans.

By B. Viola, M.E.

The Kestner Evaporator.

The principle of the Kestner evaporator is the climbing film and it introduces quite a novel condition in the evaporator business, having special advantages for the evaporation of delicate materials. Numerous experiments made have demonstrated that the liquor is in contact with the heating tubes for almost an infinitesimal time, thereby permitting the use of higher pressures without damage to the material, or lower pressures, thereby producing a material of high quality.

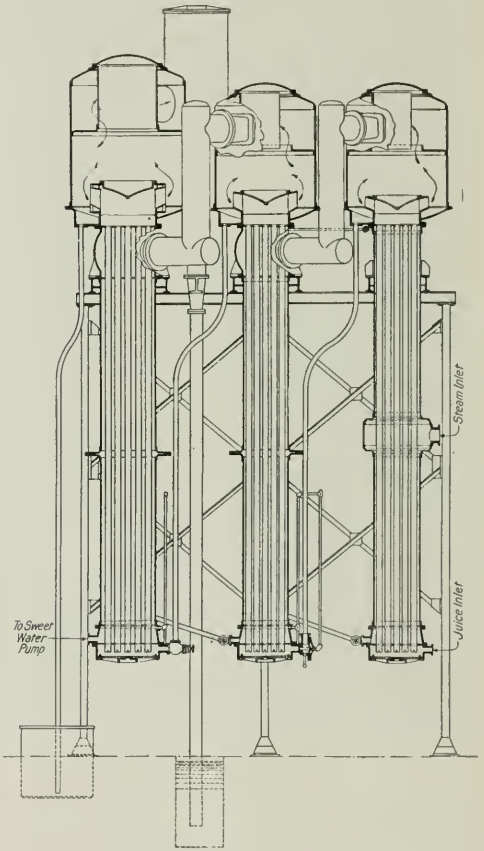


FIG. 29—KESTNER EVAPORATORS.

The liquid enters the base of No. 1 cell (*Fig.* 29). This should be fed in at a temperature approximating the boiling point in this body. The steam, as shown, surrounds the outside of the tubes, and as the liquor is at the boiling point it is, of course, ready to begin boiling at once. Small bubbles are formed at the base of the tubes, which readily grow larger until the entire core is filled with a solid mass of steam passing rapidly up the tube. The speed of this steam or vapor is such that it carries with it a thin film of liquid on the inside of the tube, and in virtue of the rushing steam this thin film is continually passing up and is pressed in close contact with the hot

walls of the tube. On reaching the upper tube sheet the mixed vapor and liquid pass through the so-called centrifugal separator, which consists of a series of curved blades having tangentially presented openings through which this mixture passes at high velocity. The liquid, in virtue of its greater specific gravity, is thrown farthest and is projected against the walls of the vapor belt or containing vessel. As this strikes these walls at an angle they impart to it a rotary motion,

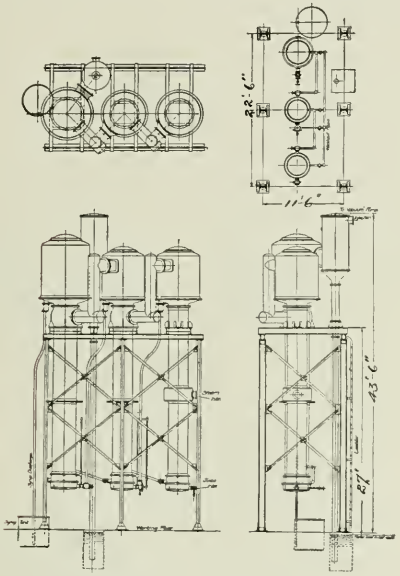

FIG. 30—TRIPLE-EFFECT KESTNER EVAPORATOR.

which further permits the complete separation of the vapor from the liquid. The major portion of the vapor, on account of its lower specific gravity, is not thrown so far as the liquid, and passes up at an intermediate point through the baffle or catchall, which forms the upper portion of the vapor belt. This catchall is arranged in the well-known manner and is inserted simply as a precautionary measure.

The vapor then passes through the vapor pipe between bodies No. 1 and No. 2 and enters the steam belt of No. 2, performing the same operation as in No. 1. The liquid, however, separated from the steam, passes down the pipe and through the automatic valve into the bottom of body No. 2, where the same operation takes place as in No. 1.

The automatic valve is a balance valve operated by a diaphragm. One side of the diaphragm is subjected to the pressure of the liquid in the pipe between bodies Nos. 1 and 2. The other side of the diaphragm is connected through what is termed the balance pipe with the steam belt of body No. 2. It is the practice to fill the vertical leg of this balance pipe with water. The hydrostatic head on one side of the diaphragm is, therefore, equal to the head of water in the balance pipe; and on the other side the head of juice in the liquor pipe. The pneumatic pressure on both of these columns is the same because steam belt No. 2 is at the same pressure as vapor belt No. 1. When these two hydrostatic heads are equal the valve is closed.

Should the head of liquor rise in the liquor pipe so that it exerts a greater hydrostatic pressure on its side of the diaphragm the valve will open and allow the liquor to pass until the hydrostatic head balances that of the balance pipe. In practice this valve remains partly open the whole time the evaporator is working. A similar valve might be used on the liquor pipe between 2 and 3. The drawing, however, shows an angle valve which can be adjusted by hand.

The water of condensation from body No. 1 is ordinarily carried into body No. 2 and use is made of the thermal units set free in virtue of its higher temperature. In the same way the water of condensation passes from No. 2 into No. 3. As the steam belt of No. 3 is at a partial vacuum, the water of condensation must be removed by means of a pump.

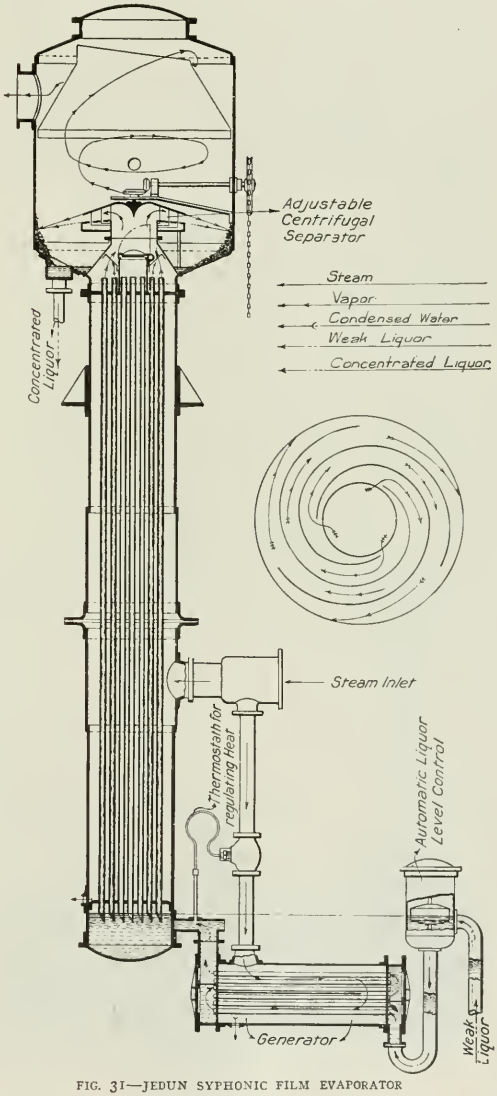

FIG. 31—JEDUN SYPHONIC FILM EVAPORATOR

The discharge of liquor from the last body takes place by virtue of the barometric height. The vapor from the last body passes into the condenser through the opening shown in the back of the last vapor belt. *Fig.* 30, the plan view of a triple effect, shows clearly the connection to the condenser.

Jedun Syphonic Film Evaporator.

As shown in *Fig.* 31, this evaporator's action, which has a

great similarity to the Kestner evaporator and works on the same principles, begins with a generator whose object is to generate a proportionate amount of vapor bubbles which enter the base of the evaporating tubes, carrying with them small pistons of layers of liquid which are contained in the expansion chamber. If the vapor bubbles are generated and supplied continuously the rising of the bubbles and layers of liquid will also be continuous within the evaporating tubes. The height

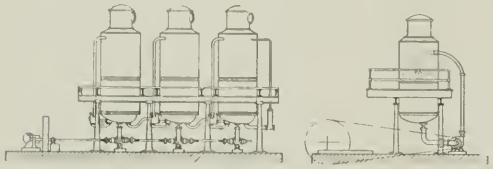

FIG. 32.—MEYER & ARBUCKLE'S REVOLVING DISTRIBUTOR ATTACHED TO A TRIPLE EFFECT.

to which the layers of liquid and vapor bubbles rise is governed by the amount and temperature of the liquid admitted to the expansion chamber.

The action of this evaporator is explained by the following: if a liquid and a vapor having the same temperature are allowed to rise in a current in small tubes the vapor bubbles, notwithstanding their lower specific gravity, will always rise through the tubes, carrying in front of them small pistons of liquid. Now, if the tubes which receive the bubbles of steam and liquid are surrounded by a heating medium, say steam of a temperature somewhat higher than the temperature under which the liquid or pistons of liquid and bubbles are to be evaporated, it is reasonable to say the evaporation of the liquid carried into the tubes by the vapor bubbles is very rapid, this depending upon the amount of vapor bubbles and liquid admitted into the tubes.

The vapor bubbles expand enormously and burst and the liquid evaporates owing to its contact with the heated surface of the tubes, which increases the volume of the vapor in a very large proportion, while the volume of the liquid decreases. As

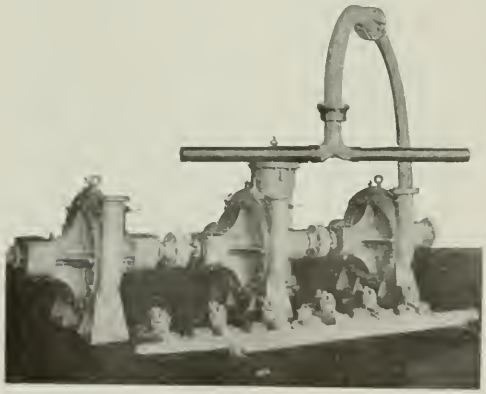

FIG. 33—MEYER & ARBUCKLE'S REVOLVING DISTRIBUTOR CONNECTED WITH THE CENTRIFUGAL PUMPS.

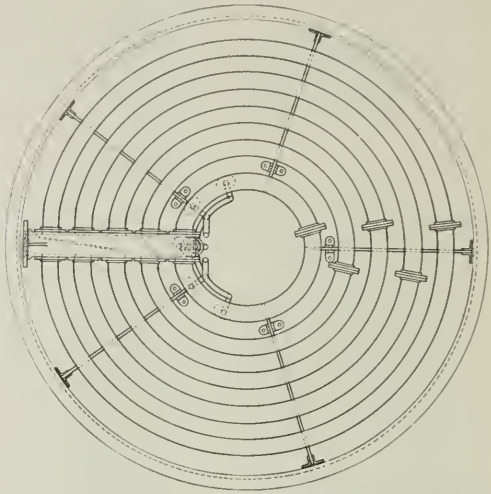
the vapor in proportion is many times larger in volume than the liquid, this causes it to rush through the central portion of the tubes at such a velocity that it syphons or pulls with it along the heated walls of the tubes a thin film of liquid, which is discharged together with the vapor through an adjustable centrifugal separator into the vapor belt or chamber.

The action of this centrifugal separator is based on gravity, centrifugal force and the converting of vapor bubbles into solid drops through causing them to burst by allowing the bubbles to expand from a higher to a lower temperature.

The vapor and liquid discharged from the evaporating tubes enter the centrifugal separator and by the arrangement of the centrifugal vanes therein have imparted to them a centrifugal motion, and also an increase in pressure or temperature through the adjustment of the head or cover of the separator. The average velocity of the vapor through the separator is from 80 to 120 ft. per sec., while the average velocity of the



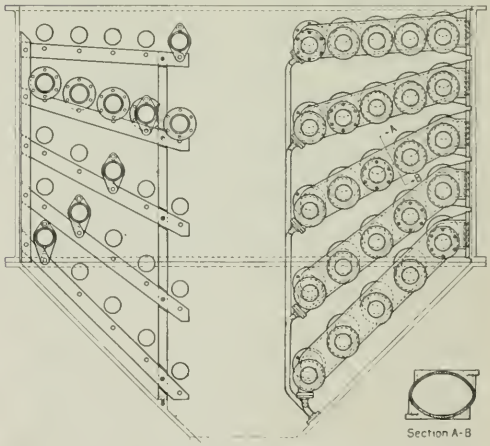


FIG. 34—DYER MANIFOLD HEATING COIL.

vapor ascending in the vapor belt into which the separator discharges is 3½ ft. per sec.

The drops of liquid and vapor thrown off from the separator retain their original velocity. The drops of liquid being heavier than the vapor, combined with the centrifugal motion or force imparted to them by the separator vanes, and the downward angle at which they are thrown from the periphery of the separator, cause them to strike against the wall of the vapor belt, where they flow downward to the discharge pipe, while the vapor ascends free from all moisture and entrainment and passes on through the vapor main to the next effect or condenser.

Arrangements are made also whereby the evaporator can be worked at full, half, quarter or any capacity that may be required. To meet these varying requirements a hood is arranged encircling any given number of tubes. Thus the capacity is controlled at will.

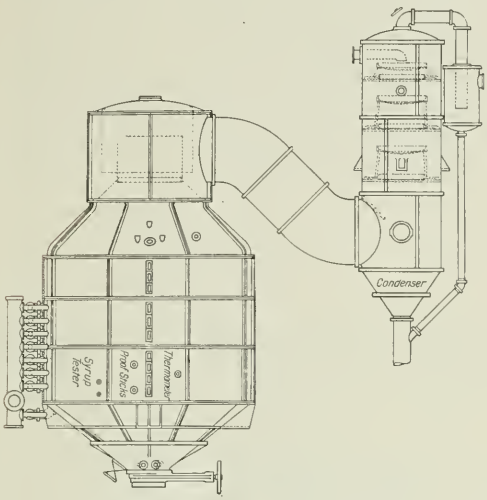

FIG. 35—DYER VACUUM PAN AND CONDENSER.

Meyer & Arbuckle's Film Evaporator.

This evaporator, or in other words, a film sprinkler, is a very original idea. It is in fact nothing else than an attachment to any evaporator with horizontal or vertical heating tubes. It is an automatic revolving distributor suspended over top tube plate in vessel, combined with centrifugal or other pumps for mechanical circulation, is the principle applied in obtaining an ideal film over the whole heating surface. Fig. 32 shows how it is attached to a triple effect, being provided with centrifugal pumps for bringing the liquid into the evaporator. The distributors, which are entirely automatic, are actuated by the escape of liquid through perforations in the arms bolted to the tee piece over the tube plate. The perforations in one arm are diametrically opposite to those in the other arm, thus there are no working parts beyond the ball bearings in the tee piece. The velocity is readily controlled by the increasing or diminishing angle perforations in relation to the top of tube plates.

Centrifugal velocity is imparted to the fine jets of liquor by distributors, resulting in a swirl down the interior heating surface of the tubes, leaving at the same time the center of the tubes free for rapid escape of vapors.

According to experience this attachment increases the efficiency of an evaporator 33 per cent (Fig. 33).

The Concentrating of Solutions Without Heat.

Experiments have been made lately for concentrating solutions without heating them, which process is based on the well-known osmosis. Vegetable membranes and artificially produced membranes of precipitates are known already which are semi-pervious, namely, which permit the solvent but not the dissolved crystalloids to pass through them. Numerous experiments made by A. Farago have demonstrated that most of the precipitates which cannot be dissolved in water or in other solvents possess the same property. In other words, they are semi-pervious, if prepared in a sufficiently thin layer.

The semi-pervious substances which are used in carrying out the process to which this invention relates are prepared as follows: Porous clay tubes, which can be closed at their edges, are filled with a solution of salt, one of the components of which is the component of the semi-pervious membrane to be produced. The tubes are then closed and placed in a bath which contains another solution of salt, one of the components of which is the second component of the semi-pervius membrane to be produced. The two solutions meet in the walls of the tubes and from there a new compound which in a finely divided condition fills the pores of the clay tubes. The tubes after being removed from the bath, emptied and washed out, will now be semi-pervious.

Now the essential novelty of this invention consists in the fact that the liquid to be concentrated is caused to pass through a system of tubes produced in the manner above described while a concentrated salt solution is caused to flow in the opposite direction around this system of tubes. If, from tubes of the character above described, there be constructed a system of tubes of sufficient length, surrounded by a second set of tubes made of glass, copper, stoneware, wrought-iron or any suitable material, and if the aqueous solution to be concentrated, be caused to flow slowly by means of a pressure pump through the inner of the two sets, while a concentrated salt solution is at the same time caused to flow in the opposite direction through the surrounding outer tube-system, there will arise between the two solutions an osmotic reaction through the semi-pervious clay tubes which will result in the passage of water from the aqueous solution into the concentrated salt solution.

As the two liquids flow in opposite directions it follows that the more concentrated liquid will gradually meet with the more

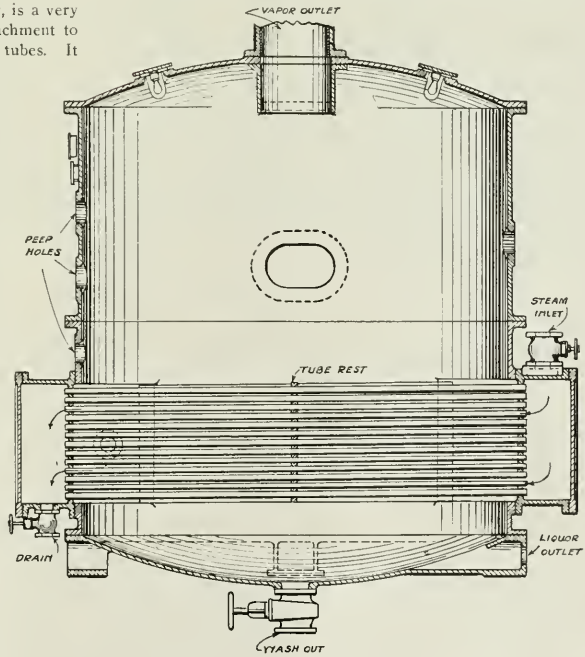

FIG. 35A—ZAREMBA VACUUM PAN.

concentrated salt solution, and as osmosis will continue as long as the two liquids differ in their degree of concentration the liquid to be concentrated will finally pass out of the tubular system with a degree of concentration corresponding to that

of the salt solution in the outer tubular system, while the salt solution used to effect concentration will pass out of the outer tubular system diluted to an extent corresponding to the dilution of the liquid to be concentrated.

The form of the tubular system used in carrying out the process may be of any desired kind, so long as it fulfills the condition of presenting as large surfaces as possible without taking up much room. The advantage of the process to which this invention relates, in comparison with those hitherto in use, consists in the fact that solutions which can be heated and evaporated only with a certain amount of risk, such as explosive substances or solutions which easily become decomposed when heated, can by means of this process be concentrated without any risk whatever.

This shows clearly that long heating coils will give hardly more than one-third of the efficiency compared with short, inclined tube heating systems. This is natural, for after steam enters the coils the condensing water will cover the lower part of the inner surface of the coil and the more it nears the end the more condensing water will be present. This water isolates the heating surface of that part of the coil entirely. Therefore the most efficient heating surfaces for vacuum pans should be made from short inclined tubes. By adopting this system, which has the advantage of greater economy and larger output in a shorter time, the present vacuum pans with long horizontal and vertical tubes will have to be reconstructed.

To improve this disadvantage of the heating-coil system, a very ingenious idea was worked out by a well-known Ameri-

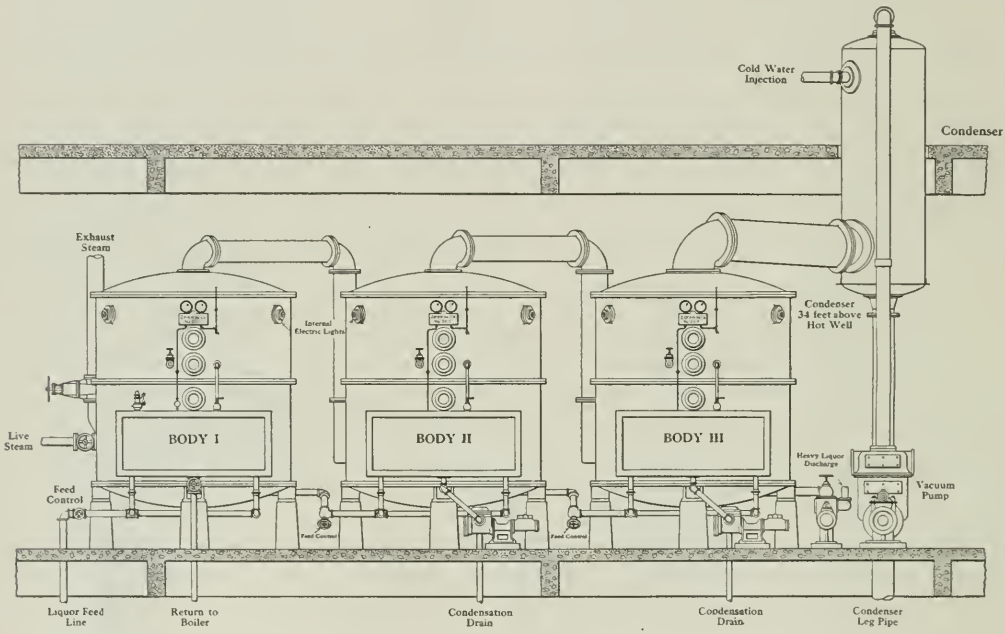

FIG. 35B—ZAREMBA TRIPLE-EFFECT EVAPORATOR.

Another advantage of this process, should it be practiced, consists in the fact that it is no longer necessary to employ complicated evaporation apparatus or to use fuel.

Vacuum Pans.

The vacuum pan is in fact nothing else than a single effect evaporator with the difference that in this apparatus is done the evaporating of the thick juice to massecuite in the sugar line. Formerly this process was effected in open kettles, which were treated by open fire or steam. Evaporation is produced now only in vacuum pans with the assistance of condenser and vacuum pumps.

It has been shown above how advantageous evaporation is by vacuum and low temperature. In vacuum pans mostly direct steam is used with higher pressure. Their shape is usually cylindrical and they are heated by heating coils, whose length is not more than 200 times the diameter. As mentioned before, the heating capacity of a heating coil is the largest where steam enters the coil, and decreases until it reaches the outlet. Researches inaugurated in the engineering laboratory of the Technical High School of Dresden by Dr. Eng. William Nusselt have led to the surprising result that the coefficient of transmission of heat is dependent not only on the difference of temperatures, but also on the length of the piping.

can vacuum pan building firm as follows: The manifold form of the coils is arranged in such a way that the number of pipes through which the heating system circulates is reduced from time to time, and this is in proportion to the estimated reduction in volume, so that the velocity of the vapor is maintained, as is also the pressure in all parts of the heating system (*Fig.* 34).

One of the most modern improved vacuum pans supplied with the heating coils shown in *Fig.* 34 can be seen in *Fig.* 35. This is a Dyer vacuum pan, 16 feet in diameter and equipped for live and exhaust steam heating, and is connected with a very efficient barometric counter-current condenser. There the drips or drains from all heating coils are connected to two manifolds outside of the pan.

One manifold, called the "live steam drip manifold," receives the drain water from all coils which at any particular time may be using live steam. The exhaust steam manifold in the same way receives the drains from the coils which are using exhaust steam. The water of condensation from the live steam drip manifold flows by gravity to a closed receiver, from which the boiler feed pump delivers it directly into the boilers without loss of temperature due to reduction of pressure. The drain from the exhaust steam manifold is handled in the same

way by a separate receiver and pump. The total heating surface of this pan is 2280 sq. ft., it has a juice catcher in the top and a very suitable connection to the condenser.

A cylindrical vacuum pan, with horizontal heating tubes is shown in Fig. 35*a*. This is the Zaremba system, with cast steel; it is also built of steel, copper or other metal. The heating surface is made of seamless drawn tubing of copper, brass, steel, etc., as the conditions may demand. The tubes are all of one length and are secured in place by an improved type of elastic packing that is absolutely tight and at the same time is easily taken out when the tubes are to be removed. Sagging of tubes at the center, in large machines, is prevented by the use of a tube rest. Steam chests can be so arranged as to make possible a large increase in heating surface whenever desired, by merely inserting additional tubes.

The steam circulation is from right to left through the tubes, which are rapidly drained of their condensation by being given ample incline. Liquor circulation is upward around the tubes and downward through large segment-shaped downtakes between the tube nest and the sides of the evaporator. Both steam and liquor circulation is very rapid, thus yielding a great efficiency of the heating surface.

The steel structure is simple, with only three readily kept tight joints; no internal bracing is required and yet an internal pressure can be carried with perfect safety. The bottom plates are so designed as to give either much settling space under the tube nest, or no such space, as may be desired.

The vapor space above the tube nest is made high and is so arranged that its entire volume is efficiently used to prevent entrainment loss. As an additional safeguard against entrainment the pans are equipped with an internal separator which returns to the liquor body any liquor particles that may have escaped with the vapor.

This construction (Fig. 35b), combined with a multiple effect, is used with excellent result as an evaporator.

(*To be continued.*)

Pittsburgh Meeting of American Foundrymen's Association

While going to press this year's convention of the American Foundrymen's Association and allied societies is still in progress in Pittsburgh. The attendance is again enormous, and it may be stated that there are an unusual number of chemists, metallurgists and assayers in attendance. In the following we give brief notes on some of the papers presented.

Standard Test Bars for Cast Iron.

Dr. Richard Moldenke, the untiring secretary of the association, presented a memorandum on standard tests for cast iron.

At the Copenhagen Congress of the International Society for Testing Materials the so-called "arbitration test bar for cast iron" was fully discussed, and comparisons made of the practice prevalent in the several interested countries of the world. The test bar in question is 1¼ in. in diameter, and 14 in. long, being broken transversely on supports 12 in. apart.

The comparison of the practice showed that so far as the diameter of the bar is concerned there is a general accord. Germany, Italy and the United States have adopted to 1¼ in. diameter, or metric dimensions very close to this. England, while quite favorably inclined, has not yet acted officially on the subject.

Further, the manner of preparing the test bar seems to be in accord everywhere in its main features. Bars are to be cast on end, in dry sand. Germany differs only in pouring from bottom up, whereas all the other countries pour directly into the top. German practice is undoubtedly the better one, though more expensive.

The radical difference in the several standards seems to lie entirely in the length of the bars for test. We break at 12 in. between supports. Germany makes it almost two feet, while Italy takes the distance only six inches. It was, therefore, suggested at the Copenhagen Congress that a series of tests be made in the several countries interested, with bars ranging from six to twenty-four inches between supports in breaking them, and from the results obtained that length be selected which will give the best all-around values.

Mr. Walter Wood, of R. D. Wood & Company, the chairman of the Commission on Cast Iron, took up this work for the United States, and reported at the last meeting of the American Society for Testing Materials. Both transverse and tensile tests were made. One set of the transverse tests would indicate a steady downward progression of the modulus of rupture for cast iron, as the span increases. But from the results so far obtained the need has become evident to extend the series of tests to smaller spans, say as low as 6 in. With the results extended over spans from 6 in. to 20 in. it would be possible to plot a curve showing the relation of the span to the modulus of rupture of the material, the turning point being found when too great a stiffness and consequent high results change to too great a weakness, or possible lack of sensitiveness on the part of the test, on the other side. This point, when found for the several classes of iron at issue, would be the desirable length of the span for a standard test.

Foundry Coke and Foundry Chemistry.

Mr. H. E. Diller, as secretary of the company, presented a set of the proposed standard methods for determining the constituents of foundry coke. This will be published in full in one of the next issues.

An instruction paper on foundry chemistry by Mr. Herbert E. Field gave definitions of entectics and segregation, and discussed the effect of phosphorus on cast iron.

The Electric Furnace for Steel Castings and General Foundry Work.

This interesting subject was discussed in a brief note by Dr. Paul Héroult.

At the present time some of the Héroult electric furnaces are busy on steel castings; in fact, some are exclusively erected for that purpose; for instance, at the Fischer Steel Foundry, Schaffhausen, Switzerland; Lake and Elliot, Baintree, England, and out of forty others in operation most of them are intermittently employed for castings, as for instance, at Worcester and South Chicago. The steel is perfectly sound, of high quality, and is good and hot when cast. It is so dead when poured that they do not need to increase the percentage of silicon and they run 0.15 and lower.

This, however, has been proved long ago. A more interesting feature of the electric furnace is that it is capable of improving the quality of foundry iron, and this at very low cost and by a very simple operation.

The main feature of what is called strong iron is the low content of sulphur. The removal of sulphur is one of the easiest and most effective operations that can be performed in the electric furnace. It consists simply in pouring into the furnace a charge of molten pig iron, if possible direct from the blast furnace; if not, from a cupola or other melting apparatus, then heating the metal under a basic slag which does not have to be scraped or removed except when it is teemed into a ladle with the metal ready for pouring. The contents in carbon, silicon, manganese and phosphorus are not affected by this operation unless this be desired. Common Bessemer iron, worth anywhere from $10 to $14 per ton can be changed into strong iron, charcoal iron, carwheel iron, or so-called cold-blast charcoal iron for a cost of about $1 per ton.

It seems probable that on account of the high grade of material so cheaply produced most iron castings of the future will be made of this improved quality. This new improved product will help to give new life to the iron foundry industry and will enable it to compete with the steel-casting industry.

Titanium in Iron.

The effect of titanium in iron was discussed in a paper by Mr. Charles V. Slocum, of the Titanium Alloy Manufacturing Co. The gist of the paper is contained in the following conclusions: Very small percentages, as low sometimes as 1/10 of 1 per cent (0.1) of alloy (only 0.01 Ti), are sufficient to cleanse the iron of impurities not touched by limestone or fluor-spar, while larger percentages increase the improvement in other directions, making the iron more fluid (usually hotter), making the castings sharper, finer grained, free from blow-holes and pin-holes, and easily machined, while at the same time the expense runs from 25 cents per ton of castings up to say $3 as a maximum, all of which is often repaid in the reduction of bad work and in improving poor irons.

Manganese and Silicon in the Foundry.

A paper by Mr. Alexander E. Outerbridge, Jr., deals with the use of manganese and silicon for foundry purposes. With respect to manganese he referred to the long series of his investigations with this element in connection with the special kind of cast iron used for making chilled cast iron car wheels. Formerly such wheels were made entirely from cold-blast charcoal iron, but this was replaced by the author's manganese treatment in the ladle. (*Jour. Franklin Institute*, March, 1888.)

Mr. Outerbridge points out that manganese acts in two different and opposite ways in cast iron.

When alloyed therewith in the cupola in considerable quantity, say 2 per cent or over, it has a chilling and hardening effect, producing what he terms a spurious chill of coarse crystalline nature, in contradistinction to the normal chill in a good car wheel which has a fine and closely interwoven crystalline structure.

When the alloy ferromanganese is added in a ladle of molten car-wheel iron in small quantity (1 pound of alloy, containing about 80 per cent manganese, in 600 pounds of iron), it acts not as an additional contribution of 0.133 per cent manganese to the metal in the ladle, but simply as a deoxidizing and desulphurizing flux, cleansing the metal from impurities, softening it and greatly increasing the ductility and strength without injuring the chilled tread of the wheel.

In view of these two directly opposite effects of manganese the author thinks that the ignorant and improper use of ferromanganese in general foundries is sure to lead to disappointments.

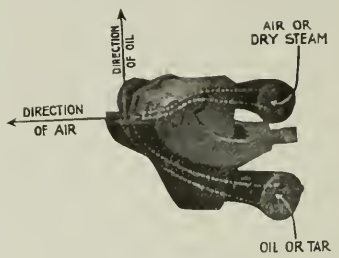
While ferromanganese is best adapted to the treatment of high chilling iron for carwheels or chilled rolls, or other chilled castings, where the proportion of combined carbon is large, on the other hand ferrosilicon is best adapted to treatment of foundry iron when from any cause it is hard and brittle, since it possesses the peculiar property of softening and at the same time strengthening such iron. It also enables the founder to vary the grade of iron in individual ladles to suit individual castings or groups of castings. It gives the founder control of his iron after it has been withdrawn from the source of melting, a matter of great importance and value, and it enables him to use cheaper grades of iron.

But neither ferromanganese nor ferrosilicon can be regarded as universal panaceas, and while each in its proper place is of great value, they must, like all other good things, be used intelligently, and if impure adulterated materials are employed they will not only prove to be of no benefit but must be absolutely harmful.

Oil as Fuel for Air Furnaces.

Mr. W. N. Best pointed out that, according to analysis, oil has a much higher calorific value than coal, and therefore ought to be able to melt the metal in a much shorter period of time than coal. Further, when oil is used as fuel the castings contain no more sulphur than the metal did when charged into the furnace, and the tensile strength is consequently greater than of metal melted by coal fire. As the melter has the furnace under perfect control the heats can be taken off much quicker than while burning coal, and the temperature of the charge while being tapped can be maintained without varying more than 25° Fahr. until all the charge has been run from the furnace.

The change from coal to oil is said to be a very simple matter. In the original firebox he constructs a combustion chamber of such form and proportions that the air necessary for perfect combustion can unite with the atomized fuel before it



USE OF OIL FUEL FOR AIR FURNACES

reaches the furnace, which prevents oxidation of the charge. Also this chamber causes the heat to be deflected upon the entire surface of the bath.

In the end of this combustion chamber he places a hydrocarbon burner of peculiar form, which makes a fan-shaped blaze, filling the entire chamber with flame. This burner exteriorly atomizes any gravity of liquid fuel which will flow through a ½-in. pipe, such as fuel oil, crude oil and tar. Its construction is such that it cannot carbonize, and there are no parts to wear away or get out of order.

A very small quantity of compressed air is used through the burner to atomize the fuel and distribute the heat, while the balance of the air necessary for perfect combustion is supplied at from 3 to 6 oz. pressure through a volume air nozzle.

The furnace is charged in the usual manner. The burner is started by opening the air valve, holding a piece of burning waste (which has been well saturated with kerosene) by means of a pair of pick-up tongs under the burner, and then turning on the oil.

The reduction in the time required to get the charge ready for tapping is not the only point wherein oil is more economical than coal. There is no handling of fuel and ashes, consequently the service of the fireman and coal passers are dispensed with. There is great saving in floor space for the oil tank is placed underground and the former coal bins used for other purposes. The fire brick lining of the furnace lasts 20 per cent longer than with coal. Poor castings or imperfect ones caused by the metal being cool or sluggish are obviated entirely.

This method is used by the Barlow Foundry Company, in Newark, N. J., and the Malleable Iron Company, Oriskany, N. Y.

Cupola Melting Practice.

A paper by Mr. P. Munnoch dealt with various phases of cupola practice, with special reference to British practice. A few points were considered more in detail.

One of these is oxidation during melting. There are two effects which result from oxidation, one of which is the reduction in the amount of silicon and manganese during melting, the other is the oxidation of the iron. The amount of oxidation depends largely upon conditions of melting.

Dr. Moldenke has pointed out that the method of using large charges in the cupola is the chief cause of this trouble, and by reducing the size of the charges and therefore preventing any great variation in the height of the coke bed above the tuyeres this oxidation is prevented.

A charge of below two hundred pounds per square foot of cross sectional area might be considered a small or suitable

charge and a charge above this amount is called a large charge.

The lower the melting ratio and the lower the density of the coke, the smaller the charge desirable. Therefore, in some cases one hundred pounds per square foot sectional area might be ample.

Other special points discussed in the paper are the total coke ratio, the changes occurring during melting, the removal of the sulphur, and the action of slags in regard to oxide in metal. The author considers the use of limestone in the slag as useful for removing oxygen from the oxidized iron.

As to the limestone requirements of the cupola charge the author considers the fact that in the cupola slags seldom contain more than one part of lime or two parts of silica to be a suitable basis for calculation. This leads to the rule that equal weights of limestone to silica in the components of the charge used will give suitable amount to add, after making allowance for silica from lining.

Generally the amount required will vary between thirty and sixty pounds per 2000 pounds of iron.

Gas Cavities, Shot and Chilled Iron in Iron Castings.

This subject was discussed in a long paper by Mr. THOMAS D. WEST, of Cleveland, Ohio.

The reason of the creation of the small, hard particles or metal shot found in some castings is that they become suddenly separated from the general mass of metal during the pouring of a mold. When thus separated they solidify so quickly that not sufficient time is given for the carbon to be separated out as graphite. Hence the shot does not have the softness of the rest of the casting which had more time to cool.

The longer the distance a shot is sent through the air before it lodges and the cooler the air it passes through, the harder the shot. Affecting this, also, is the degree of dampness of the spot upon which the shot may lodge. Where shot is caught and covered by incoming metal before it has time to become cooled below a red heat the chances for their being hard and discoverable in a casting are not, of course, nearly as great as when they can become of a dark color before being encased by the liquid metal.

Particles of iron or shot may be formed during the falling of the metal from the ladle's pouring lip by striking the sides of a pouring basin or gate. Again, by falling upon a flat bottom inlet gate. Or when the metal, reaching the mold, strikes some obstruction fronting the gates to splatter the metal. In ordinary plain work there is probably no feature so harmful in causing a splattering as having flat-gate bottoms. The bottom of all pouring gates should be more or less of a well, as by this formation, if there is hesitation for a moment or so when starting to pour, the first droppings from the ladle fall into the well, to say there is a liquid bulk and not be spattered to create shot.

In starting to pour the majority of molds, especially those of a light work and stove-plate character, there should be no momentary stoppage for starting, but from the instant the falling metal first strikes the bottom of a gate there should be a steady and unbroken stream to rapidly fill the pouring gate, and have it kept so until the mold is filled. This applies to the flat-top pouring gates generally used for stove plate, etc., as well as those of the joint character.

The too free use of a swab or sponge in wetting the joint of a mold, before drawing a pattern, or after this is done in finishing a mold, can easily harden or chill the metal parts of a casting formed where this excessive dampness existed. Again, also, by too damp a mixture of sand hard ramming or insufficient venting. Metal striking these damp sections will often bubble and splatter to a greater or less degree. This action can in some cases create suddenly chilled shot that will be carried to other sections of a mold to become encased in liquid metal and thereby give the white iron or chilled shot found in some castings.

The author next discusses globules in gas cavities and blow-holes. These defects can be due to two conditions, but emanating from one cause, and that is the creation of excessive gases or steam that cannot find its liberation from imprisonment within a body of solidifying metal. They are found chiefly in the upper body or cast end of castings.

Excessive gas, causing blow holes or cavities, may come directly from the metal or wholly from defects in molding or pouring. Those due to the iron may be caused by oxides of iron or manganese reacting on the iron's carbon, the former producing carbon monoxide gas, or on liberated graphite creating kish (although of the latter there is a very little in remelted iron, it being chiefly found in direct metal at blast furnaces). Also indirectly through sulphur, by reason of the formation of sulphide of manganese.

And again by a foreign body like that possibly created by the mixture of iron oxide and dross (the latter may contain some kish in connection with the dirt generally coming from clays of the cupola tap hole and spout, and other sources) forming a slag on the top of a ladle's metal that could pass in small bodies into a mold at the starting of pouring, or later on before a mold is filled, through defective skimming. Thereby often large as well as small blow holes or gas cavities are formed.

As a side issue it can be said that a ladle's surface dross can easily cause dirt holes, pin holes and a dirty surface to the finish parts as well as the rough surface of castings when skimming is at fault in pouring a casting.

Gas cavities and blow holes due directly to defects in molding and pouring are often due to not having properly tempered sand, regulated degrees of hardness in ramming, efficient means of venting and correct methods of finishing cores and molds, combined with needed experience in grating and pouring. These are all factors demanding the experience of a decade or more in the actual work of general molding.

Molding machines, owing to the following of an exact routine adopted after much experimenting as the best to insure desired results, cannot but be helpful to a large degree in removing the liability of stream and gas cavities, or blow holes, chargeable to molding.

The author then discusses methods of deciding whether globules are due to defects in metal or molding. Sulphur and phosphorus causing blow holes are said to be a weak excuse for defects.

The work of Mr. P. Munnock, of the British Foundrymen's Association, is then discussed. The present author attributes the defects cited by Mr. Munnock to the molds.

The present author's contention that the molds are more responsible as a general thing than the iron for the creation of blow holes, etc., is not to be taken as meaning that there is nothing to be feared by gases that may emanate directly from some irons.

The author briefly discusses the use of alloys for dioxidizing and purifying iron and finally discusses the very rare and mysterious occurrence of "inside chill," or white iron inside of gray or soft iron.

Electricity in the Foundry.

A paper by Mr. BRENT WILEY, of Pittsburgh, Pa., on "Electrical Applications in the Foundry," gives some interesting and valuable figures on the electric power requirements of foundries with a capacity of 1500 to 2000 tons per month. The figures are based on the experience of a number of modern foundries of this size with electric drive throughout, and equipped with overhead traveling cranes in each department. The weight of the castings range from 100 to 100,000 pounds, with an average of 250 pounds. The electrical equipment was 220-volt, direct-current, with one exception, which included 400-volt, three-phase motors. The average conditions for these foundries are as follows:

Floor motors, one 75-hp air-compressor, one 20-hp cold saw, two 30-hp sand mills, eight 5-hp grinders, six machine-shop

motors of together 50 hp, one 25-hp repair-shop motor, six miscellaneous motors of together 58 hp. Total, 323 hp.

Crane motors, two of 50 tons each (280 hp), three of 25 tons each (250 hp), four of 10 tons each (180 hp), two of 5 tons each (90 hp). Total, 800 hp.

Crane hoist motors. Total, 400 hp.

A general rule for power-house capacities is that the average load will be approximately one-half of the total capacities of floor motors and crane hoist motors. In figuring the crane load on the power station it is to be noted that as the hoisting motion of the crane gives the heaviest load, and as it is seldom that more than one motion is used at a time, it is sufficient to consider the load on this motor only. As the crane work is very intermittent the load is very fluctuating, and the total capacity of power generators should not be less than twice the average load. As a general rule a spare generating unit will prove a paying investment to insure ample power at all times.

For the above conditions the average power house load is $723 \div 3 = 241$ hp $= 180\frac{3}{4}$ kw, and two 175-kw generators would be sufficient.

Or, figured on another basis, it requires approximately 35 kw hours per ton of steel castings, and approximately 45 kw hours per ton of iron castings, for foundries ranging in capacity as given above. The blast for the cupolas of the iron foundry and the greater amount of small work increases the electric power per ton output.

The values given for power-house capacities include power for lamps and other auxiliaries, such as electric welding for the steel foundries, repair shop and pattern shop.

The following general conditions for foundries, as mentioned above, have been established. The capacity of the floor or constant-speed motors is approximately equal to the capacity of the crane hoist motors.

The average station load equals one-half the total capacity of floor motors and crane hoist motors.

The maximum station load equals approximately twice the average load.

The average distance for distribution of power is 600 feet or less.

The applications of varying-speed motors are few except where considerable machine work is done, in which case the power required will seldom be over 15 per cent of the total station capacity.

The lighting load will average from 10 to 12 per cent of the total load.

As to the question of direct current versus alternating current the author points out that for the small plant, with a power station capacity of 300 to 500 kw, and an average distributing distance of approximately 600 ft., the 250-volt, direct-current system offers many advantages. Direct-current motors can be used for all the applications.

However, if a foundry has its own power plant the cost of generating power is high on account of the rapidly fluctuating load. It is doubtful if the average steam power plant of the foundry, under the most favorable conditions regarding price of fuel, etc., can produce power for less than 2 cents per kw-hour, and for the majority of the plants the cost will be even higher.

A central station, being of large capacities, would not feel the direct effects of the load fluctuations. The load, being practically continuous, improves the load factor. Thus, to the small plant, especially, the central station companies can often offer good inducements to purchase power.

Lighting is the principal load of the central station, and the system mostly adapted is 60-cycle, alternating current, which offers decided advantages regarding economy of distribution of power. In the case of an existing plant having direct-current motors installed, a rotary converter could be used to convert the power to direct current of suitable voltage.

If the proposition relates to a new plant then a more economical plan will be to use the alternating current direct, although in a majority of the cases it will be necessary to reduce the voltage. Usually the transmission voltage will be over 1000 volts, and transformers should be used to give 240 volts for distribution within the foundry.

Considerable discussion has taken place between the electrical engineers of the iron and steel industry during the last two years regarding the most suitable voltage for inner works distribution, and from a safety standpoint it has been decided that 240 volts for 220-volt, alternating-current motors, and 250 volts for 230-volt, direct-current motors should be used, and these voltages are becoming standard for this class of industry.

The alternating-current, squirrel-cage, wound motor offers several advantages over the direct-current motor for the floor machines, with the exception of the applications requiring varying speed, such as machine tools, and for these applications it would be best to instal a small motor generator set to give direct current.

Lifting Magnets in Foundries.

The application of lifting magnets for foundry service was discussed in a paper by Mr. H. F. Stratton, of Cleveland, Ohio. While the lifting magnet has found very extended application in the steel industry, and is also used largely by the railroads for handling their scrap material, the foundries have been reluctant to introduce it.

However, to prove the adaptability of the lifting magnet for foundry work the author gives the following estimate of cost for a foundry melting 35 tons of metal daily, 300 days in the year. The cost of the magnet and crane installation, with a lifting capacity of 1350 pounds of pig iron, is $4,000. A crane and a magnet of this size can handle 35 tons per hour at an operating cost (wages, fuel, oil) of 48 cents per hour, or 1.4 cents per ton.

The annual depreciation on the $4,000 equipment at 12 per cent would be $480, and as 35 tons handled twice per day for 300 days represent 21,000 tons handled annually the depreciation cost on this tonning basis is 2.3 cents per ton. This brings the total cost of handling, including wages, fuel, oil and depreciation, up to 3.7 cents per ton.

The author is told by a gentleman well versed in foundry practice that 10 cents per ton is a fair figure to assume for the cost of loading or unloading pig by hand, and on this basis the saving would be $1,323 annually, or 33 per cent on an investment of $4,000.

To sum up, a foundry melting 35 tons of metal daily can install both a crane and a magnet, and expect a return upon the investment, after allowing all charges, of more than 30 per cent. If it happens that a foundry is already equipped with either an electric or locomotive crane a magnet can then be installed on a very profitable basis when the tonnage to be handled is considerably less. For instance, if an assumption be made that a foundry melts 20 tons daily, and that a magnet be installed on an existing crane, the cost of the magnet being about $900, then the cost of handling, per ton, including wages, fuel, oil and depreciation on the magnet, is about 2.3 cents, which would represent a saving in this foundry of about $924 each year, or more than 100 per cent on the investment.

"It is very earnestly hoped that these figures be not brushed aside with the assumption that they are theoretical and must be largely discounted. As a matter of fact, the costs of handling by a magnet are stated conservatively, and are being bettered in service daily."

Handling scrap, in general, will be more expensive than handling pig iron, whether it be done by hand or by magnet, but the advantage in favor of the magnet is more marked in the case of scrap than in the case of pig.

Efficiency.

"The Efficiency Movement in the Foundry" was discussed in a paper by Mr. C. E. Knoeppel. He emphasized two conclusions from practice: That a man can accomplish considerably more than he does, and that the management, as business is at

present conducted, does not know what constitutes the best a man can do.

It is necessary to build up an effective organization from the bottom upwards. This requires a constructive type of organization that erects on a firm foundation and in a scientific manner a structure that will consider the various elements entering into making the enterprise successful. These elements are: (1) The man. (2) The work to be done. (3) The conditions under which he does his work. (4) The planning of the work he has to do. (5) Reward for individual effort. (6) The records affecting the factors of the business. These six different items are discussed in succession.

Brass Founders' Association.

Bronzes.

A paper by Mr. JAMES R. HUBER, of the Lumen Bearing Company of Buffalo, N. Y., on the analysis of manganese bronze gave an account of some improvements on the method described in this journal, August, 1910. The complete paper by Mr. Huber will be published in one of our next issues.

A paper by Mr. C. P. KARR gave results of determinations of the pouring temperatures of various bronzes under foundry conditions, and on the use of the pyrometer, especially the radiation pyrometer, in the foundry.

Non-Ferrous Foundry Economics.

A paper by Mr. E. A. BARNES, of the Ft. Wayne Electric Works of Ft. Wayne, Ind., gave interesting and concise notes on refinements in non-ferrous foundry installations and operations. He discussed the design of the building, heating and ventilating systems, office, pattern storage, metal storage, sand bin, crucible storage, core oven, welfare work, power plant arrangements, meters, air compressor radiators, etc.

In the matter of furnaces, ladle heaters, scrap-recovering furnaces, enormous saving can be effected by intelligent handling. With the old system of coke and hard coal pit furnaces, which of course are adhered to for many kinds of production, the greatest injury done to the crucibles is from the rough handling with the tongs and the uneven heating and cooling. With the fuel oil system and tilting furnaces, which are becoming more and more popular, combined with the propagation of suitable reducing flame in a combustion chamber of sufficient volume and absolute control of temperature, this crucible loss is greatly reduced.

One of the greatest items of loss in a brass and aluminum foundry is the shrinkage. This is occasioned in many ways. Poor system is responsible for all of them. Volatilization loss in the methods of melting is the most important.

In their furnace they employ the concentric burner, using compressed air at about 35 pounds per square inch to pulverize to a mist the fuel oil which is supplied at about 25 pounds pressure at the nozzle. This fuel oil and atomizing air are both preheated by proper arrangements before they issue from the burner.

The volume air for combustion which is supplied through a truncated nozzle surrounding the concentric portion is maintained at about 8 ounces pressure and by valves and gates both the compressed air and fuel oil and the volume air are controlled, maintaining the "reducing flame" whether a slow or a fast fire is desired.

It is very necessary to have absolute control of combustion in order to produce the reducing flame, otherwise at these high temperatures the oxygen of the air will combine with the free graphitic carbon and other components of the crucible and furnace lining and very rapidly disintegrate the same through chemical combination, and the metal itself will suffer loss and injury through oxidation.

Ladle Heaters.—Their ladle heaters, which are arranged to use the same burner, are made with a telescoping hood that is raised up when the pouring crucible is introduced and then dropped down enveloping the same. In this way the crucible is evenly heated. These ladle heaters are very useful for getting out small batches of work, as the heat generated in them can be as high as that produced in the larger furnaces.

Conservation of Heat in Spent Gases.—On visiting any foundry one is struck with the enormous amount of apparent lost heat and energy that issues from the vents. This heat, in the form of spent gases, can be utilized for many useful purposes if proper arrangements are made in the design of the foundry to conserve them. Core ovens can be heated, as can also wash water for use in the lavatories; these are two of the most important. The preheating of air and oil is another. This, of course, involves piping and arrangements which may to some appear complicated and unnecessary, but they are nevertheless well worth taking into consideration.

Scrap Melting Furnaces.—In a manufacturing industry like the one with which the author is connected they get skeleton brass from the punch press department, borings and turnings from the machine shop in large quantities each day. The regular practice is to run these through an efficient magnetic separator connected with a blower system which takes out the iron, paper and light particles, passing the good metal into bins. In place of selling this stuff to the junk dealer at prices depending on varying conditions they save and separate these borings, etc., and use them in their foundry at once.

The copper and red brass borings are taken to the melting floor and are used up with gates, sprues and new metal. Much of this stuff, however, is of a mixed nature and cannot be so handled; it is therefore taken to the scrap melting furnace and run into ingots. These ingots are analyzed by the chemist, who determines closely their components. These ingots are further alloyed with pure copper and other new metals in varying proportions and first-class metal for all general purposes produced from them.

They also handle in their scrap melting furnace copper wire which they get from burned-out field coils, armature coils and scrap generally that is known to contain pure copper. The resultant pigs are analyzed and used as base copper for more important mixtures. The furnace is cleaned out, skeleton brass, borings, yellow brass, etc., are run off and stored.

With their scrap melting furnace they developed an endless chain arrangement for carrying the chills. The contents of these chills are automatically dumped into water, which cools, cleanses and softens the metal simultaneously. This system involves the continuous melting and pouring principle which they have found in practice to be preferable to the "hot bath" system where the metal is melted and tapped out into crucibles and repoured. This does not, however, indicate that the "hot bath" system is not better adapted to some other foundry requirements.

As to the actual runs of scrag and the losses incident to the recovery of the same the following figures are given:

Bare copper wire: Total wire melted, 9054 lbs.; total ingot recovered, 8888 lbs.; loss or shrinkage, 166 lbs., or 1.83 per cent.

Fine wire (includes burning off of insulation): Total wire melted, 3089 lbs.; total ingot recovered, 2773 lbs.; loss or shrinkage, 316 lbs., or 10.24 per cent.

Yellow brass punched scrap: Total scrap melted, 3000 lbs.; total ingot recovered, 2860 lbs.; loss or shrinkage, 140 lbs., or 4.5 per cent.

Aluminium.—In their aluminium department for years they had been using the open-flame form of reverberatory furnace and were always confronted with a heavy loss amounting often to 6¾ per cent. Their aluminium work is of a peculiar nature—light and of an odd pattern. For every pound of casting they produced they had to pour one pound for the runners and one pound for the riser or header. They therefore only received 33 1/3 per cent net of the gross metal melted. The loss, therefore, had to be multiplied by three, making 20 per cent net. They figure gross weight, because they charge so much metal to the melting floor, making a bi-monthly inventory of the castings turned over to the factory and the metal in the form of ingots, sprues and risers remaining over.

They could not see any immediate relief from this loss, so carried on experiments from time to time and finally decided that a tilting furnace similar to their regular crucible furnaces, but arranged with an iron kettle of the proper dimensions and shape, was the solution.

With this new type of furnace they are able to handle the same number of pounds of aluminium per heat as with the old open-flame furnace with a loss of only 2½ per cent gross, as it eliminates entirely the losses due to the cutting action of the flame. In the iron kettle the flame does not touch the metal at all and while the time employed in getting out the first heat is necessarily longer, it does not materially affect the total output.

Another great advantage in the kettle type of furnace is that the slag and oxide which form on the top of the pot act as a protection of the metal, and the spatter, skimmings, etc., instead of being thrown into the scrap pile, are returned to the melting pot, where the globules of metal held in suspension in the slag separates from the slag and mix with the metal below, the slag itself remaining on top in the form of a protecting blanket.

In the melting of their metals such as aluminium they employ pyrometers. They have found by using these instruments that the overheating of the metal is avoided.

A great economy results from the pre-alloying of metals. In alloying aluminium and copper it is a well-known fact that the copper, which melts at a much higher temperature than the aluminium, must be melted first. The aluminium is then added, combines with the copper and through chemical action the temperature is liable to rise to a point that vaporizes off much of the aluminium.

To rob this phenomenon of its most harmful effects they have made a practice of compounding a rich alloy of half and half copper and aluminium, which they thrown into pigs. The copper is melted first and the aluminium is added in small quantities, allowing the temperature to gradually reduce with each addition of aluminium, thus preventing overheating any considerable quantity of metal. This rich alloy, which now necessarily melts at a very much lower temperature than the original copper, is used in the final compounding of their aluminium mixture. All risk of overheating or mis-mixing large and individual batches is thus eliminated. Not only this, but the remelting has a refining effect and a much better product is insured.

The use of fluxes, such as phosphor tin, baron, magnesium, etc., is much more effectively carried on under the direction of a chemist who makes a special study of the action of these fluxes on the metals. The author is convinced that the employment of a chemist or foundry chemical engineer in a foundry of any size soon pays a handsome dividend on his sallary. As a rule the practical foundryman has too many other things to attend to in producing to spend much time in developing.

Alloys.

A paper by Dr. W. R. Whitney, director of the Research Laboratory of the General Electric Company, called attention to the possibilities in the way of useful discoveries, which may well lie more nearly within reach of some of the foundrymen than they realize, because of their particular knowledge or possession of special materials. These discoveries should be made by the more extended use of the "more recent metals," particularly in the manufacture of alloys.

Dr. Whitney thinks it highly improbable that the cost of copper will ever be greatly changed by the discovery of new uses. On the other hand, with aluminium it is still possible that considerably wider uses and reduction of production costs may develop in its future.

Dr. Whitney then gave an interesting, concise résumé of those elements which only recently have come into commercial use.

The element *calcium*, which a few years ago was listed only as museum specimens and at several dollars per gram, was sold in 1908 at $1.50 per pound, and could certainly be sold for a small part of this price if a greater use could be found for the metal. It slowly decomposes water, giving hydrogen, and it differs from the alkali metals in producing such a feeble alkaline solution that it is generally harmless. It ought to serve as a good deoxidizer, and should be a very cheap metal. It is not fair to relegate it to a list of useless metals. History of the metallic arts points to there being no such list.

Thallium is an element quite similar to lead, but probably possessing some property which will some day warrant its exploitation. It is softer and heavier, and could be obtained in quantity if a demand were created.

The elements *chromium, molybdenum, tungsten* and *tantalum*, the three latter now obtainable in wire-form, are tempting elements to study in mixtures with others. Who knows the useful properties of a chromium bronze, for example?

Tellurium has long been an apparently useless metal, and any market price is fictitious, as there is but little isolated in metallic state. It is not necessary that a great use, such as a substitute for zinc in brass, should be found for it. Our industries are so great that if a pound of tellurium added to the ton of aluminium was of benefit to the latter the production of the necessary tellurium would be real industry.

Consider *cobalt* a moment. The world's rate of supply of ore has been greatly augmented. It may take time to actually realize a greatly reduced cost of metallic cobalt, but we ought, notwithstanding, to realize it when uses have been developed. Our natural impulse in such a case is to try direct substitution of one metal for another in some well-developed use. Cobalt, for example, might replace nickel in most uses when the cost fell below that of nickel, but this is a second order use. A first order use would be the supplying of a want which no metal previously supplied, or supplied distinctly less perfectly.

In this connection an interesting alloy of cobalt and chromium has just been developed by Elwood Haynes, and it is altogether probable that technical use will soon be made of it. (See our Vol. VIII, p. 652.)

Many tons of metals are annually consumed as resistance wire for electrical purposes. At one time iron was the element most used. German silver replaced it in some cases, where a lower temperature coefficient was needed and the increased cost was permissible. Now there are a dozen or more special alloys for this particular electrical use. The new ones have far outclassed the old in most of those properties for which the electrical engineer uses them. In such alloys nickel, chromium, manganese and others are now used by the ton.

Silicon, which in 1900 was a curiosity and sold for 40 cents per gram, is now a necessary component of special iron alloys and of high-grade transformer iron, and the world uses thousands of tons of the alloy annually. Silicon is now sold at about 5 cents per pound. The use of this metal in other alloys is still quite limited. In the case of iron, it greatly decreases hysteresis loss and increases electrical resistance.

Boron, still a quite expensive material in metallic state, is coming into commercial use in assisting the making of solid copper castings of high electrical conductivity.

Vanadium seems to be a young wonder-working metal. Its use has increased very rapidly in the past few years, but the quantities consumed are not known to the author. As several companies are producing the iron alloy it is safe to assume that it is being sold by the ton. The price for the metal in the alloy is not far from $5 per pound.

Cadmium is a beautiful metal in many respects, and it is certainly awaiting use. It is whiter and less crystalline than zinc, and doubtless the high price of nearly a dollar a pound keeps practical workers from trying it in their experiments. It should be produced as cheaply as aluminium, if there were a good demand for it.

Titanium is an element long the subject of criminal negligence. It is a high-melting, ductile, white metal, which, at present, is only separable from its ores at high cost. It exists in

many cheap ores widely distributed in nature. It is now apparently coming into use in steel manufacture, particularly for railroad rails, and for this purpose it is fortunately unnecessary to isolate the pure titanium from its ores, an iron titanium alloy being produced directly. What will happen when the pure element has been tried in special field can only be surmised. The optimist sees great chances. The pessimist feels himself busy living with the optimist.

If one omits the common alloys, brass, bronze, solder, etc., and considers only possible alloys of two metals, and still confines himself to 20 of the common metals, like vanadium, manganese, chromium, boron, etc., he is interested at once to recognize that there must be one hundred and ninety different pairs of binary alloys. When, in addition, the effect of varying proportions in these alloys is considered, it becomes evident that the field of alloy research is truly a large one. Many of the alloys apparently unstudied are those which melt at extremely high temperatures.

The brass founder who knows the upper limiting temperature of his melting furnaces may at once point out that this temperature is fixed both by the life of crucibles and the particular coke or oil-heating schemes with which he is familiar. If he thought that a molybdenum bronze of 86 per cent molybdenum would have useful properties compared with all other alloys he might at once conclude that he must give up this alloy because of the difficulty of melting it.

If it were not for the advances in our available temperatures there would seem to be little more than amusement in considering alloys high in tantalum, in chromium, in titanium, in molybdenum, in silicon, in uranium, in vanadium and a number of other high-melting metals, but hand in hand with the discoveries leading to isolation of such metals go also discoveries of aluminothermics, oxyacetylene and oxyhydrogen temperatures and electric furnace processes.

The time is always ripe for the study of new alloys with new tensile strengths, elasticities, colors and wearing powers. The automobile and the aeroplane have forced the aluminium and iron alloys to make rapid strides, and it is natural that we should want to inventory our possibilities.

The physical chemist has started along the way of a systematic co-ordination of certain properties of binary, and in a few cases tertiary alloys. He has shown how to plot a few freezing points of two-metal and three-metal mixtures and to construct therefrom curves showing not only all possible metals but what may be expected in the way of segregation and structure and such effects as caused by annealing or quenching.

He has found that there is a solubility of metals in one another which varies just about as the solubility of substances in water varies. Metals may be melted together and well mixed, but the quality and permanency of the mixture is determined by just such solubility laws as control ordinary solutions. We know that in some cases well-mixed melted metals will separate into two layers if allowed to remain even a few moments in molten condition at low temperatures. Such a pair are zinc and lead. They act like a mixture of water and ether. The two separated layers contain both metals, no matter what the temperature, but the quantitative compositions depends on the temperature.

The other extreme of metal solubility is found in such a case as zinc-cadmium, which acts much like a mixture of alcohol and water, the two components going into solution in all proportions and remaining in solution at all temperatures. Having seen this analogy between the facts of solubility of substances in water it is natural to search among the metal mixtures for all the peculiar kinds of solution observed in aqueous solutions.

Two such classes interest us at once. They are those corresponding to aqueous solubilities where temperature widely influences the quantities dissolved, and those in which the solvent (as water) combines with the dissolved substance more intimately than by simple solutions, as by chemical combination. In the case of zinc and lead we have one of the metal alloys of limited solubility. If these two metals are well mixed in liquid state they separate into layers—one, the zinc, carrying a few per cent dissolved lead floats on an alloy made up of lead carrying a few per cent of dissolved zinc. In general, the quantity of the one metal dissolved and held in solution by the other depends on the temperature, and the higher the temperature the greater the solubility. Between 900 and 1,000 deg. C., they are apparently completely soluble. It follows from this that when a dissolved pair of metals is cooled slowly one of them may separate on cooling, if the limiting solubility is reached, and the extent of effective separation may depend on the rate of cooling.

Our second case, that of chemical combination between the metals, is made most evident by the form of the freezing point curve of the possible alloys. A compound of two metals which is stable at a temperature above the melting point of one or both of the metals shows very clearly on the melting-point curve and acts towards each of the elements just as a new or third element. Its melting point cannot be predicted from any knowledge of the component metals. It may even melt higher than either of the components. Such cases are seen in alloys of aluminium-antimony, in lead-tellurium, etc.

Man first used the metals as he found them; then, as he reduced them from the ores, and finally, when specified requirements became more and more exacting, he not only brought into use previously unused metals, but also greatly modified the old familiar ones. For a harder iron he used steel, a carbon alloy; for a harder steel, or one capable of cutting iron more readily, he added tungsten, nickel, chromium and other metals. For permanent magnets molybdenum was added, for high electrical resistance nickel, chromium, etc., were added; for low electrical hysteresis, silicon and aluminium were added; for toughness in springs a little vanadium was used, and for wearing qualities titanium is now introduced. These are only a few of the successful alloying experiments with iron. They will probably be repeated with other metals, such as copper, zinc, and aluminium, where the cost of the base metal is not high.

On the other hand, the study of those metals which have not yet advanced to a stage where first order cost reduction is impossible, is equally interesting. Consider again the element chromium. What do we know about it? Is it a workable metal? Can it be hammered or cast? Is it permanent in the air? Is there a considerable possible ore supply? Has the cost of obtaining the metal been reduced to what seems a reasonable rate? etc., etc.

As it is unlikely that such an element will suggest itself for use by men as did copper and iron, it is probable that its properties must first be determined and made known. As a metal it is only about fifteen years old. It is made in the metallic state by reduction of the oxide by metallic aluminium and also by electrolysis of its salt solutions. It cannot yet be produced at a lower cost than that of the aluminium required, and it now sells at about 80 cents per pound. In the oxide from which it was made it may be had for less than half this cost, and in its alloys with iron, which are made by direct reduction with carbon; it is sold for 29 cents per pound. This gives a rough idea that ultimately, by perfection of metallurgical processes, etc., we may possibly obtain the metal much below 80 cents per pound.

It withstands heat exceedingly well. When pure it melts at very high temperature (Ostwald, about 3000 deg. C.) and it does not scale when heated red hot in air, as copper and iron do. It is for this reason that it is used in resistance alloys for electric heating devices. It has been plated onto metals, and then looks and acts like nickel plate. Doubtless its use will quite rapidly increase in special alloys, as it has already come into use in tool steel.

* * *

In the following we give an incomplete alphabetical list of the exhibitors at the sixth annual exhibit of the Foundry and Mining Exhibition Company held in connection with the Foun-

drymen's Association convention. This exhibition was really an immense affair and all the exhibits were looked over with greatest interest by the visiting foundrymen.

The Adams Company, Dubuque, Iowa.
Albany Sand & Supply Company, Albany, N. Y.
American Vanadium Company, Pittsburgh, Pa.—Vanadium cast steel and cast-iron specimens.
Arcade Manufacturing Company, Freeport, Ill.
Atlas Car & Manufacturing Company, Cleveland, Ohio.—Storage battery locomotive, new type sand-blast car, portable track and side-dump sand car.
Jonathan Bartley Crucible Company, Trenton, N. J.—Crucibles, retorts, stoppers and a variety of graphite specialties.
Carborundum Company, Niagara Falls, N. Y.—Carborundum and aloxite grinding wheels, carborundum fire sand and carborundum rubbing bricks.
Chicago Pneumatic Tool Company, Chicago, Ill.—Franklin tube G C B compound bell, driven air compressors, improved Keller sand rammers, tripod sand sifter, pneumatic geared wire rope hoists, Boyer-Keller chipping hammers, electric grinder, side spindle electric drill, Little Giant pneumatic grinder and castings cleaner, Chicago Universal hose coupling.
The Chisholm & Moore Manufacturing Company, Cleveland, Ohio.—Chain hoists, trolleys, hand-power traveling cranes and malleable castings.
Cutler Hammer Manufacturing Company, Milwaukee, Wis.—Lifting magnet adapted for foundry use.
The Deming Company, Salem, Ohio.—Hand and power pumps, whitewashing machines.
Jos. Dixon Crucible Company, Jersey City, N. J.—Crucibles for both brass and steel melting, special shapes and formulas for various purposes, phosphorizers, stirrers, skimmers, stoppers, nozzles, sleeves, etc.; graphite refractories, foundry facings, motor brushes and graphite products.
Stanley Doggett, New York City, N. Y.—Foundry specialties, parting compounds, manganese dioxide, soapstone, graphite facing, facings, powdered charcoal, dioxide of manganese flux, ferro-manganese, ferro-silicon, iron and steel cement, metal workers' soapstone, crayons and pencils.
Electric Controller & Manufacturing Company, Cleveland, Ohio.—Lifting magnets and controllers, automatic motor starters.
General Electric Company, Schenectady, N. Y.
Goldschmidt Thermit Company, New York City, N. Y.—Full line of metals produced free from carbon, heating thermit cans, titanium thermit cans, thermit welding process and appliances.
Harbison-Walker Refractories Company, Pittsburgh, Pa.—Ordinary shapes and standard cupola blocks in fire brick.
Hauck Manufacturing Company, New York City, N. Y.—Oil-burning appliances, including cupola lighters, ladle heaters, core oven and furnace burners, mold dryers, preheating and brazing outfits.
Hawley Down-Draft Furnace Company, Chicago, Ill.—Metal melting furnaces.
Ideal Furnace Company, Chester, Pa.—Brass melting furnaces.
Ingersoll-Rand Company, New York City, N. Y.—Twelve-inch stroke "NE-1" air compressor, pneumatic chipping, caulking and scaling hammers, pneumatic riveting hammers, sand rammers for bench and floor work, pneumatic motor hoists, pneumatic stationary motors and pneumatic piston and rotary drills.
Monarch Engineering & Manufacturing Company, Baltimore, Md.—Latest improved furnaces using oil or gas as fuel for melting and heating, Acme core oven, steel foundry ladle, heating equipment, aluminum furnaces, Alls' "Eclipse" bolt-heating furnaces, blowers, etc.
Northern Engineering Works, Detroit, Mich.—Type E electric crane trolley and joint exhibit with Cutler Hammer Manufacturing Company, Milwaukee, Wis.
Norton Company, Worcester, Mass.—Grinding wheels, alundum and crystolon, abrasive materials, India oil stones, crystolon sharpening stones, Norton alundum refractories consisting of small electric furnace parts, cores, tubes, muffles, crucibles, combustion boats, filtering dishes, etc., for laboratory use.
Thomas W. Pangborn Company, New York City, N. Y.—Sand-blasting machinery.
Pittsburgh Steel Foundry, Pittsburgh, Pa.
Pittsburgh Valve Foundry & Construction Company, Pittsburgh, Pa.
Rockwell Furnace Company, New York City, N. Y.—Centric pouring crucible furnace.
Rogers, Brown & Company, Cincinnati, Ohio.—Pig iron, coke, ferro manganese "Rosiclare" fluor spar.
Shepard Electric Crane & Hoist Company, Montour Falls, N. Y.—Trolley for three motor electric traveling crane with cage, including the controllers, cage controlled electric traveling hoist and back-geared electric motor.
The W. W. Sly Manufacturing Company, Cleveland, Ohio.—Miniature display of Cleaning mills, cinder mill and dust arrester and sand-blast equipment and machines.
J. D. Smith Foundry Supply Co., Cleveland, Ohio.
Frederick B. Stevens, Detroit, Mich.
Tate, Jones & Company, Inc., Pittsburgh, Pa.—Brass crucible furnace, oil pumping, heating and regulating system, oil burners, portable burner for ladle drying and cupola lighting.
Taylor Instrument Co., Rochester, N. Y.—Recording pyrometer, radiation pyrometer and other small instruments.
United States Graphite Company, Saginaw, Mich.

Resistance Wire.—A recent British patent (14,743, March 30, 1911) of the British Thomson-Houston Company (General Electric Company of this country) refers to an alloy which can be rolled and drawn and which is suitable for resistance wire or heating elements. It consists of twenty parts by weight of iron, sixty-two parts nickel, twelve and one-half parts chromium, five parts manganese, and between 0.1 per cent and 0.4 per cent of carbon. This alloy oxidizes only very slowly at a red heat. (London *Elec. Eng'ing*, April 6.)

Electrodeposition of Copper Free from Arsenic from Electrolytes Containing Arsenic

The effect of organic and inorganic "addition agents" upon the electrodeposition of copper from electrolytes containing arsenic is the title of a thesis submitted by Mr. Ching Yu Wen, to Columbia University, for the degree of Ph.D.

The investigation is interesting in two respects. First, it has a distinctly practical bearing on copper refining, and, secondly, it is of interest in connection with the problems of the action of addition agents in electrolysis which originated on a large scale with Mr. A. G. Betts in his lead-refining process. They have been studied quite extensively, especially by Dr. E. F. Kern, of Columbia University, under whose direction the present research was also conducted.

In the production of good pure copper by electrolysis, the composition of the electrolyte is one of the important factors. The cause of poor copper is chiefly due to the impurities which accumulate in the electrolyte and which, under usual conditions, are precipitated along with the copper. Of those impurities the most harmful and troublesome ones are arsenic and antimony, the presence of which in the deposited copper makes it brittle and nodular.

It has been a known fact that during electrolysis part of the arsenic and antimony contained in the anode dissolves and remains in solution. These two elements, especially the arsenic, are allowed to accumulate in the electrolyte till a critical point is reached, which has not yet been definitely determined. When this point is passed they begin to be deposited with the copper on the cathode and render the deposit bad and brittle.

To prevent this it is therefore of utmost importance to maintain the electrolyte within a certain degree of purity, in other words to keep the amount of arsenic and antimony in the electrolyte below the critical point. This is usually accomplished in practice by withdrawing a certain portion of the electrolyte and replacing it with an equal quantity of fresh solution, and the copper in the impure electrolyte is recovered either by crystallization or by electrolysis with insoluble lead anodes. This not only complicates the process of electrolytic refining of copper, but also entails an extra item of expenditure in the production of electrolytically refined copper.

Another thing that is observed during the electrolysis is that "sprouts" or dendritic "trees" often form, especially along the edges of the cathode. The formation of such "trees" interferes with the work, renders it more difficult to operate and prevents the electrodes from being placed together, as there is danger that the electric current would be short-circuited. In conducting the electrolysis in a commercial way, the removal of these "trees" becomes absolutely necessary and is usually done by the tank inspectors, thus increasing the cost of refining.

The object of Dr. Ching Yu Wen's investigation was, therefore, two-fold; first, to prevent the deposition of arsenic and antimony on the cathode, and second, to prevent the formation of dentritic "trees." This problem was worked out, having in mind the production of solid and smooth deposits, from copper electrolytes containing high percentages of arsenic, by means of organic and inorganic "addition agents."

Dr. Ching Yu Wen's thesis is quite voluminous; first abstracts of former literature relating to the subject are given and then his own experiments are described in great detail. For the description of the apparatus and details of the results the reader must be referred to the original thesis. In the following we give the chief conclusions.

The experiments as performed may be grouped under four main headings: (1) Impure electrolytes, which contained no "addition agents." (2) Impure electrolytes, which contained inorganic "addition agents." (3) Impure electrolytes, which contained organic "addition agents." (4) Impure electrolytes, which contained organic and inorganic "addition agents."

(1) With electrolytes which contained no "addition agent" much arsenic and antimony was deposited with the copper, even

when the electrolytes contain 1.5 per cent arsenic. With electrolytes containing 2 per cent and 3 per cent arsenic a still greater amount of these two impurities were deposited with the copper, and large dentritic "trees" also formed on the surface of the deposits. These impurities rendered the copper dull colored and brittle.

At temperatures between 50° C. and 60° C., and with electrolytes containing over 6 per cent arsenic, the arsenic acid appeared to act as an "addition agent," as it prevented, to some extent, the deposition of the impurities (arsenic and antimony) with the copper and also retarded the formation of dentritic "trees." At temperature of 40° C. and below, however, this action of arsenic as "addition agent" in the electrolyte did not appear to take place in the electrolyte containing under 6 per cent arsenic, whereas in the electrolyte containing 8 per cent arsenic the deposited copper was purer, brighter, more solid and coherent, and less brittle.

This shows that the good effect of arsenic acid depends not only upon the temperature of the electrolyte, but also upon the amount which is present in the electrolyte. This phenomenon cannot be explained from the data obtained in these experiments, but it may be attributed as the result of the hydrolization which converts the arsenic sulphate $As_2(SO_4)_3$ into arsenous acid H_3AsO_3 and sulphuric acid H_2SO_4. The reaction is $As_2(SO_4)_3 + 6H_2O = 2H_3AsO_3 + 3H_2SO_4$.

Temperature and the amount of arsenic in solution both appearing in this case to be functions of the reaction. As the arsenic is in the form of an acid radical, it would not be precipitated on the cathode, but would act as a reducing agent in the electrolyte and thereby give results similar to those of the ordinary "addition agents."

(2). Hydrochloric acid, sodium sulphate, aluminium chloride and sodium chloride, all, when present in small amounts, have a distinct action upon the improvement of the deposited copper both chemically and physically. They cause the deposits to become more or less smooth, dense, pure and free from "trees."

Of these inorganic "addition agents" the best and most effective is sodium chloride, hydrochloric acid to a slight degree. The effect of sodium sulphate is still less; it produces little or no effect if present in too small amounts, especially at temperatures of 40° C., and when the electrolyte contains 3 per cent arsenic.

Aluminium chloride, though it improves the copper deposits to some extent, does not seem to be a suitable "addition agent," while aluminium sulphate is, on the other hand, a satisfactory one, it causing the copper to deposit low in impurities and more ductile.

From the results of the trial of inorganic "addition agents" it appears to be true that the salts of those metals, which stand by far higher in the emf series than copper, are generally satisfactory "addition agents." They possess the property of preventing, to a considerable extent, the deposition of arsenic and antimony and the formation of "trees." The latter action of inorganic "addition agents" is difficult to explain, but, according to Dr. Edward F. Kern,* it is due to the reducing effect of these metals (in ionic state). The higher that the metal of the "addition agent" stands in the emf series the purer, smoother and less brittle the deposit appears.

Temperature plays an important part in the electrolysis of copper. With higher temperature the ductility of the copper seems to be increased and the potential between the electrodes decreases. In the case of sodium sulphate as "addition agent" with higher temperature it becomes more effective.

(3). In the case of organic "addition agents," both gelatine and tannin produce a remarkably beneficial effect upon the copper deposits and are satisfactory "addition agents." The presence of gelatine at the beginning of the electrolysis has the effect of causing the formation of small fern-like "trees," but after operating for a period of time the deposits are smooth and ductile. Peptone, unlike gelatine, exerts a detrimental influence on the deposits and, therefore, is an unsatisfactory "addition agent."

To explain the good and bad action of the organic "addition agents" mentioned above is no easy matter, as their chemical structure, except tannin, is not yet fully and definitely known. It may, however, be of value to cite their properties. Tannin $C_{12}H_3(OH)_3(COOH)_2$ possesses characteristic acid properties and contains three hydroxyls per molecule. Gelatine, whose chemical structure is not yet fully known, is also essentially acid in character, as it possesses, when pure, an acid reaction and dissociates carbonates.

Peptone* is of two kinds, which differ from each other in one molecule of H_2O. Their chemical compositions may be shown as follows: $C_{25}H_{34}N_6O_9$ and $C_{22}H_{36}N_6O_{10}$. The former is called A-peptone and the latter B-peptone. Peptones are pronounced acids, which redden litmus paper and form salts with carbonates after having expelled the carbonic acid gas; adopting the simplest formula, peptones are monobasic acids, but such a simple formula has to be multiplied.

(4). The deposits of copper obtained from electrolytes containing the combined "addition agents" are all satisfactory, particularly when the combination of gelatine and sodium chloride is used. The striking effect of the inorganic substances, when present with the organic, is that it counteracts the bad effect of the latter. Of the two inorganic compounds (sodium chloride and hydrochloric acid) that were used for the combined "addition agents," sodium chloride is in every case better, more satisfactory and more effective in producing good copper.

This shows that the better effect is due to the presence of the sodium ion in the electrolyte. As evidence a particular case may be cited, that is, a case in which peptone and sodium chloride and peptone and hydrochloride acid were used as combined "addition agents." The copper deposits obtained in the former case were found better, both in physical character and purity.

In considering what has been said above, the question may now arise: What causes the organic compounds to behave so differently in the electrolytes when an addition of a small amount of either sodium chloride or hydrochloric acid is made? Does the presence of either of these two inorganic compounds cause the organic ones to undergo a chemical change? These questions cannot be answered without special investigations and were not within the scope of the present research.

With the results that have been obtained, and with the effects of various "addition agents" that have been tried, this may be said: The combined "addition agents" of gelatine and sodium chloride, when present in a small amount (say 0.01 to 0.02 per cent gelatine and 0.01 per cent Cl as NaCl), proves to be the most suitable and most satisfactory "addition agent" for copper sulphate electrolytes containing, especially, a high proportion of arsenic, as the deposited copper possesses the greatest ductility and the highest purity.

Calcium and Molybdenum for Hard Copper Wire.—A recent British patent (7657, April 20, 1911) of the Electrochemische Werke Ges. (Berlin) refers to a process in which up to 1 per cent of calcium or molybdenum or smaller percentages of each are added to electrolytic copper instead of aluminium and magnesium as is now usual to produce hard wires for overhead lines. Whereas a usual requirement for such wires is a conductivity of 95 per cent with a tensile strength of 40 kg to 46 kg per square millimeter, a wire with 0.35 per cent of calcium is stated to give on test 98 per cent conductivity and a tensile strength of 54 kg per square millimeter. Similarly, a wire with 0.05 per cent of molybdenum is stated to give 96.2 per cent conductivity and a tensile strength of 52.9 kg per square millimeter. By adding 0.35 per cent of both calcium and molybdenum to pure copper a conductivity of 98 per cent and a tensile strength of 52 kg per square millimeter are said to be obtained.—London *Elec. Eng'ing*, April 27.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our London Correspondent.)

The Causes of Corrosion.

The corrosion research committee of the Institute of Metals is making arrangements for conducting an extensive series of investigations into the causes of corrosion in brass condenser tubes, for which purpose a condenser is being made with 48 tubes, 24 of which are of commercially pure brass, while the rest will severally contain one of the following metals: Lead, tin, aluminium, manganese, or any other substance the effects of which the committee may desire to ascertain. The water speeds will be varied in numerical ratios, 2 being the average speed generally employed. The experiments will be continued for several months and will be carried out under the personal supervision of Mr. G. D. Bengough at the University of Liverpool.

An Unusual Cause of Rusting in a Shipyard.

At last month's meeting of the Newcastle Section of the Society of Chemical Industry, Mr. F. C. Garrett said it was generally found that during the building of a ship rusting proceeded only to such extent that when ready for painting the plates could be easily cleaned of scale, but a case had recently occurred where rusting was so extensive that the extra scraping was very expensive and caused some anxiety on the part of the builders lest it should recur after completion.

The ship in question was near the eastern boundary of the yard; and another ship, about a quarter of a mile further to the west, built of the same make of plates, was but slightly more rusty than usual, showing that the fault was not with the plates. The aqueous extract from the rust of the western ship gave 0.342 per cent of a brown substance which slowly absorbed moisture from the air, while the rust from the eastern ship yielded 0.804 per cent of a nearly white and very deliquescent solid.

Analyses of these substances showed for the eastern ship 10.43 per cent calcium, 7.72 magnesium, with 41.6 chlorine, and for the western ship 5.68 per cent calcium, 4.24 magnesium, with 21.78 chlorine. The chlorine calculated for the Ca and Mg amounted respectively to 41.38 and 20.7. The rust from the western ship, therefore, contained 0.1047 per cent of mixed chloride of calcium and magnesium, and that from the eastern ship, 0.478 per cent of the mixed chlorides; and as the rust on the latter was at least twice as much as on the other, it must have contained about 10 times the quantity of chlorides per square foot.

It was found that excavation had been carried on just over the eastern boundary of the yard, involving disturbance of some alkali waste. A sample of this waste could not be obtained, but the local limestones commonly contain much magnesium, and the air was found to contain a chloride—probably hydrogen chloride.

A Ferro-Concrete Pier.

At a meeting of the Concrete Institute Mr. C. P. Taylor mentioned some novel features in the design and construction of the ferro-concrete pier at the Swanscombe works of the Associated Portland Cement Manufacturers.

The foundations consisted of 32 columns, which, except at the corner, were constructed in pairs on 25-ft. centers, the longitudinal pitch being 28 ft. Each pair of columns was connected just above low-water level by a horizontal brace and at the top by a cross-beam. Between the last three pairs of columns at the outer end of the pier there was also a reinforced diagonal strut. The top cross-beams were extended at each end to form a cantilever and the ends of the nine rows of longitudinal beams were built into them.

The nature of the river bed made it desirable to use a construction involving a *minimum* of long piles. The other chief idea underlying the designs adopted was the desirability of carrying the full diameter of the columns right down to the bed of the river without necessitating the deposition of concrete through water. The author considered that the practice of depositing concrete down a shoot inside a shell through a considerable depth of water produced a structure of very questionable strength. Mr. R. G. Clark, therefore, worked out a system of constructing the columns in which the concrete carrying the weight of the structure was in the form of blocks molded on shore and matured before being placed in position. The blocks were laid one on the other surrounding a central pile, and keyed together, and also by rails passing through vertical holes around the pile. The only concrete which had to be deposited under water was that used for filling around the pile and the rails. The central pile alone was not sufficient to carry the total weight borne by each column (about 150 tons) and the base of the column rested on piles driven round the center one and cut off near the ground level.

When the columns were completed the longitudinal beams, all of identical design, were lifted into place by the crane and were temporarily supported on rolled steel joists reaching across the pier on each side of the tops of the column. This plan saved much heavy shuttering which would have been necessary to mold the beams in place and also falsework to support the shuttering. After placing the nine longitudinal beams, the crane and other plant were moved forward for building the next pair of columns, and the molding of the main cross-beam and stiffener was put in hand.

Novelty was not claimed for making the longitudinal beams separately and lifting them into place, although the author did not know of any case where such large beams had been dealt with in this way. The author concluded with a detailed discussion of the especial stresses involved.

Concrete Water-Pipes.

The laying of the reinforced concrete water pipes on the Bonna system for the conveyance of the new water supply to Clydebank has been completed, and the pipes are now taking the water from Burncrooks to the filters at Cochno, distant about 10 miles. There is good authority for stating that the jointing problem has been solved and that no trace of leakage can now be found. The work was begun by contractors, but the corporation had to complete it themselves. The entire cost, including repairs while the work was suspended, is said to be less than that of iron pipes.

Tungsten and Tool Steel.

In an article in the *Times* of April 19 the statement was made that "the first commercial application of tungsten in steel manufacture was by the Bethlehem Steel Company of U. S. A. at the Paris Exhibition in 1900." Mr. Julius L. F. Vogel, a week later, wrote to point out that, although the Taylor-White steel then demonstrated was perhaps the first tool steel of which tungsten was publicly stated to be an important ingredient, Messrs. Osborne, of Sheffield, had very many years earlier incorporated a certain amount of tungsten in what was known as "Mushet" steel, and long before the Paris Exhibition this was employed in a small way in engineering works where specially hard cutting edges were required. Machines in use some 10 years ago were quite incapable of employing such steels to advantage, if at all, as they had not sufficient strength to do the work.

The growth of the high-speed tool was, therefore, dependent upon their replacement by others of special strength and design to work with the heavy cuts and high speeds of which the improved tools were capable. At the present day suitable machines for using high-speed tools are the rule and not the exception; hence the consumption of tungsten has continued to grow steadily.

In view of the fact that the supply of tungsten is comparatively limited it is fairly obvious that competition for the control of tungsten between three rival manufacturing countries such as Great Britain, United States and Germany must inevitably follow. The importance of Great Britain being self-supporting is apparent.

Rapid Method for Estimation of Sulphur in Coal-Gas, or of Ammonium Sulphate.

At the meeting of the Newcastle Section of the Society of Chemical Industry Mr. H. BLAIR read a paper on this subject. Ammonia can be determined rapidly and accurately by utilizing the reaction of Malfatti, viz., the formation of hexamethylenetetramine and liberation of acid on adding formaldehyde to solution of an ammonium compound:

$$4\,NH_4Cl + 6\,CH_2O = N_4(CH_2)_6 + 4\,HCl + 6\,H_2O$$

The liberated acid is titrated by standard alkali with phenolphthalein. For the determination of sulphur in coal-gas the liquor obtained in the "referee's test" is made up to 500 c.c., and 50 c.c. are boiled for a few minutes to expel carbon dioxide; to the hot solution 10 c.c. of formaldehyde solution (about 30 per cent) are added, and the titration is at once made with decinormal potash, 1 c.c. of which is equivalent to 0.0247 grain of sulphur. The potash solution is best standardized by means of a standard solution of ammonium sulphate containing a little ammonium carbonate.

The results come out consistently and a little higher than those obtained by the barium sulphate method, but the discrepancy is not important—figures obtained being 5.064 against 4.53; 10.89 against 10.19; 33.97 against 32.81; and 25.04 against 24.98. The method can be employed for the estimation of sulphur in a smaller volume of gas, such as 1 cu. ft. or 2 cu. ft. The required volume is burned under an adapter and the products of combustion are aspirated through solution of ammonium carbonate which is treated with formaldehyde as above.

For the estimation of ammonium sulphate the salt is dissolved in water and its acidity neutralized with caustic potash; an aliquot part is boiled, formaldehyde is added, and the whole is again boiled for a few seconds, phenolphthalein is added and the titration is made with decinormal potash: 1 c.c. $= 0.0049\ H_2SO_4$; $0.0017\ NH_3$; $0.0066\ Am_2SO_4$. The results agree closely with those obtained by the barium sulphate method.

Volumetric Determination of Tungsten.

E. Knecht and E. Hibbert reduce the tungstic acid or its salts with granulated zinc in a strong hydrochloric acid solution until a brown solution of tetrachloride is produced. Potassium thiocyanate is added as an indicator, and the tetrachloride is reoxidized by standard solution of iron alum in an atmosphere of carbon dioxide. During titration the brown color changes to blue, which persists until the end-point and may serve as an indicator instead of the thiocyanate. The presence of ferrous iron does not affect the titration. In the case of ferro-tungsten the authors recommend decomposition with potassium persulphate—fusing 0.1 gram of the alloy with 4 grams of persulphate in a porcelain crucible, taking up with water, making alkaline with sodium hydroxide and filtering. The tungsten is determined in the filtrate, and the iron on the filter may be dissolved and estimated.

Recovery of Zinc from Ores and Waste Material.

Mr. A. Gutensohn (Eng. Pat. 9818, 1910) mixes the ore, or other material containing zinc, in a powdered state, and after roasting if necessary—with carbon and a collecting material consisting of 20 parts lime, free as possible from silica, with one part each of iron borate and manganese borate. The quantity of carbon employed is the same as the estimated weight of the zinc in the ore, etc., and the collecting material used is one-fifth of that weight. The mixture is heated in a retort at such a temperature that the zinc is the only ingredient melted. For the production of zinc oxide the condenser pipes are fitted with air inlets.

Uranium.

W. P. Jorrissen and A. P. H. Trevelli have found that on exposing commercial metallic uranium to the action of cathode rays nitrogen was given off in considerable quantity. Further research demonstrated the presence of 13 per cent of uranium nitride, U_3N_4, and 1.25 per cent of carbon.

Hydraulic Bronze Castings.

Sergius Kern states that castings suitable for high-pressure hydraulic and steam apparatus can be made by melting 78 parts of best copper with 10 of good brass in a covered crucible holding at least 2 cwt. and then adding successively 12 parts of tin, 1.4 of zinc and 0.12 of cupro-silicon containing 10 per cent of silicon. As soon as diffusion of the components is complete the alloy should be poured into the molds.

Market Prices.

April, 1911.

Copper has remained fairly steady, between the limits of £53.12.0 and £54.15.0 per ton. It opened at £54.11.3, was depressed from 10th to 20th to £53.12.0 or about, then rallied slightly, and is now quoted at £54.

Tin has, over the whole month, risen. It opened at £188.15.0, rose to £192 by the 5th, fell smartly to former price, recovered on 7th, and has since kept fairly steadily on the upgrade though always a nervous market. Closes, £193.15.0.

Lead steady at £13.2.6 to £13.5.0 throughout the month. Opened at £13.5.0, closes at £13.3.9.

Iron Hæmatite opened at 65/-, but continued to fall, reaching 62/6 on the 20th; since recovering to 63/3.

Scotch Pig also inclined to be lower. Opened at 53/7½, and dropped to 52/9 by the 5th, recovering 3d. by the 12th, since steady at 52/7½.

Cleveland Warrants opened at 47/7½, and had dropped to 46/4½ by the 19th, since recovering to 46/6½.

	£	s.	d.
Alum, lump, loose, per ton	5	12	6
Antimony, black sulphite powder, per ton	22	0	0
Borax, British Refined Crystal, per ton	16	0	0
Copper ore, 10 to 25 per cent, per unit	0	9	6
Copper sulphate, per ton	19	15	0
Carbolic acid, liquid, 97/99 per cent, per gal	0	1	5
Creosote, ordinary good liquid, per gal	0	0	2
Camphor, 1-oz. tablets		1	9
Caustic soda, ash, 48 per cent, ordinary, per ton	5	10	0
Litharge, flake, per ton	15	10	0
Mica, small slab, original cases, per lb.		2	0
Naphtha solvent, 90 per cent at 160° C., per gal			9
Petroleum, Russian spot			4⅞
Sal ammoniac, lump, firsts, delivered U.K., per ton	42	0	0
Sulphate of ammonia, f.o.b. Liverpool, per ton	13	15	0
Sulphur, recovered, per ton	5	0	0
Shellac, Standard T. N., orange spots, per cwt	4	4	0
Tin ore, 70 per cent, per ton	£123	to	125 0 0
Hydrochloric acid, per cwt	0	5	0

Platinum, per ounce, has been steady at £8.6.6 throughout the month.

India Rubber, Para fine, has been steadier and lower. Opening at 5/9½ it rose to 6/- by the 5th, and thence dropped to 5/3, and ultimately 5/0½. Now quoted at 5/3½.

On the month the following differences are noticed:

Lower.	*Amount.* £	s.	d.
Copper	0	15	0
Lead		1	3
Hæmatite		1	0
Scotch pig		1	0
Cleveland warrants		1	1
India rubber, Para fine		0	6
Copper sulphate		2	6
Camphor			1
Sulphate of Ammonia		12	6

Higher.	*Amount.* £	s.	d.
Tin	8	2	6
Mica		1	0
Shellac		11	0
Tin ore	11	0	0

Synopsis of Metallurgical and Chemical Literature.

Gold and Silver.

Amalgamation of Gold in Banket Ore.—In the March, 1911, issue of the *Journal* of the Chem. Met. & Mining Soc. of South Africa, W. R. Dowling presents a review of the methods of amalgamation used on the Rand before and since the war. The improvement in methods of metallurgy on the Rand has made it possible to treat lower grades of ore, and the large scale of operations has made it necessary to simplify procedure.

In the early days of the Rand the main source of gold recovery was amalgamation, assisted by concentration and Chlorination. To obtain maximum recovery it was considered necessary to catch the gold as soon after its release as possible, and therefore inside amalgamation was practised. Outside were the usual apron plates with mercury wells between. Mercury also was fed to the mortar. It appears that the percentage recovery in the early days on an oxidized and rich ore by the various methods then in use was not much less than is obtained by the present fine crushing from low-grade pyritic ore by the ordinary straight mill plate and shaking tube mill plates as used to-day.

A most important change was brought about in 1890 by the introduction of the cyanide process. It was at first applied only to coarse leachable ore, and as it was the practice to make as little slime as possible it follows that amalgamation recovery dropped on account of the coarse crushing. When the slime methods came into vogue in 1894 the fine grinding was again possible and the amalgamation recovery assumed its normal condition. The use of lime as a settling factor also was of benefit to amalgamation as it caused the slime to agglomerate

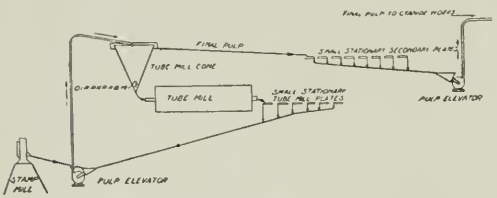

FIG. 1.—RANDFONTEIN CENTRAL ARRANGEMENT. SIX SMALL STATIONARY TUBE MILL PLATES AND EIGHT SMALL STATIONARY SECONDARY PLATES FOR FINAL PULP.

in particles which could come in contact with the plates better than fine disseminated slime. Finally the introduction of tube mills raised the recovery by amalgamation to 65 to 70 per cent of the contents of the ore, of which some 10 to 15 per cent was from the tube mill plates.

Coming nearer to the present time we find that the increased use of tube mills for regrinding permits of coarser crushing at the stamps and consequently the necessity of recovering the plates from the stamps on account of the scouring of the coarse pulp. The author finds that this change gives rise to five possibilities of arrangement of the tubes and plates, and these are illustrated in diagrams, Figs. 1 to 5.

(1) Amalgamation of the tube mill pulp by one set of plates and the overflow final pulp by another set.

(2) Amalgamation of the tube mill pulp only.

(3) Amalgamation of the mixed pulp after regrinding of the coarse portion of tube mills, as in recently erected plants.

(4) Common arrangement, and (5) author's proposal.

It will be noted that plans 1 and 3 involve two elevations, while plan 2 involves only one. In this respect the latter is preferable. Plan 4 also involves but one elevation of pulp, but it also has stamp mill plates, which, the author points out, are better removed, as they make immediately available the gold which otherwise is tied up in them, and permits placing all the plates in a separate house.

The number of plates required after tube mills, and the question as to whether they should shake or be stationary, is referred to by the author. We refer our readers to our May issue, p. 279, for data on this subject.

To ensure successful and economical work the ratio of water to solid should be reduced to the minimum, as not only does this decrease the velocity of the stream over the plate, but the cost for re-elevation is also less. The fall given to stationary plates is 18 per cent, and with this fall it is found that the minimum percentage of water in the pulp is 55 per cent. The

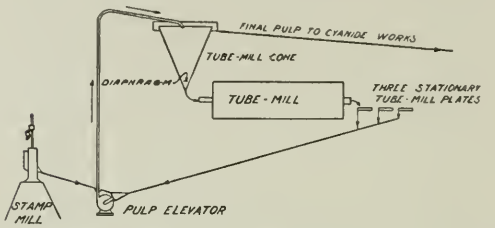

FIG. 2.—SIMMER AND JACK ARRANGEMENT. THREE STATIONARY PLATES IN TUBE MILL CIRCUIT.

point to be reached in water ratio and fall is just short of the banking of sand on the plate.

The author favors the removal of plates from the stamp mill to a separate house, as such an arrangement will result in increased running time by not having to hang up the stamps for cleaning the plates and more attention can be given the crushing apparatus. Better amalgamation also should result by the closer attention made possible, and there would be less opportunity for pilfering gold by employees who necessarily have to work about the stamp mill, but who could be kept from the plate house. Where the plates are removed from the stamp mill the water ratio may be considerably reduced.

The author is of the opinion that the ratio of amalgamation plate surface to stamp unit is entirely too large. At the Randfontein Central the area amounts to 9.6 sq. ft. per stamp unit, but it is now proposed to reduce this to one-half that area. In the Simmer and Jack rearrangement the plate area is about 2 sq. ft. per stamp unit. Advantages resulting from this reduced plate area are reduced cost of installation and operation and reduced cost of mercury consumption. Less gold also will be required to set the plates, and as a well set plate will have about 1 oz. of gold per square foot it will be seen that the sum thus tied up can amount to considerable in a large mill.

Dry Washing for Placer Gold.—The Altar district, So-

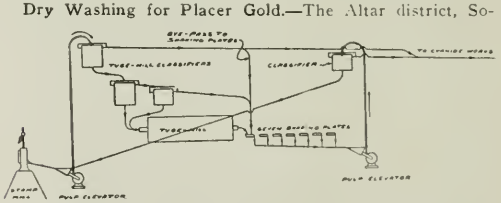

FIG. 3.—RECENT ARRANGEMENT. SEVEN PLATES AMALGAMATING TOTAL MIXED PULP.

nora, Mexico, is for the most part a desert, with but little rainfall and few running streams. On account of this dry condition it is necessary to "dry-wash" the cement gravels containing gold. The operation is described by J. V. Richards, of Spokane, Wash., in the April *Bulletin* of the American Institute of Mining Engineers.

It is said that as long as a century ago the Yaqui Indians discovered rich cement gravel, known as *argo masa*, at Las Palomas, and that there has been a more or less steady pro-

duction of gold from the property ever since. The *argo masa* is a fairly coarse gravel, the pebbles being held firmly together with a lime cement. Gold is scattered through this cement in particles ranging from fine specks to pieces several grams in weight, and occasional large nuggets are encountered. The contents vary so widely that it is difficult to estimate the value of the gravel, but returns of $10 to $50 per cubic yard are common, and it is doubtful if the Indians considered anything less than $4 to $5 per yard as pay dirt. The *argo masa* occurs in channels varying in thickness from a few inches to several

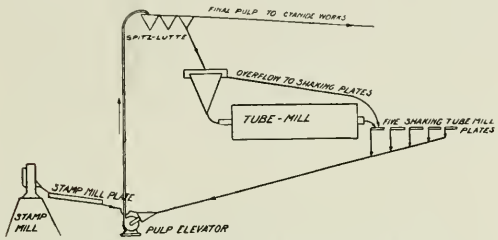

FIG. 4.—COMMON ARRANGEMENT. ONE PLATE FOR FIVE STAMPS AND FIVE SHAKING TUBE MILL PLATES FOR ONE TUBE MILL.

feet, and in width up to 300 ft. These channels are probably ancient stream beds and are overlaid with more recent gravel garying from 30 to 50 ft. in thickness. The overburden contains values as high as $1.50 per yard.

The old Yaqui method of working the ground was to sink shafts and gouge out the cement gravel as far as possible from the bottom of the shaft. Owing to lack of timber for supports, the ground frequently caved, and but little work could be done from any one shaft. After the cement is hoisted, it is pounded between boulders, the coarse gravel removed and the fine cement panned in *bateas*. While this method is laborious, the Indians and Mexicans are expert in the operation, and but little coarse gold is lost. More material can be handled by the dry washer, but the preliminary pulverizing is the same as for the *batea*.

The dry washer is an air blast machine working on the difference in specific gravity of metal and gangue. It is a small table with a cloth top and a bellows below. The table is about 4 ft. long by 2 ft. wide, and has a hopper at one end through which the gravel is fed. The top of the table contains a fine wire netting like ordinary fly screen. On this is placed one and sometimes two layers of burlap, and over this a layer of thin cotton cloth; old flour sacks are sometimes used. Four ½-in. riffles are fastened at equal intervals across the surface, and detachable sides are used to keep the gravel from spilling over. The machine is usually set on the edge of a dump at an angle of 20 deg. from the horizontal, but is carefully leveled in cross-section.

A hand crank belted to a small drive wheel operates the bellows, which has the ordinary clap valves. Intermittent puffs of air come through the cloth at the rate of 150 per minute and cause the sand and gravel to jump the riffles and travel off the table. Most of the gold and black sand is caught behind the first two riffles. The capacity of such a machine is from 2 to 2½ cu. yd. per hour.

After several yards of gravel have been run the machine is stopped and the material behind the riffles brushed into a gold pan. It is then fed back to the machine and nearly all the free gold is caught behind the first riffle. The resulting gold, sand and black sand are then tossed in a *batea* and the gold recovered clean.

The material must be absolutely dry for this operation, only a small amount of dampness tending to clog the cloth and disturb operations. Hand pulverizing has to some extent been displaced by the Quennor disintegrator, which is a cylinder 7 ft. long and 4 ft. in diameter, made up of 1½-in. steel strips set ⅛ in. apart. In the center is a shaft to which are attached chains having tough, manganese-steel lugs at the free ends. The cylinder revolves at the rate of 40 r.p.m. in one direction, and the center shaft revolves in the opposite direction at four or five times this speed. The cement gravel fed in at one end is thoroughly disintegrated by the lugs and falls through the slits, the coarse pebbles being rejected at the end.

At first sight the dry washer appears to be a crude machine, but a test made by the author showed that gravel worth 70 cents per yard gave tailings worth only 10 cents, or a saving of over 85 per cent, and he believes that the general recovery of fairly coarse gold is in excess of 80 per cent.

Zinc.

Modern Zinc Problems.—In his presidential address delivered before the Institution of Mining and Metallurgy, London, Mr. H. LIVINGSTON SULMAN gave an interesting and instructive review of zinc metallurgy and the problems yet to be solved.

In no department of metallurgy has development been more rapid than in the treatment of "complex ores." Just as the terms "free milling" and "refractory" applied to gold ores have lost their older significance, so a few years hence the word "complex" will cease to be used as a prefix to zinc-lead-silver-copper ores, and as a reproach to reduction practice. Many millions of tons of such material have been found, and in some instances partly developed, whose contained metals at current prices render them equivalent in value to two-ounce gold ore. The "complexity" usually is due to blende, usually more or less ferruginous, in intimate physical association with galena and other minerals. Most lead mines are also zinc producers, and every zinc deposit carries lead. When it is possible to dress these ores so as to produce a clean galena concentrate and a zinc portion containing 40 to 45 per cent metal, the ores are not "complex," but the finer parts and slime are still complex in the sense that their separation still awaits solution. The Broken Hill deposits with their intercrystallized galena and ferruginous blende, rhodonite and garnet gangue, which formerly prevented the separation of zinc, are of decreasing complexity since the advent of flotation methods. The slime reserves, however, still present difficulties of treatment.

A more truly complex problem is that which occurs in Tasmania, where the presence of copper adds to the problem. The difficulty in this instance is that the ore contains but little gangue, and concentration by any method is of little or no effect. Succesful reduction must be sought by direct smelting, or the removal of the zinc by leaching processes. Complex carbonates also are known, as those of the Rhodesia Broken

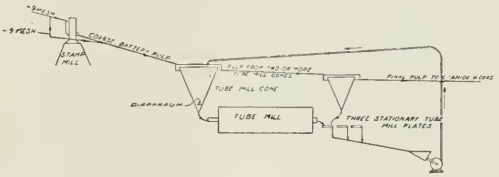

FIG. 5.—PROPOSED ARRANGEMENT. THREE STATIONARY TUBE MILL PLATES.

Hill region, where zinc and lead occur as mixed carbonates. Again, there are those ores in which the presence of fluorspar prevents the usual retort reduction methods for zinc, and which probably will have to be reduced in the electric furnace.

The methods of attacking such ores may be divided into proximate or mechanical, and ultimate or leaching and smelting processes. Proximate methods are limited by the conditions encountered in crushing heterogeneous materials to free the component parts, and usually are inefficient by reason of having to produce several grades of mineral, or a low grade

if all be mixed. Among the proximate methods which have come into prominence is the flotation group.

The simplest type of flotation methods is represented in the DeBavay process used at Broken Hill, and in the Macquisten tube, reference to which was made in our issue for May, 1911, p. 236. In these the surface tension of water is used to float off the sulphide particles, which are not easily wetted, whereas the more readily wetted gangue particles sink when a mixture of mineral and gangue is presented to a surface of flowing water. A second variety is the Potter process, in which submerged sulphide particles are caused to rise to the surface of a hot acidified pulp by the fixation of gas bubbles; the gas in this instance being carbon dioxide generated by the acid on siderite. The third variation includes the well known oil processes of Elmore and Minerals Separation, Ltd., which secure the flotation of submerged minerals by means of bubbles of air, such mineral particles having previously received a slight film covering of oil for the purpose of effecting the air or gas attachment. To Elmore undoubtedly belongs the honor of first bringing oil-mineral processes into the realm of commercial practicability. To Froment and especially to Cattermole we are indebted for the next important development. The latter first demonstrates the efficiency of a very small quantity of oil in place of the large bulk hitherto employed.

The physical reactions which underlie all such methods have been insufficiently explored, and in many respects are still obscure; the striking practical results so far achieved have been reached quite empirically. The author mentions a new fact in relation to the measurements of the "contact angles" which exist between the surfaces of aqueous liquids and those of certain sulphides, silicates and other solids. In investigating previously accepted figures for these, he finds discrepancies in the readings, which on further investigation prove to be due to the existence of a variable range for the contact angle between various liquids and solids, though of constant magnitude of variation for each. This range of angular variation has been called by C. G. Lamb, "the angle of hysteresis," and its existence and magnitude in regard to many substances have been independently confirmed and quantified by A. Howard Higgins. It is not a fact of merely academic interest, as it appears to be intimately connected with the ability of a given solid to condense upon itself a gas film; and when submerged in a liquid to determine the attachment of a gas when generated, or on the point of generation, from a solution. It follows that angular hysteresis reaches its highest values for minerals which are most susceptible of flotation, and *vice versa*. Hundreds of observations have been made which place this relationship beyond doubt. Besides roughly quantifying the gas condensing power due to the surface energy of solids, it brings us somewhat closer to an explanation of the efficiency of acidification. Thus, whereas the angular hysteresis of silica in plain water may exceed 30 deg., thus indicating that substance to have a definite power to occlude gas and to float, it drops from 4 deg. to 0 deg. in water acidified with sulphuric acid. Galena, on the other hand, retains its full measure of angular variation or is but slightly affected.

While certain difficulties remain to be solved, especially in regard to blende and galena slime, the Broken Hill problem may be regarded as solved by the flotation processes. It must be remembered however, that the methods referred to work effectively only on particles of sensible size.

The slime problem has been studied by Horwood, who operates by superficially attacking one particle while leaving the other unaltered, and thereafter submits the product to oil flotation. He usually employs heat to effect this differentiation, a low temperature oxidizing the surface of the galena while the blende remains unaltred. The Minerals Separation process is preferred for this work as it deals better with slime.

Magnetic separators employing fields of high intensity still have a wide range of usefulnes, although on dry ore have given trouble on account of dust. Wet types have been extensively experimented with, and lately Mr. Ullrich has introduced a multipolar ring machine which overcomes the difficulty of removing small particles from a liquid. Several of these machines are already working, and their possibilies regarding slime mineral are receiving close attention.

Electrostatic methods are revived in the Huff machine. To L. I. Blake is due the credit for first introducing a commercial separator on the electrostatic principle. He was followed by Sutton and Steele, in whose machine the electrode was charged inductively by a brush discharge, and was furnished with an ingenious interrupter whereby any desired degree of saturation of the separating roller could be obtained to suit the varying electrical capacities of the minerals to be separated. An electrostatic generator also was employed in this machine. The main advance in the Huff machine is the substitution of a dynamo current of suitable intensity for the electrostatic energy of a Wimhurst machine. The limiting factor of electrostatic separators is their inability to handle fine powders, and their liability to dust troubles unless the dust first be removed.

In the mechanical treatment of slime we reach the limit of proximate methods of handling zinc ores, and must take up ultimate methods such as smelting and hydrometallurgical processes. Dealing with smelting, the author mentions H. Pape's process in Germany. Low grade zinc-lead ores are smelted with sufficient silicious ore to slag off the zinc and reduce the lead. The slag of zinc silicate is then crushed and briquetted with sufficient carbon and a binding agent, and charged into a blowing furnace, fitted with a special grate on which the briquets are charged to a depth of three or four feet. Upon ignition, the zinc is first reduced and then blown off as oxide, while the depleted slag flows through the grate. The separation goes on alomst to completeness, and the zinc oxide is collected in chambers and bags.

Referring to leaching methods, the bisulphite process is described as follows: Roasted ore is subjected to the action of water and dissolved sulphur dioxide gas, the latter being derived from the roasting operation. The zinc is dissolved as bisulphite and separated from the residues which contain lead, silver and other metals. From the solution the zinc is thrown down as insoluble monosulhphite by removing one of the equivalents of sulphurous acid gas. The precipitate is then calcined, resulting in the production of a dense zinc oxide suitable for reduction to spelter. Sulphate of zinc accumulates gradually in the liquors until they are strong enough for recovery of the salt by crystallization.

A means for the reduction of zinc sulphate is provided by electrolysis, the deposited zinc being stripped from the cathode and remelted to spelter, while the acid regenerated at the anode is used for the leaching of fresh oxidized zinc from roasted ore. In practice it is found that about 5,500 electrical horsepower, as a mean figure, is required to produce a ton of deposited zinc, or roughly two-thirds of an electrical horsepower-year. Wherefore, localities favored with cheap water power will hold an advantage in the production of electrolytic zinc, for the process could hardly supersede the present distillation processes if located at existing reduction centers.

The author concludes with a review of electric processes for zinc, but as these have been given full attention in our issue for May, 1911 (see also our Vol. VIII., pages 49, 99, 289, 317, 688, 689), they will not be mentioned here.

Physical Chemistry and Electrochemistry.

Specific Heats of the Elements.—In a recent number of the *Zeit. f. Elektrochemie* J. Koenigsberger publishes a compilation of values obtained by himself, Nernst, Richards, Dewar and others for the atomic specific heats of the elements. It is shown that there is a distinct difference between the specific heat of a good conductor and that of an insulator. The values for metals cooled to very low temperatures are very near those

for insulators at high temperatures. The value c_p for carbon, in the shape of diamond, is almost zero at $-180°$ and at 1500° it has increased to $c_p = 6$.

Colloids.—*In the Zeit. f. Elektrochemie,* April 15, A. LOTTERMOSER gives a very careful review of all important papers and patents on colloids that appeared in 1908. Among the headings under which the subject matter is treated are: Electro-osmosis, the theory of dyeing, floculation, production of colloidal metals and metalloids on a commercial scale, lubricants and albumen.

Thermodynamics of Galvanic Cells.—In the same number R. LUTHER publishes a note on *Lead-Mercury Cells.* He finds that according to electromotive force determinations the heat of reaction of $Pb + 2HgCl = PbCl_2 + 2Hg$ is equal to 21,900 calories; from thermodynamical data of Nernst and Thomson the value 20,100 is derived. This leaves a difference of 18000 calories between the two values. No satisfactory explanation of this discrepancy has as yet been found.

Sharpening of Tools by Electrolytic Etching.—In *Dingler's Polytechn. Journal,* Vol. 35, 1910, page 747 (abstracted in *Elek. Zeit.,* Jan. 26, page 93), E. SCHNECKENBERG discusses the use of the electric current for the sharpening of tools by electrolytic action. Barthel formerly used a mixture of three parts of 66 per cent sulphuric acid and 6 parts of 40 per cent hydrochloric acid. The file or cutter to be sharpened was first cleaned from fat and dirt and then suspended together with a carbon electrode into the above solution. This represented a short-circuited cell and the file or cutter was automatically sharpened. Gratwohl has recently modified the method by employing an inert load electrode instead of the carbon electrode and a primary battery or storage battery giving 1 volt or 2 volts as an external source of current. He uses an electrolyte of a sulphuric acid solution of specific gravity 1.18.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Briquets of fine iron ore may be made according to the formula of GEORGE K. HOLLISTER, JR., of New York City. He proceeds preferably as follows: Say 2,000 pounds of fine iron ore are mixed with 15 pounds of clay in a dry and pulverized state. To this is added, during a mixing operation, 3½ gallons of molasses slightly acidified with two ounces of hydrochloric acid, and three gallons of water containing two pounds of sal soda and one pound of powdered alum. When the ingredients are thoroughly mixed the mass is placed in a pug mill and heated evenly to a temperature of about 350° F. until the material has lost its wet appearance and feels dry to the touch. It is then passed through a briqueting machine. By this procedure the inventor claims to obtain a hard, practically unbreakable briquet, due to the bond formed by the salts and clay, and to the carbonization of the molasses. It is claimed that the briquets can be used in the smelting furnace immediately after leaving the machine. (990,049, April 18, 1911.)

Copper.

Improving Conductivity and Tensile Strength.—The improvement of copper and its alloys for electrical work by increasing the tensile strength and conductivity is the basis of a patent granted to RUDOLF FRANKE, of Eisleben, Germany. The process has been assigned to the Elektrochemische Werke (G. M. B. H.), of Berlin, Germany.

Three classes of wire are used in telegraphic and telephonic work in Germany, viz., chemically pure copper wires, bronze wires and double bronze wires. The bronze and double bronze wires are treated with a composition consisting of 64 per cent aluminium and 36 per cent magnesium, together with a little tin. The inventor has experimented to see whether the composition could not be replaced by calcium or by molybdenum. He produced both soft and hard-drawn wires as follows: 1. Wires without any addition. 2. Wires with the addition of calcium in the form of calcium-copper containing 12.2 per cent calcium. 3. Wires with the addition of molybdenum in the form of metallic powder containing 97.1 per cent molybdenum and 3 to 4 per cent oxide, 1.4 per cent insoluble matter, 0.65 per cent iron and aluminium as carbide. 4. Wires with the addition of aluminium and calcium in the proportion of 42.3 per cent calcium and 55.85 per cent aluminium. 5. Wires with the addition of molybdenum and calcium, the latter in the form of calcium-copper. 6. Wires with the addition of aluminium-molybdenum-calcium, the calcium in the form of aluminium-calcium and the molybdenum as metallic powder.

The results of the tests showed that the addition of calcium as calcium-copper was far superior to the magnesium-aluminium composition; that molybdenum similarly gives better results than the composition referred to and about equal to those of calcium; that the addition of aluminium-calcium gives poor results; that calcium-molybdenum additions give the good results shown by the addition of either metal; and finally, the aluminium-molybdenum-calcium addition gives poor results and should not be used on account of the presence of the aluminium.

The tests establish to the satisfaction of the inventor that (1) calcium and molybdenum addition can be advantageously substituted for the aluminium-magnesium composition for hard-drawn bronze wires, and that (2) with an addition of at the most 0.35 per cent of calcium or molybdenum or both, hard-drawn wires can be produced with a tensile strength of 50 to 52 kg. per sq. mm., and a conductivity of 95 per cent. The patent specifications give the engineering results on many tests which are instructive and bear out the inventor's claims. (990,040, April 18, 1911.)

Aluminium.

A new solder formula recently has been patented by JOSEPH N. DAUDELIN, of St. Hyacinthe, Quebec, Canada. It comprises a mixture of silver, phosphorus, copper, lead, tin, aluminium and zinc. The main object of the invention is to produce a solder having great tensile strength; one which will run easily; which may be used for aluminium as well as other metals; one which has a very low coefficient of expansion; one which is homogeneous, will not easily corrode and will be tough without being brittle. The various ingredients are claimed to give these properties to the solder. The inventor prefers to mix the metals in the following proportions: 22 grains of silver, 42 grains of phosphorus, 238 grains of copper, 1338 grains of lead, 5,051 grains of tin, 50 grains of aluminium, 939 grains of zinc. (989,573, April 18, 1911.)

Electric Furnaces.

Pinch Effect for Electric Furnace.—In his recent American Electrochemical Society paper (our May issue, page 277), Mr. CARL HERING, of Philadelphia, Pa., described in detail an electric furnace in which he makes use of the "pinch effect" for circulation of the charge. A patent has now been granted to him on this process. Since the principles were already described quite fully in our last issue, we give here only two of the 34 claims. The first claim reads as follows: "In an electric furnace, a hearth for containing a mass of molten material, columns or channels communicating with said hearth and adapted to be filled with molten material in communication with said molten mass to constitute the furnace resistor, and electrodes in end on communication with said columns or channels, the square of the current transmitted through said electrodes to the molten material in said columns or channels with relation to the cross-section of said columns or channels being great, whereby said mass of molten material is automatically stirred." The twelfth claim reads as follows: "In an electric furnace, the combination with a mass of molten material, of a molten mass in communication therewith serving as resistor, the ratio of the square of the current through said resistor to its cross-section being great, whereby circu-

lation of molten metal is produced, and an electrode in communication with said resistor having such dimensions that the C^2R heat developed in said electrode by the current traversing said resistor shall be equal to substantially twice the heat conduction loss through said electrode when no current is flowing." In the specification the laws of the pinch effect and of the heat losses through electrodes are given and rules are derived for calculating the dimensions of the essential parts of the furnace. Various modifications of the simplest arrangement, employing two vertical columns to communicate with the hearth, are described. By arranging the resistor columns not vertically but inclined to the vertical, less hydrostatic pressure is developed in the columns. With three columns the furnace is adapted to three-phase currents. A double furnace is described for the production of steel directly from ore; in one of the furnace chambers the iron ore is reduced, in the other chamber the refining of the steel is performed, both chambers being heated from the bottom, each by a set of resistor columns. Combinations of this resistance furnace with the use of arcs at the top are also described. (988,936, April 4, 1911.)

Electrode Arrangement for the Reduction of Radiation Loss.—Mr. E. C. Speidex, of the International Acheson Graphite Co., of Niagara Falls, has patented an arrangement of the electrodes above the bath for the purpose of reducing the direct radiation of heat from the surface of the molten bath. The electrodes are disposed in overlapping series, whether in parallel planes or in angular relation to each other, but in such a way as to protect, shield, or shadow the upper portion of the furnace structure, including the roof, from the effect of heat radiated from the zone of maximum temperature. (992,281, May 16, 1911.)

Combination Bessemer-Electric Steel Process.—A new combination process for refining Bessemer metal in the electric furnace has been patented by Mr. James H. Gray and assigned to the Illinois Steel Co. By the ordinary acid Bessemer process silicon and carbon are removed from molten pig iron; the metal is then dephosphorized in a ladle by means of a slag of lime and iron oxide (previously prepared in a cupola furnace); the metal is finally treated in an electric furnace for the removal of sulphur and oxygen. (987,715, March 28, 1911.)

Electrolytic Copper Refining.

Purification of Electrolyte.—In copper refining the solution becomes gradually impure and it is necessary to remove large quantities of the same periodically. The common practice is to crystallize out the bulk of the copper as blue vitriol (sometimes with the previous step of neutralizing the free acid of the electrolyte by passing over shot copper), and then precipitate the remaining copper on scrap iron. The residue is generally discarded. Messrs. C. H. Aldrich and J. K. Bryan, of Perth Amboy, N. J., propose to subject this residue to further purification. They concentrate the impure electrolyte (18 to 25° Be.) to 45° Be. in a lead-lined tank, heated by means of lead coils and concentrate it further in a lead-lined iron pan to 50° Be. The anhydrous salts are allowed to crystallize out until the bulk of the copper is removed. Thus far the process is the one usually pursued. But now instead of precipitating the copper, nickel and iron salts in one pan, the inventors let the mother liquor pass through a number of heated iron pans arranged in cascade. The mother liquor is thereby concentrated to 60 or 70° Be. and the salts are fractionally precipitated in the cascade of pans. The precipitate in the first pans is relatively rich in copper, that in the intermediate pans contains copper and nickel in about equal quantities, and that in the last pans is rich in nickel.

The resulting solution is allowed to settle in a tank from which it is then pumped into refining tanks arranged in cascade. This solution contains not only traces of copper, iron, nickel and zinc, but contains a material amount of arsenic and antimony in solution. In the electrolytic tanks a temperature of 170° to 180° F. is maintained, insoluble anodes are used and cathodes of lead, copper or iron. The electrolysis is continued until the bulk of the arsenic, together with traces of the copper and antimony, have been deposited on the cathodes. The arsenic deposit contains copper, antimony, etc., from which it can be easily separated and recovered by burning in a small furnace with suitable condensing flues. The residue is composed principally of copper oxide which is worked up in a blast furnace in the usual way. The purified liquor is allowed to settle and then returned to the copper refining tank. (991,685, May 9, 1911.)

Petroleum.

Separation of Oil and Water.—Four patents recently issued to Mr. Frederick G. Cottrell and associates, of Berkeley, Cal., are interesting for their application of the electric current to the separation of water from oil.

Crude petroleum as it comes from the wells is frequently accompanied by more or less water mixed with the oil in drops of macroscopic and microscopic size. The larger drops might settle in a natural manner, but the small ones will not so separate from the oil. Centrifugal action is wholly satisfactory and distillation is expensive. The inventors have conceived the idea of applying a high-potential alternating current to the mixture, causing the water particles to coalesce into large enough drops to settle out of the oil.

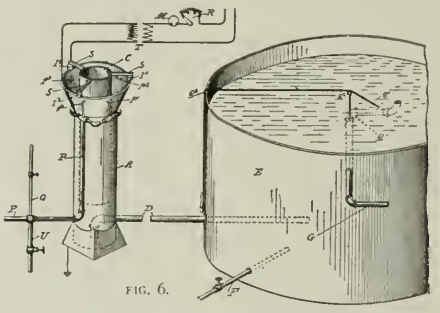

FIG. 6.

Fig. 6 gives a complete view of a diagrammatic apparatus for carrying out the invention. The vessel A contains the oil undergoing treatment and is itself one of the electrodes, being connected with one of the high-potential terminals of the transformer T. The other terminal is connected to the electrode C which is represented as an inner concentric shell in the vessel A, although its exact form is a subject of another patent. The two electrodes are insulated as shown in the diagram at I^1, I^2, I^3.

The oil and water mixture to be treated is received through the pipe P, and may be heated by steam delivered from Q, and diluted if necessary by dry oil through U. The mixture enters the top of the vessel A through jets p^1, p^2, p^3, p^4, and flows down between the electrodes, and finally out through a pipe D, which is of sufficient diameter to insure a quiet flow, free from a churning effect which would again emulsify the separating oil and water. On entering the tank E, the water, which has been caused to gather into drops of large enough size to settle naturally, drops to the bottom. Dry oil can then be drawn off through G and water and sludge is drawn off through F.

Care must be taken to have the active portion of the electrodes deep in the mixture to avoid the possibility of the separated water forming surface layers and causing short-circuiting. The heating of the oil prior to its treatment improves its physical condition and in the present instance this can best be done by steam, since there is no objection to the introduction of water in the oil. Many other details of the operation and construction of the parts will be apparent on a study of the original patents. (987,114-5-6-7, March 21, 1911.)

Automatic Gas Analysis for Boiler House and Chemical Works Control.

The following is a general description of the automatic gas analyzers made by the Precision Instrument Company, of Detroit, Mich., under license from Alexander Wright & Company, Ltd., engineers, of Westminster, England, and their two English directors, Messrs. John F. Simmance, M. I. M. E., and Jacques Abady, A. S. M. E.

These recording analyzers may be divided into two classes: Those for non-corrosive and those for corrosive gases. In the first class is the precision Simmance-Abady CO_2 recorder, so-called because it periodically analyzes samples of flue gas for the per cent of carbon dioxide which they contain and records

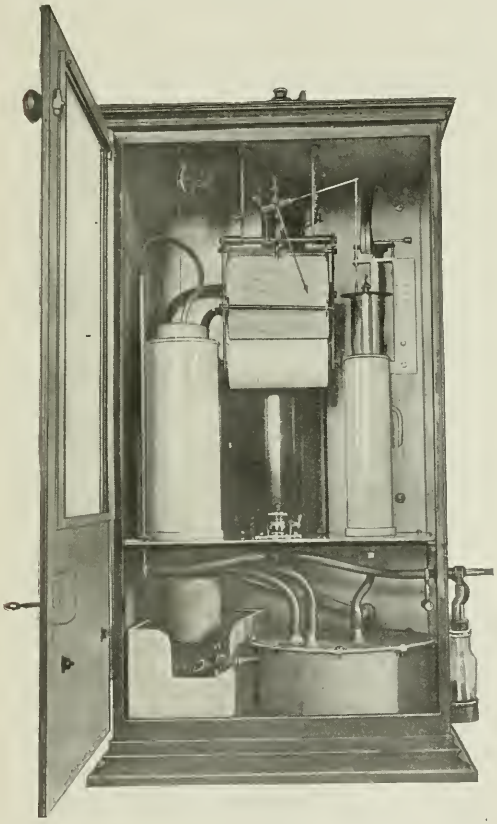

FIG. 1.—HIGH PERCENTAGE RECORDER FOR CHEMICAL WORKS.

this percentage on a chart, showing graphically and at all times of the day or night the completeness or incompleteness of combustion. The boiler house CO_2 recorder is perhaps the most thoroughly discussed of all automatic analyzers, for the reason that it is an established fact that a high percentage of CO_2 in the flue gas is one of the principal factors in economical combustion.

As the theoretical maximum of CO_2 in burned fuel gases is about 20 per cent, the charts for the five standard types of boiler-house recorders are graduated from zero to 20 per cent. Charts may be disc, drum or tape charts. These standard types may be used on furnaces fired with natural gas; they are also used for recording the percentage of CO_2 in producer gas, CWG, purified gas and gases in retort settings. Where the gas is under pressure a governor is fitted at the inlet, and a burner is also supplied for combustible gases.

Recorders are also built for ranges other than 20 per cent, as, for instance, 0 to 35 per cent, and 0 to 50 per cent for lime kiln control in beet sugar factories, etc.; also such high ranges as 0 to 100 per cent, 65 to 100 per cent and 80 to 100 per cent for special chemical machinery. The latter need a strong solution and require about ten minutes for a complete absorption of the CO_2 by the KOH, as compared with about three or four minutes with a weaker solution in the low per cent recorders. Furthermore, it is occasionally necessary to draw the gas sample against a high draught, and one recorder is now in operation in a large manufacturing plant where it is drawn against a maximum of 18½ in. water vacuum. A high percentage recorder for chemical works is shown in Fig. 1.

In the second class are the recording analyzers for corrosive gases, such as SO_2, HCl and chlorine gas, and which are used in paper mills, acid works, etc. They are built to record various per cents as are the CO_2 recorders, and operate on the same

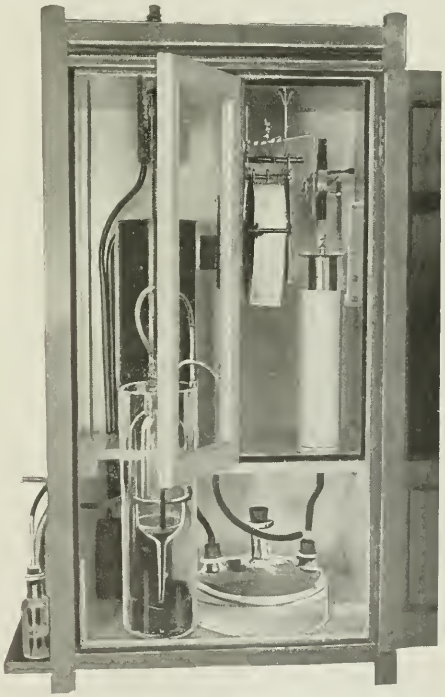

FIG. 2.—RECORDER FOR CORROSIVE GASES, SUCH AS SO_2, HCL, CHLORINE, ETC.

general principle. The main difference in the construction is that the parts which handle the gases, including extractor bell and tank and solution vessel, are made, not of metal, but of glass, to withstand the corrosive action of the gas. Also on account of the fumes from the gas the indicating and recording mechanism is contained in an air-tight compartment. A view of the recorder for corrosive gases is shown in Fig. 2.

Generally speaking, the recorder may be called an automatic chemist. Samples of gas are drawn into a waterjacketed burette called the extractor bell *d*, Fig. 3, where the sample is cut off and the gas reduced to atmospheric pressure. The recorder is thus independent of varying draft conditions. The bell is water sealed and open at the bottom, and gas is drawn

in by means of the vacuum created in the bell when the latter is raised. After the complete sample is drawn into the bell, cock *h* automatically closes and the bell starts to sink; pressure is built up in the bell, which forces the gas through the caustic solution in tank *m*, where the carbon dioxide is absorbed. The balance of the gas passes into the recorder bell *j*, which rises to a point on the scale indicating the volume of gas that has been absorbed. A pen then marks on the chart the same per cent of absorption as is indicated on the scale, after which the bell vents through cock *h*.

The motive power which operates the extractor bell is a float *b* rising and falling in the siphon tank *a*. A constant stream of water flows through cock *x* at the top of the recorder and into tank *a*. When float *b* rises to the top of the tank, valve *e* is tripped, allowing to come into the tank a flush of water which immediately siphons out of the tank through *g*, allowing float to sink and raising extractor bell.

This same stream of water which is the motive power actuates an injector below the inlet cock, and this injector brings

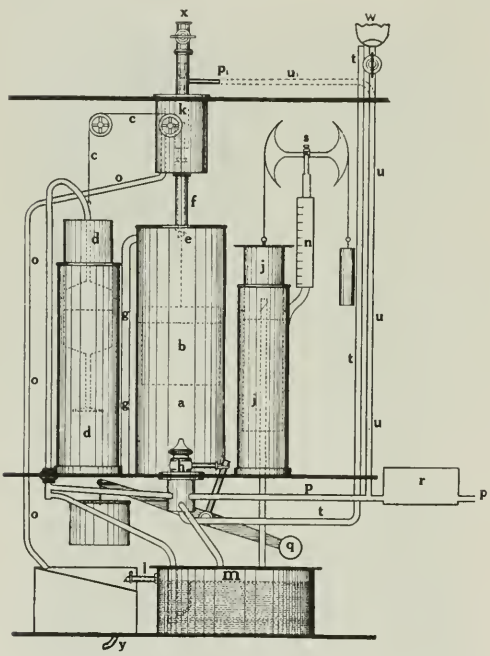

FIG. 3.—DIAGRAM OF CO_2 RECORDER.

along a constant stream of gas through auxiliary connection p_1 so that there is no dead gas in the sampling pipe.

In boiler-house service there is practically no "lag," the operations of the recorder being about three minutes behind the actual operations in the furnace. The cycle of operations is completed in about three minutes in the boiler-house recorder, whereas for gas containing higher percentages of CO_2 the cycle may take as much as ten minutes, owing to the longer time taken for absorption.

For recorders handling non-corrosive gases, such as flue gas, all the working parts are made of metal and are enclosed in a metallic case, so that it is suitable for use in exposed situations.

To the gas inlet nozzle are attached two tell-tale bottles, one of which shows that the stream of gas is flowing constantly, and the other indicates when the sampling pipe is plugged with soot or other material. When used on a battery of boilers a pair of oil cups is located at each boiler, these oil cups taking the place of cocks or valves; to take records from any particular boiler in the battery a dust filter is shifted along by hand from one boiler to the next.

The recorders have been frequently tested by the best authorities, including chemists of some of the largest plants, and invariably check up to within one-half of 1 per cent or less of the most exhaustive hand analyses, and this under varying conditions of draft.

A New Electrolytic Cell for Hypochlorite Solutions.

By R. H. Pearsall.

Chlorine is to-day used in the large majority of bleaching processes and is also coming more and more into use for sterilizing water. Its value for bleaching is well known, and it may be pointed out here that it is so powerful a sterilizing agent that as small a quantity as one part in one million is enough to entirely destroy the bacilli of typhoid and diphtheria in one minute, even in bad water.

Chlorine is generally used in the form of chloride of lime, or bleaching powder, as this is cheap and portable. But this has the disadvantage that it leaves a residue of lime which is a cause of decay in fibrous materials which have been bleached. The powder is highly poisonous and, moreover, does not retain its valuable properties long after exposure to the air with the consequence that where smaller quantities are needed, as for water sterilization, it is difficult to maintain stocks of powder in good condition and at the highest efficiency.

This involves larger doses for sterilization purposes in order to be certain of results and irregularities in the quality of the powder result in the water occasionally tasting or smelling of chlorine.

An improved method which entirely avoids this is to use a solution of hypochlorite which as made to-day will retain practically its full strength for long periods, and is much more powerful in its action than bleaching powder. It has the further advantage that it forms no deposit in the pipes, valves, etc., as does the bleaching powder solution, so that much greater regularity and reliability of action is secured.

As it is most economically made in weak solutions containing from ½ per cent to 2 per cent of available chlorine, it is preferable to make the solution on the spot as it is required, a process which has become very simple and economical by virtue of recent improvements in electrolysis which are described in this article.

We may describe the principles of the formation of hypochlorites by electrolytic means. If a current is sent through a solution of sodium chloride in water the chloride is split up into the component parts sodium and chlorine. The chlorine is liberated at the anode and the sodium at the cathode, forming by reaction with the water sodium hydroxide and hydrogen.

In the manufacture of chloride of lime and caustic soda the products at the electrodes are kept separate, the chlorine being drawn off to lime beds and the caustic soda being withdrawn at the other electrode. In the manufacture of hypochlorite solutions, on the other hand, the liberated chlorine and sodium hydroxide have to recombine to form the hypochlorite NaOCl.

A widely accepted explanation of this reaction (due to Mr. Bertram Blount) is

$$2NaOH + 2Cl = NaOCl + NaCl + H_2O.$$

A different view is, however, held by the inventor of the new form of cell for this purpose, Mr. W. Pollard Digby, of London, England, namely, that for low strengths the reaction is

$$2NaOH + 2Cl = 2NaOCl + H_2.$$

His reasons for favoring this most simple hypothesis are two-fold. Firstly, the large number of authenticated cases in

which the electrochemical efficiency of production has not been 50 per cent or under as would agree with the first hypothesis but upwards of 80 per cent or 90 per cent, and secondly, when the reaction takes place under special control there is a gaseous evolution on the mixture of the anodic and cathodic products.

In early forms of cell two electrodes were immersed in the electrolyte and the current switched on. Trouble was met from the cathodic hydrogen which with heavy current densities rose in a constant stream from the electrode and caused discomfort to the workers. In this class of apparatus the reunion of the anodic and cathodic products is a haphazard affair depending wholly upon the circulation of the main body of the electrolyte in which the recombination takes place.

It is also found that the electrochemical efficiency of the cell depends upon the richness of the solution in hypochlorite. That is to say that as the proportion of hypochlorite rises the efficiency falls. The consequence is that in order to avoid undue waste of electric energy it has been necessary to draw off the electrolyte when it has reached only a low hypochlorite content and has still a large salt content. In other words, it has been necessary to waste salt in order to save current, and this in large quantities.

For instance, at Maidenhead, England, when the hypochlorite solution produced contained about 3.5 grams of available chlorine per liter, the amount of sodium chloride present was about 6.5 per cent. That is to say, each gram of available chlorine produced carried with it over 18 grams of salt. In other words, only one-twelfth of the chlorine initially present in the salt became available in the hypochlorite form.

This difficulty has been got over in the new cell referred to above, known as the Digby electrolyzer.

In this cell the manner in which the anode and cathode products recombine is controlled so that the body of the electrolyte is not altered in composition and the electrochemical efficiency is maintained while drawing off a hypochlorite solution with a very small saline content.

The principle of the cell may be explained by considering a cell with two carbon electrodes separated by two porous diaphragms—in this case of asbestos. The diaphragms divide the cell into three portions, the two end ones being connected together by a glass tube and separated from the middle space.

The electrodes are placed in the end portions which are designed to fit them with but small clearance, while the main body of electrolyte is in the middle portion. When the cell is working caustic soda is formed at the cathode end and the consequently denser solution passes by gravity through the glass tube to the anode compartment where chlorine is being liberated. Thus the caustic soda is brought directly to be acted upon by nascent chlorine.

The main body of electrolyte in the middle portion of the cell is a saturated salt solution for better conductivity. The solution which replenishes the cathode compartment may be pure water or a dilute alkali solution, as sodium carbonate.

The ions migrate under the influence of the current, the chlorine to the anode and the sodium to the cathode and the caustic solution there formed passes round to the chlorine without taking any appreciable amount of salt with it to be wasted, while at the same time the body of the electrolyte remains a salt solution pure and simple, and the electrochemical efficiency is maintained.

In practice these cells are made with three or five plates, arranged in series, and channels connect the different elements of the whole cell so that the anode reaction takes place on the side of the middle plates and the cathode reaction on the other.

The most economical current density to employ depends on the relative cost of electric energy and brine in the district in question, and the cells are worked at this density, while the strength of the resulting solution is controlled entirely by regulating the rate of inflow of water to the cathode end. The main electrolyte is kept a saturated solution with excess of salt, and more salt is added as this excess is absorbed.

In previous cells it has been found necessary to cool the electrolyte artificially in order to maintain stability in the reactions, and Mr. Digby, in his patent, refers to arrangements for cooling the caustic solution as it passes on its way to the anode. But in practice it has been found unnecessary to use artificial cooling in this type of cell, the anode and cathode portions being directly connected by short ducts.

The Digby electrolyzer is remarkably simple and inexpensive in its construction. The ends are formed of slate slabs and the partitions of asbestos sheet. The sheets are separated by slate distance pieces and the whole bolted together while the carbon electrodes are fitted into their proper elements.

In some cases the slate has been replaced by wood suitably treated with tar to further reducing the cost of the cell. There are no moving parts and the whole action is perfectly simple, with practically no possibility of getting out of order. Should dirty brine be used for economy the cell may be periodically scoured out with a jet of water without disturbing any mechanical connection in any way.

Cells with two elements in series are made to work on a pressure of 10 volts and to give an output of half a pound of available chlorine per 24 hours when taking 7 amperes. Such a cell complete costs about $200.

A Boiler Plant Waste Meter

It has been thoroughly demonstrated that waste of heat in boiler plants may be greatly reduced by more careful attention to what is going on in the furnace. As with the improvements which have been obtained in the engine-room by the use of the indicator, the thermometer, the steam gage, and in the use of electrical measuring instruments, so in the boiler plant the measurement of coal and water on scales or by meters, and the measurement of waste by a CO_2 recorder result in considerably decreasing the cost of power production.

On the average it may be stated that only 60 per cent of the heat in the coal enters the boiler; 40 per cent is wasted. Of this 40 per cent the total waste is distributed about as follows: Loss in radiation, 5 per cent; loss in soot and smoke, 1 per cent; loss represented by actual loss of coal through the grates, 2 per cent; loss due to combustion of the carbon to carbon monoxide instead of dioxide, 2 per cent; heat carried away by the chimney gases due to their temperature, 30 per cent.

The amount of coal waste due to loss of heat up the stack is quite fully realized, as is the fact that considerable reduction may be obtained in the extent of the chimney loss by measurement of carbon dioxide. The relation between per cent carbon dioxide and heat lost may be shown diagramatically by the chart of Fig. 1. The areas in each case are proportional to the amount of heat wasted, and as these areas are reduced by decreasing the excess air, the per cent of CO_2 is increased.

The CO_2 recorder was thus devised to automatically inform the engineer of the amount of waste occurring. The CO_2 measurement gave an indication of how much air was being used per pound of coal, the most important item in determining the amount of loss in the waste gases going up the chimney. The other important item, the temperature, is taken by pyrometers, mercury thermometers or other means.

Caustic potash absorbs carbon dioxide. This is the fundamental principle of all instruments for making a measurement of CO_2. In the older types of automatic recording instruments bells or jars for measuring the gases before and after the CO_2 was absorbed were used. The difference in volume of the gas before and after the CO_2 was abstracted gave a measurement of carbon dioxide in the gases. Valuable as they are, such instruments have, however, certain limitations.

If, instead of measuring the per cent carbon dioxide by measuring the actual volume of a given amount of gas before and after the carbon dioxide has been abstracted from it, the *pressure* of the gas is measured, then the change in pressure of the gas due to the reduction in its volume when the CO_2 is

absorbed will give a ready and reliable method of measurement.

The diagram of Fig. 2 shows how this principle is employed in the Uehling waste meter for measuring both percentage of carbon dioxide and temperature. Gas is drawn through the apparatus continuously by a small steam aspirator. Between the two apertures—that is, in the chamber marked *C*—the carbon dioxide is absorbed (in the case of the carbon-dioxide instrument) and thus the volume of the gas between the apertures is reduced by an amount depending upon the amount of CO_2 present. Any reduction in the volume of the gas between the two apertures increases the vacuum. These changes are proportional to the amount of CO_2 absorbed and thus the suction or partial vacuum forms a basis for indicating and recording variations in carbon dioxide in flue gases.

The indicating instruments are simply columns properly calibrated and are supplied at the machine proper and also as shown in Fig. 3 for the front of the boiler. The indicators at the boiler front are found to be most useful in that reference can be made continuously to them, whereas the recording charts are more valuable as permanent records and records from which to obtain average results with different kinds of coal, different grate area, different drafts, etc. The recording instruments may be placed anywhere and any number of them may be used as all they do is to record the partial vacuum or suction.

As the same principle and similar apparatus is used to measure temperature it is evident that a very effective combined CO_2 machine and temperature machine or waste meter is built on this principle. In measuring temperature, instead of the change in vacuum being produced by absorbing part of the gas between the apertures, change in vacuum is secured by reason of the difference in temperature between the two apertures. One aperture is in a nickel tube placed in the flue and the other is maintained at a constant temperature by exhaust steam.

The appearance of a combined instrument of this type may be seen in Fig. 4, a photograph of a Uehling waste meter installed in the plant of Robert Gair Company, Brooklyn, N. Y. Here the two indicating columns for per cent carbon dioxide and for temperature may be seen at the front of the instrument proper, while on the board are the recording gages for temperature and carbon dioxide. These are at the left and right. In the boiler-room proper is placed the CO_2 indicator.

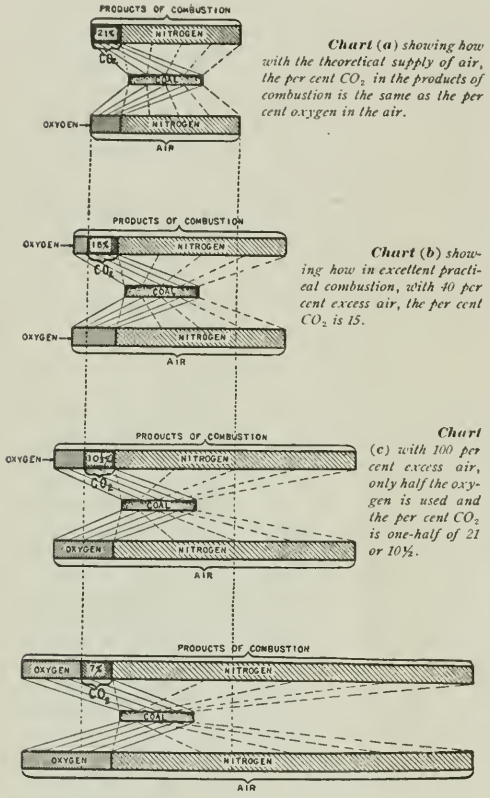

***Chart (a)** showing how with the theoretical supply of air, the per cent CO_2 in the products of combustion is the same as the per cent oxygen in the air.*

***Chart (b)** showing how in excellent practical combustion, with 40 per cent excess air, the per cent CO_2 is 15.*

***Chart (c)** with 100 per cent excess air, only half the oxygen is used and the per cent CO_2 is one-half of 21 or 10½.*

***Chart (d)** with 200 per cent excess air, only one-third the oxygen supplied is needed and the per cent of CO_2 is one-third of 21 or 7 per cent.*

Carbon Tetrachloride as Fire-Extinguisher.

The cheap electrolytic preparation of chlorine from brine has greatly reduced the cost of making carbon tetrachloride, a highly-valued solvent for fats and oils, so that it can even be used as a fire-extinguisher, as noticed in London *Engineering* of April 28.

Various compounds of carbon with chlorine and with the other halogens, fluorine, bromine, and iodine are known, and they are regarded as derived from methane (the fire-damp of the miner), CH_4, in which the hydrogen atoms are replaced by halogens. When one or three atoms of hydrogen are replaced, the resulting compounds are anæsthetics producing sleep (especially chloroform, $CHCl_3$) or antiseptics (iodoform CHI_3). Several of the other compounds are important in the dye industry; but, with the exception of the fluoride CF_4, none of them can be prepared by the direct union of the elements.

The tetrachloride is a colorless liquid, characterized by a pleasant smell, recalling that of Rhine wine; it freezes at — 25° Cent. and boils at 78° Cent., but the vapors are practically non-inflammable and non-explosive and stifle combustion, and the carbon tetrachloride thus occupies an exceptional position.

Various processes for the preparation of the tetrachloride have been patented in recent years, especially after Edward R. Taylor succeeded in making as much carbon bisulphide from coal and sulphur in his simple electric furnace as the United States requires. According to J. A. Robinson, who drew attention to carbon tetrachloride in the *Quarterly* of the National (American) Fire Association in January last, the tetrachloride is made by passing chlorine gas over heated carbon bisulphide. The condensed products contain carbon tetrachloride and sulphur dichloride; the latter is decomposed by the injection of caustic soda, and the tetrachloride is purified by distillation. It is put on the market in 100-gallon drums; the density of the

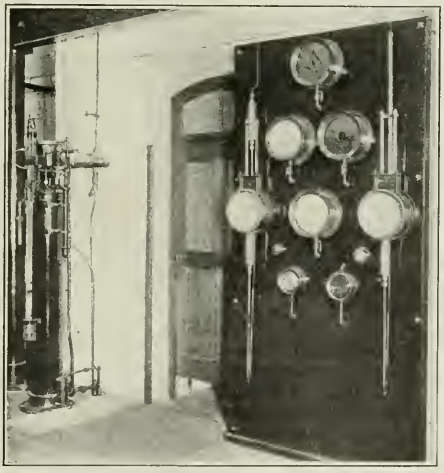

FIG. 4.—INSTALLATION OF WASTE METER IN PLANT OF ROBERT GAIR COMPANY IN BROOKLYN.

compound is 1.604, and the pound costs about 10 cents (5d.).

Fire-extinguishers filled with tetrachloride have been used by the Interborough Rapid Transit Company of New York on their cars. It has been pointed out that carbon tetrachloride, being a non-inflammable and non-corrosive substance, would be preferable to water and sand for extinguishing undesired arcs in electric installations. While no electrical engineer would probably resort to water in such a case, yet the tetrachloride may be useful.

In the oil and fat industry mixtures of carbon tetrachloride and naphtha are used, and it is interesting to note that, according to E. A. Barrier, the addition of tetrachloride would make the naphtha safe against fire and explosion. Considerable percentages of the tetrachloride would, however, be wanted. A naphtha distilling at about 55° Cent. should contain 30 per cent of carbon tetrachloride. A motor gasoline (70° Cent.) should be mixed with 50 per cent of tetrachloride to be free from explosion hazards, and with 60 per cent to be free from fire hazard; but in all these cases an additional 5 per cent of tetrachloride would technically be considered advisable.

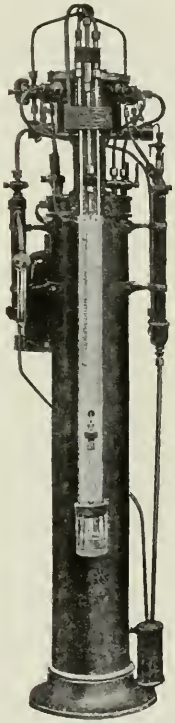

FIG. 5.—UEHLING WASTE METER.

The continued contact between hot carbon tetrachloride and water or water vapor should not cause direct dangers. The resulting products would be carbon dioxide and hydrochloric acid, not pleasant, yet not particularly dangerous gases. But it would be rash to predict that no other reactions might take place during a large fire; carbon oxychloride (sometimes called phosgene, because it is formed when carbon monoxide and chlorine are exposed to sunlight) might also be liberated, *e.g.*, in highly unpleasant vapors, which water would decompose into carbon dioxide and hydrochloric acid.

Tests and Analyses.

The Electrical Testing Laboratories, Eightieth Street and East End Avenue, New York City, which in the past confined their activities chiefly to testing work in the electrical and illuminating engineering fields, have recently extended their equipment so as to include coal testing, paper testing, tests of structural materials and thermometer tests.

Both chemical and calorimetric analyses of coal are made. An Atwater calorimeter and an Emerson calorimeter (both bomb types) are available. All thermometers used have been calibrated by the Bureau of Standards at Washington, as also has the standard combustible which is used to standardize the calorimeters.

For paper testing special apparatus has been installed, to determine the material from which the paper is made, various physical properties such as bursting strength, tensile strength, folding strength, etc., and certain facts of a chemical nature such as kind of size and filter, amount of ash, presence of acid, chlorine, etc.

For testing structural materials a 200,000-lb. testing machine has been installed for tension, compression and transverse testing of steel, iron, brick, stone, concrete, timber, etc. A torsion testing machine of 230,000 in.-lb. capacity has also been provided. The machine is capable of taking specimens from 6 in. to 20 ft. in length, and up to 3½ in. in diameter. This equipment together with the smaller machines already installed enables the Electrical Testing Laboratories to make any of the usual tests on materials used in industrial and structural enterprises, such as wire, cable, rope, chain, belting, iron, steel, alloys of various kinds, building materials, etc. A complete equipment for making and testing cement briquettes according to standard specifications has also been installed.

For the thermometer department special apparatus has been

built for the testing of thermometers of all kinds used for industrial purposes up to 500° C. and also for testing clinical thermometers. All apparatus has been built similar to the Government standard apparatus at Washington and the methods used are also the same. The standards employed by the Electrical Testing Laboratories are those of the Bureau of Standards in Washington, D. C.

NOTES

The Abbe Engineering Company, of 220 Broadway, New York City, has removed its office from the twelfth to the eleventh floor of this building, since their rapidly growing business in tube mills, pebble mills and ball mills required an enlargement of their quarters.

The American Grondal Company is the new name of the American Gröndal-Kjellin Company. This change of name has been made in connection with the broadening out of the scope of their work in concentrating and briquetting low-grade iron ores. The company will conduct complete commercial tests on any ore submitted in its testing plant, and, from the results of such tests, make a proposition for the proper method of treating the ore, design the plant, and if so desired, supervise the installation.

Vanadium.—Ever since the formation of the American Vanadium Company the entire product of vanadium alloys produced by this company has been marketed by the Vanadium Sales Company of America. The offices of both companies have been in the Frick Building, Pittsburgh, Pa., and their products, especially ferrovanadium, have been sold in every manufacturing country in the world. Recently the Universal Vanadium Company has been formed for the purpose of acting as selling agents for the American Vanadium Company in a more comprehensive and effectual manner, and it will act in a selling capacity in conjunction with the Vanadium Sales Company of America, both companies taking charge of the entire product of the American Vanadium Company.

The National Carbon Company, of Cleveland, Ohio, has just issued a publication entitled "Practical Operation of Arc Lamps." It is full of useful instructive information for the use of lamp owners and operators. A carefully prepared alphabetical index deserves special mention.

Earthenware Apparatus.—Hard, white vitreous earthenware and porous earthenware are finding increased use in chemical and electrochemical work. Messrs. John Maddock & Sons, of Trenton, N. J., who make a specialty of the manufacture of such earthenware apparatus (which should not be confounded with chemical stoneware), make these goods from either white porous clay or a white vitreous body, either glazed or unglazed, with a transparent glaze. They are making large quantities of white vitreous battery jars and also large quantities of round porous cups, there being practically no limit to their size. They also make quantities of special porous oblong boxes.

Spray Nozzles.—The Buffalo Forge Company, of Buffalo, N. Y., have sent us their pamphlet on Buffalo spray nozzles and strainers. As is well known, the spray nozzle gives an exceedingly fine spray with a minimum water pressure. Operating at pressures as low as 15 lb. the centrifugal action of the nozzle produces an atomizing effect which is further increased with the increase in pressure. The greatest atomizing effect is obtained at a pressure of about 40 lb. The successful results obtained with these nozzles are due to the fact that the water enters the circular chamber tangentially, receiving a whirling motion, and is not obstructed in any way until its exit through the opening in the disk. As it approaches this opening an increase of velocity is caused by the change in the shape of the passage until it bursts into an atomized spray, which does not depend for its fineness on the small size of the orifice. For this reason large water passages are used throughout, with consequent freedom from clogging. The nozzle is made in two parts. The cap can be replaced if the action of the liquid is such as to corrode the metal and destroy the effectiveness of the spray. While regularly furnished in brass, the Buffalo Forge Company makes these nozzles in large or small quantities of any material desired, like lead or brass. It is particularly interesting to note that monel metal nozzles have replaced others in producer-gas power plants, blast furnaces and chemical plants.

The Ashland Fire Brick Company, of Ashland, Ky., is sending out a series of very clever bulletins which impart interesting information in an easy conversational style. From one of them we learn that the flint clay from which their brick is made is permitted to weather in the yards for six months before it is used. Clay when it comes from the mine is very hard and brittle, but weathering grinds it to fine particles and many of the impurities are washed away. The result is a better and smoother brick.

Casting Alloys is the title of a pamphlet recently issued by the Lumen Bearing Company, of Buffalo, N. Y. The different bronzes made by this company are classified according to their uses and concisely described as to their properties. For chemical and metallurgical purposes their alloy No. 0 is particularly interesting. It is a copper-tin acid-resisting bronze, for pump bodies, valves and other parts coming in contact with fluids containing alkaline or acids. Its tensile strength is 50,000 lb.; specific gravity, 9.05; weight per cubic inch, 0.3258 lb.; the shrinkage in sand molds, ⅛ in. per foot.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in February, 1911, was 69. The total tonnage milled during that period was 1,749,834 tons of ore: 9627 stamps were in operation with an average duty of 7.5 tons per 24 hours. Tube mills in commission numbered 201. The yield for the month was 610,828 fine ounces gold. The number of tube mills in operation shows an increase of 30 per cent as compared with February, 1910.

Chas. C. Moore & Company, engineers, San Francisco, Cal., and the Pacific Coast managers of the Babcock & Wilcox Company, have recently prepared for distribution among the engineering fraternity a notebook specially designed for the convenience of those who have to keep many individual notes and memoranda. One of the books and extra inserts (the memoranda being detachable) can be obtained by addressing the company.

The Utah Society of Engineers held its annual dinner at the Commercial Club, Salt Lake City, on April 20, 1911. Addresses were made by John Dern, president of the American Mining Congress, and various other members of the society. The officers for the ensuing year were elected as follows: President, M. D. Grosh; first vice-president, C. F. Moore; second vice-president, E. H. Beckstrand; secretary, R. B. Ketchum; treasurer, A. S. Peters.

The General Engineering Company, Salt Lake City, Utah, has recently moved into new quarters, where it has one of the most complete ore-testing plants in the West. Tests by concentration, cyanidation, amalgamation, flotation and magnetic concentration can be made on lots of ore ranging in quantity from 50 lb. to a carload. The company also has put in a complete cement testing laboratory.

The Ohio Copper Company, Lark, Utah, is putting in 60 Deister No. 3 concentrating tables to handle the slime. This change is expected to put the Ohio mill in a better position to save fine mineral and will also materially increase the capacity.

In conveyor belt installations some of the features which require attention are the thickness, width, material, and cover of the belt, the spacing of the carriers, the speed of the belt, and the proper feeding of the materials to be conveyed. These features vary with almost every installation, and should be determined specially for each plant.

Personal

Mr. J. M. Callow, of the General Engineering Company, Salt Lake City, has been appointed consulting metallurgist for the Inspiration Copper Company.

Mr. Francis E. Drake, who for several years has been the managing director of the Société Anonyme Westinghouse of Paris and Havre and principal officer in several of the Continental Westinghouse interests, has resigned from the active management of these properties to occupy himself with certain private interests, and, after a period of rest and recuperation, will establish his office at No. 16, rue Halevy, Paris. Mr. Drake is well known, not only in electrical, but in metallurgical circles, since before he went to Europe he was the president of the Lanyon Zinc Company and it was under his presidency and direction that the first experiments in electric zinc smelting in America were carried out by his company. Mr. Drake is interested in several electric enterprises in Europe and will carry out, as engineer and contractor, certain tram and railway lines now in process of development. The efforts of Mr. Drake in behalf of electric traction, especially in the direction of single-phase development and for other aid rendered to French industries, recently received the recognition of the French government in the shape of promotion to the rank of Officer in the Legion of Honor. Mr. Drake is a member of the Engineers' Club and a life member of the American Chamber of Commerce in Paris; he is also a member of the American Electrochemical Society.

Dr. W. C. Ebaugh, professor of chemistry in the University of Utah, has been granted a year's leave of absence for 1911-12.

Mr. J. R. Finlay, formerly with the Goldfield Consolidated Mining Company, Goldfield, Nev., has opened offices at 52 William Street, New York, as a consulting engineer.

Mr. A. I. Goodell is acting as Northwestern representative for the International Smelting & Refining Company.

Mr. Philo D. Grommon has been appointed superintendent of the mines and mill of the Ophir Gold Mines Company, Ophir, Col.

Mr. H. R. Holbrook, formerly employed by the Balaklala Copper Company, at Coram, Cal., has accepted a position as chief chemist for the Mexican-American Smelting & Refining Company, at Guaymas, Sonora, Mexico.

Mr. Theodore P. Holt has been appointed assistant professor of mining and milling in the University of Utah, where he has been an instructor since his graduation.

Mr. J. E. McAllister, until recently general manager of the British Columbia Copper Company, has resigned and will enter consulting practice in New York.

Mr. A. H. Prior, who has been cyanide superintendent of the Rio Plata Mining Company, has been appointed general superintendent, vice H. W. Edmondson, resigned.

The wedding is announced, on June 1, of Mr. **Hugh Rodman,** of the Rodman Chemical Company, of Pittsburgh, with Miss **Mary Bynum Iarnagin.**

Mr. Benjamin B. Thayer, president of the Anaconda Copper Mining Company, recently made his annual trip of inspection to the mines and reduction works of the company in Montana.

OBITUARY

James B. Daniels, general manager of the milling department of the Portland Gold Mining Company, Colorado Springs, Col., died on April 3, 1911, following an operation for appendicitis performed four days previously. Mr. Daniels had been identified with the metallurgical industry in Colorado since 1879, when he came to Leadville and entered the old Harrison Reduction works, which was one of the early smelters in that city. From that time until 1903 he was connected with smelters at Denver and Pueblo. Later he left the lead-smelting industry and entered the employ of the Portland company, which is engaged in the treatment of Cripple Creek ores by the chlorination and cyanide processes. Mr. Daniels died at the age of fifty-one, and is survived by a widow. He was highly esteemed by the officials of his company, who regarded him as a large factor in the success of their operations. He was greatly interested in the new process which the company has in operation at Victor, and was instrumental in bringing it to a successful conclusion.

Samuel F. Emmons, eminent geologist and pioneer in the economic branch of that science, died in Washington, D. C., on March 28, 1911. His last illness was of but five days' duration, but for a year or two previous he had been in poor health. Mr. Emmons was probably the foremost geologist in his country, and was widely known throughout the West, where his most important work was done. He was one of the first to apply the science of geology to mining, and his work in that line has led to the most remarkable mining developments which have been known in the United States. Especially was his work on the mining and geology of Leadville a masterly production and his greatest work. This was undertaken for the United States Geological Survey, in which organization Mr. Emmons was a leader for many years. His first connection with government work was in 1867 when he accompanied the United States Geological Exploration of the fortieth parallel. He made many contributions to the published reports of this expedition, and has been a noted contributor to the various publications of the Survey. As a member of many scientific societies he was always active in their interests and received many honors at their hands.

Mrs. Ellen H. Richards, wife of Prof. Robert H. Richards, of the Massachusetts Institute of Technology, died at Boston March 30, 1911, after a week's illness. Mrs. Richards was instructor in sanitary chemistry at the institute, from which also she was a graduate in 1873. In 1875 she married Professor Richards, who is at the head of the department of mining and metallurgical engineering, and together they continued on the instruction staff of the institute until the time of her death. It is given to few women to hold as prominent a position in the technical world, and live a life of such useful service as fell to the lot of Mrs. Richards. Especially in the application of science and scientific methods to social and domestic economy she was very active and helpful. In her later years she acquired an international reputation, and was honored at home by receiving the doctor's degree from Smith College. She was a member of many scientific societies and the author of important works on chemistry.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

351,576, Oct. 26, 1886, Henry R. Cassel, of London, County of Middlesex, England, assignor to the Cassel Gold Extracting Company (Ltd.), of Glasgow, Scotland.

Gold, etc. Ores or alloys are powdered and charged into an anode compartment separated from the cathode compartment by a diaphragm of asbestos. Metal is dissolved in the anode compartment and precipitated at the cathode. The apparatus illustrated comprises a stationary tank containing a revolving drum, constituting the anode compartment. The circumferential wall of this drum is of asbestos cloth, having a removable portion to admit the charge. A series of carbon anode rods are arranged in a circle within it, extending hori-

zontally through the end walls of the drum. The drum is surrounded by a tubular sheet-metal cathode, in two halves. Illustrates a specific connection for carrying the current through the revolving drum shaft to the anode. The anode compartment contains the chloride solution, and the drum is preferably submerged in the electrolyte in the tank.

257,059, Feb. 15, 1887, Desmond Gerald Fitzgerald, of Akerman Road, Loughborough Road, Brixton, County of Surrey, England.

Gold. Employs anodes of lead peroxide for electrolytically generating chlorine. The anode may be molded of a plastic mixture of lead oxide and ammonium sulphate or chloride, e.g., being plastered onto the inner surface of the cell as a lining. Prefers, however, to build up the anode from slabs, plates, tiles, fragments or granules of a molded mixture of litharge and ammonium sulphate, or hydropotassic or hydrosodic sulphate, peroxidized by a hypochlorite solution and set in the plastic lead peroxide mixture. The terminal is a plate of platinum embedded in the upper part of the anode. The cathode may be a plate of copper. Illustrates a cell consisting of a shallow tank of slate or brick, with suitable lining, the anode being formed as a tray lying in one side of the tank, while the cathode is a copper tray coated with insulation at the other side. May use plates of lead peroxide as anodes, alternating with suitable cathodes, to produce hypochlorites or chlorates.

359,156, March 8, 1887, Jean Antoine Mathieu, of Detroit, Mich.

Treats lead ores, e.g., carbonates containing gold and silver, by crushing and grinding, submitting to the steam from boiling acetic acid from three to ten hours, and boiling in acetic acid from three to five hours, while stirring, to dissolve out the lead sulphate and the silver and gold sulphates and chlorides. The bath is then allowed to cool to slightly below the boiling point, the solid matter settling out and being separately treated. The gold and silver are deposited from the solution, using lead electrodes.

360,852, April 12, 1887, Henry Renner Cassel, of New York, N. Y., assignor to the Cassel Gold Extracting Company (Ltd.), of Glasgow, Scotland.

Treats refractory pyritic gold ores with electrolytic chlorine and oxygen. The apparatus is a rotary drum of wood, or metal lined with insulation. It contains a series of carbon-rod anodes extending from end to end or may be lined with carbon-plate anodes. The drum is mounted upon a hollow perforated shaft of copper or iron, closely surrounded by a tubular diaphragm of asbestos cloth. The shaft extends at its ends into external vertical tanks, which are connected by an outside pipe. The drum is filled to a point above the shaft with a sodium chloride solution, and is charged with the pulverized ores. Current is supplied and as the drum rotates the metals are dissolved and deposited within the shaft and upon a metal screw conveyor therein in the form of a black slime, which is conveyed into one of the external tanks. The solution circulates freely between the tanks and through the drum.

360,853, April 12, 1887, H. R. Cassel, assignor to the Cassel Gold Extracting Company (Ltd.), of Glasgow, Scotland.

Apparatus for treating gold ores with electrolytic chlorine and oxygen from a sodium chloride solution. The apparatus is a rotary drum of wood or metal lined with insulation. This drum contains a circular series of carbon-rod anodes, extending horizontally through the ends of the drum, or may be lined with carbon or graphite anode plates. The ends of the drum contain large openings, receiving flaring metal casings constituting extensions of the drum shafts. The openings contain asbestos-cloth diaphragms. The ends of the shafts pass through stuffing boxes and extend into and open within hollow standards serving as tanks. The metal casings, shafts and tanks constitute the cathode compartments. One casing has a gas-vent opening, normally closed by a spring-actuated valve. This valve is automatically opened by a cam as it rises above the liquid level to permit the gases to escape. In use the drum is filled to or above the level of the shaft with a sodium chloride solution and is charged with the pulverized ores. Current being supplied, the metal dissolves, the solution passes through the diaphragms, and the metal is deposited within the trunnions and tanks as a black slime.

BOOK REVIEWS.

Practical Alloying. A compendium of alloys and processes for brass founders, metal workers and engineers. By **John F. Buchanan.** Octavo, 205 pages, 41 illus. Price, $2.50. Cleveland, Ohio: The Penton Publishing Company.

The bulk of the matter in this book appeared in *The Foundry* and other trade magazines. A long chapter on Metal Refining (in which term the author says he means to include reducing the metals from their ores) is picturesque writing, but neither very instructive nor accurate. The next, on History and Peculiarities of Alloys, is similar, only more so; it contains several absurdities. After this bad beginning the author settles down to business, commences to talk about matters with which he is familiar and redeems himself in a dozen chapters containing a large amount of valuable first-hand information. Many good photographs, on plate paper, add to the attractiveness of the work. The proposition to designate alloys is worth mentioning: Brass (copper, 60; zinc, 40) would be expressed as Cu-Zn (60-40) thus separating the numerals from the symbols and avoiding all confusion with the ordinary chemical formulas, such as Cu_2Zn; plumbers' solder would be Pb-Sn (2-1); silicon bronze, Cu-Sn-Si (90-8-2), etc.

We recommend the book as being very practical and well written except where too flowery. Everyone having anything to do with alloys—makers, users or students—will find it worth buying.

* * *

A Course in Qualitative Chemical Analysis. By **Charles Baskerville,** Ph.D., and **L. J. Curtman,** Ph.D. 8vo, no illustrations, 200 pages. Price, $1.40 net. New York: The Macmillan Company.

Qualitative Chemical Analysis, from the Standpoint of Solubilities, Ionization and Mass Action. By **J. I. D. Hinds,** Ph.D., L.L.D. 8vo, no illustrations, 265 pages. Price, $2. Easton, Pa.: The Chemical Publishing Company.

Qualitative Chemical Analysis. A laboratory guide. By **W. W. Scott,** A. M. 8vo, 31 illustrations of apparatus, 1 spectrum plate, 165 pages. Price, $1.50 net. New York: D. VanNostrand Company.

The above books, almost alike in size and scope, are yet somewhat different in treatment.

Professor Baskerville and Dr. Curtman are connected with the College of the City of New York. Their book is clear, systematic and full of bright suggestions; it extends only to the common bases and acids; numerous "notes" will be very helpful to the students. The book is well suited for a short course in a college laboratory.

Dr. Hinds is professory at the University of Nashville. His is typographically the best of the three books. The great prominence given the terminology of the ionization theory in this book is, in the reviewer's opinion, a hindrance rather than a help to the beginner trying to learn the elementary facts of qualitative analysis. If a student reported that a white powder given him for analysis contained "lead ions" and "NO_3" ions he would be reporting according to Dr. Hind's scheme, but hardly in accordance with the facts.

Mr. Scott is chief chemist of the Baldwin Locomotive Works, and his book is the most businesslike of the three. The contents cover almost the same extent of ground as the other two, but in a more practical fashion than either, and without the "ionic" form of expression of the second. It is well and forcibly written.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metatallurgical Industry and Iron and Steel Magazine.

Vol. IX. New York, July, 1911 No. 7.

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

Western Office, 1510 Court Place, Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.

Research Clubs at Mills.

An opportunity for experiment and investigation exists at most metallurgical plants of any magnitude, which requires only a little enthusiasm and direction on the part of a leader to develop results that will be well worth the effort. We do not refer to the elaborate testing departments and research laboratories maintained by the larger companies, but more especially to less formal associations in which the esprit de corps is the basis of organization and provides the needed incentive for their work.

Conditions are favorable for such an organization at almost every plant of importance. In the first place, it may be assumed that every man employed is, or should be, interested not only in the routine work but in his own progress and education as well. As most mills are operated twenty-four hours in the day, it is possible to carry on some experimental processes continuously by having men on each shift give a little time and attention thereto. And last, but not of least importance, such an organization would be of special value to men working at mills which are more or less isolated from other centers of interest. The social feature of life at these places is generally recognized by companies, and clubs usually are provided for the men. It would not detract seriously from the relaxation which the club is designed to afford, if say, one evening a week were devoted to an informal discussion of professional work and if this interchange of ideas was further extended to planning experiment and research.

Both the men and the company would profit from such a plan. To the former it would be a stimulus, creating genuine personal interest in the work and bringing out latent ability. This would enlarge their view and offer opportunity for advancement. The benefit to the company would lie in improved work, cheapened cost of operation, elimination of unnecessary steps in the process, and a spirit of co-operation among its employees. Even more substantial results might follow, such as the successful treatment of an ore formerly refractory to the process employed.

As said before, a leader who can suggest lines of investigation is invaluable in such a plan, and the company must acquiesce in making the necessary expenditures. We recall several instances where this arrangement is working successfully. At Goldfield the Florence mill is equipped with a special laboratory where the men are encouraged to make experiments bearing on the cyanidation of gold ores. The Portland Metallurgical Society was formed of employees of the Portland Gold Mining Company, and was the direct means of evolving the process now used by the company at its Victor mill. Recently Mr. Dorr has organized his men at the Mogul mill in South Dakota into a research club from which good results are expected. Doubtless other instances of clubs organized on this plan could be found, but there is still room for many more.

Continuous Cyanidation.

Hitherto in these columns emphasis has been laid on the value of continuity in metallurgical processes. Compared with intermittent procedure, the continuous method gives greater service per unit of time and labor, adds to net profits and reduces the losses sustained in the repetition of an intermittent method. In two of the principal steps in the cyanide process, agitation and filtration, we have seen remarkable progress owing to the introduction of the continuous feature, and this idea has persisted in the minds of metallurgists so that they are endeavoring to secure continuous operation wherever possible.

In this connection we are glad to present to our readers a timely article on continuous cyanidation, by Mr. John E. Rothwell, who has been studying and developing this idea for several years. A study of the flow sheet accompanying the article will reveal the advantages claimed by the author for the method. Mathematical accuracy and definiteness are substituted for guesswork and rule-of-thumb procedure. The operator may know just what is going on in any part of the process at any time. By means of measuring devices, such as diaphragm pumps, the quantities of solution or pulp delivered from one point to another are determined exactly. There is a definite quantity of solution of definite value drawn from the system for precipitation of the dissolved values. And yet, with all the mathematical nicety which marks continuous operation, there is ample elasticity to provide for accidents or other contingencies in that part of the treatment which concerns extraction by cyanide.

The complete absence of filters in this method is a notable feature considered from the financial standpoint. The cost of installation of a continuous treatment method probably would be less, and certainly not more, than that of a plant using filters, while the cost of subsequent operation certainly would be less. Extraction also should be improved owing to the manner of applying the countercurrent of solution to the ore. It will be noticed that the weakest and lowest grade solution is applied to the ore when it has been almost exhausted of its precious metal content, and that the solutions can be strengthened by the addition of cyanide as they come in contact with richer ore. As pointed out by the author, this feature insures the highest efficiency from the solvent.

As a contribution to progress in cyanidation the idea of continuous treatment is very timely, and we invite metallurgists to a free discussion of its merits.

The Cyanamide Process in Gold Metallurgy.

Experimental work with the Clancy cyanamide process continues to absorb the attention of metallurgists in the West. The experiences are varied, and the indications are that the ordinarily capable experimenter is not equipped, either by education or experience, to account for all the results he obtains, or to obtain uniform results continuously. This does not reflect unfavorably on the merits of the Clancy process, nor does it derogate from the correctness of the underlying principles. It mainly calls attention to the fact that the chemistry of the organic compounds of gold is not as well known as it will be a few years hence, and that the conditions for successful operation may be confined within comparatively narrow limits.

It is, therefore, timely to caution against promiscuous experimentation, as well as against the error of drawing hasty conclusions from a few results. There are so many variables to be taken into consideration that it requires patient, continuous and intelligent experimenting to determine them singly and in combination. The difficulties are increased because the present accumulation of knowledge on the subject is small, and hence each investigator must work according to the best light he can obtain. It would be of great benefit to the fraternity if metallurgists would contribute their results; not putting them forward as from ripe experience, but as tentative statements of observation.

One of the difficulties encountered is the satisfactory chemical control of the process. We are informed that the titration of regenerated cyanide solutions offers some difficulty. Results are varied, and for reasons not always apparent. It is stated that some regenerated cyanide solutions will show a decided solvent action on gold and silver, but that the same solutions will not give a titration for cyanide according to the usual methods. What condition exists in these solutions? What is the solvent, and how is it to be determined as regards quality and quantity? What are the effects of various current densities, and what arrangement and size of electrodes will give the best results? Can regeneration of the cyanide solution be well accomplished in contact with the ore pulp, or is it better effected in clear solution after filtration?

These and many other questions have confronted the present investigators, and the answers are not yet made to their satisfaction. The free exchange of opinons and results will solve these points, just as similar problems were solved in the standard cyanide process which has been brought to such a high state of perfection.

Co-operation and Competition in the Iron and Steel Industry

The public was given further enlightenment last month as to the attitude of Mr. E. H. Gary, chairman of the United States Steel Corporation, with respect to the corporation's position and the campaign of price maintenance, technically known as "co-operation," which he has conducted so successfully for several years. Inasmuch as Mr. Gary's attitude has not changed of late, and as the pursuance of the campaign necessitated his expounding his views from time to time, there was nothing strictly for him to say on these subjects when he appeared before the Stanley committee of the House of Representatives, pursuing an investigation of the affairs of the United States Steel Corporation and its relations with the independent manufacturers. However, the occasion was afforded for Mr. Gary to re-state his views, fully and distinctly, and he made most of his opportunities.

The policy of "co-operation" is offered as a modern invention, a substitute for the old practice of "destructive competition." The work is conducted very simply, the steel manufacturers merely meeting from time to time and then and upon other occasions freely exchanging information as to their business affairs, there being in particular an arrangement

whereby, while no manufacturer is bound not to reduce his prices, he is expected to communicate news of his intention to the other manufacturers before he announces the reduced price to purchasers. The policy is simplicity itself, being essentially based on a frank and full exchange of information between the different manufacturers in the iron and steel industry.

Mr. Gary was candid, apparently, to the members of the committee, startlingly candid, when he expressed his strong wish that there should be a department of the government to which the management of the Steel Corporation could go when in doubt as to what the law allowed it to do, and, upon giving adequate information as to its position, receive counsel which if followed would relieve it from responsibility. We opine that Mr. Gary's attitude in this matter is due to his having stronger views as to the scope and bearing of the Sherman anti-trust law than are entertained in many quarters. There is no reason to infer that Mr. Gary courts government supervision, with regulation of prices, for any other reason than because of the potency of the Sherman law or the force of public opinion, which would be likely to make another law were it not in existence.

To draw a word picture illustrating the differences between the so-called "destructive competition" and this modern policy of "co-operation" may readily appeal to the senses, but it is not stating or developing a scientific law. What is this "destructive competition"? Is it not destroying that which is inefficient and making more durable that which is efficient? This in itself is more likely to be good than bad. It is true Mr. Gary suggested that without the formation of the Steel Corporation there was danger of a monopoly being created, for he stated as his firm belief that had the Carnegie Steel Company continued in its old position and with its old management it would have driven all other steel producers out of the field. We can hardly concur in that belief. Prior to the formation of the Steel Corporation, April 1, 1901, the Carnegie Steel Company was making 2,500,000 tons of steel, which at that time represented approximately one-fourth of the country's steel ingot production of 10,000,000 tons. The country's production last year was in excess of 25,000,000 tons. Certainly a war of destructive competition would have tended to increase, rather than decrease, the demand, and it is inconceivable that a single concern could carry on such a warfare and at the same time accumulate funds sufficient to multiply its productive capacity by ten.

Mr. Gary's testimony brought out what was emphasized at the time the Steel Corporation was formed that one of its objects was to forestall a large amount of new erection which was planned by the various interests consolidated, new erection far beyond what seemed to be in keeping with the country's requirements and which would probably have involved the most serious competition. Quite likely it was an economic gain to the country that such unnecessary duplication of plants should be avoided. In the light of the actual history of the iron and steel industries during the last years this economic gain, as a consequence of the formation of the Steel Corporation, can hardly be denied.

Even granting that the "destructive competition" is altogether bad, the history of the past few years does not necessarily indicate that the new principle which it is sought to put in its place is necessarily good. We observe in the first place that there was a period of three years, from late in 1904 until late in 1907, when demand was sustained and the increasing productive capacity of the iron and steel industry was continuously and fully engaged. During that period it was urged that steady prices meant steady demand, but in the retrospect it appears that the slightly advancing tendency which the market displayed during that period tended to encourage buying and in some cases induced the anticipation of wants. Usually there are some who wait, but these did not and the result was a twelvemonth in which demand was scarcely more than half what it had been in the preceding twelvemonth. Never before had there been so violent a decrease in demand and this despite the ever repeated preachment that steady prices meant steady demand.

A still more serious feature, however, is this, that the encouragement of buying in 1906 and 1907 created a false impression as to the ordinary iron requirements of the country; it set a standard which the trade expected to be lived up to nearly all the time. There was an inducement to new erection, and the policy of co-operation undoubtedly added a great incentive, for it involved, directly or indirectly, the maintenance of prices and the distribution of whatever demand there was along the different producers according to their capacity. Naturally the larger one's capacity the larger the share of the going business. Accordingly we find the industry's capacity, including a few furnaces not yet completed, at about 35,000,000 tons of pig iron per annum, practically 50 per cent in excess of the average demand in the three years of extreme prosperity, 1905-6-7, and still more in excess of the demand which has been experienced more recently in the past six or nine months.

Thus we cannot avoid the conclusion that if the policy of "co-operation" has eliminated the old fashioned "destructive competition" it has instituted a practice of unnecessary new erection. We are not prepared to give unqualified approval to either result.

It is said that the country must "grow up" to the new capacity. In point of tonnage perhaps it will. Certainly it will if the old law of increase in tonnage demand holds good, but we are not certain that it will. The requirements, in service to be performed, presumably will, but nothing is more certain than that much of the steel now being employed is not as suitable as might be for the purposes to which it is applied. Frequently the service can be more effectively performed by lighter but better steel, and we may find that, while the service performed by the new steel made doubles in the future as often as in the past, the tonnage required to perform the increased service will not increase in proportion. If that is so much of the new construction now indulged in, anticipating future requirements, is misplaced, whereas by waiting until the demand appears the investment could be made much more intelligently and with much greater effectiveness.

And yet, after all that may be said on the shortcomings of the policy of co-operation, the fact remains that this policy with its fixation of prices is in line with the tendency of the times toward scientific socialism. And as such it is not only logical but eminently practical.

Indianapolis Meeting of the American Chemical Society.

The Indiana Section of the American Chemical Society is making special efforts to make the summer convention unusually successful. This will begin on Tuesday, June 27, and last throughout the remainder of the week. The council will meet on the afternoon of Tuesday, June 27, and after a business meeting will be taken for an automobile ride to the Indianapolis Speedway.

On Wednesday the general session will begin and three general addresses will be given. Prof. Charles Baskerville, of the College of the City of New York, will speak on "The Chemistry of Anaesthetics." Prof. Edward Kremers, of the University of Wisconsin, will follow with a paper on "The Quinhydrone Hypothesis of Plant Pigmentation." The third address, by Prof. W. Lash Miller, of the University of Toronto, will be upon "The Chemical Philosophy of the High-School Textbooks."

These papers will be followed by a complimentary luncheon at the German House, and after luncheon meetings of the Agricultural and Food, Industrial, Organic, and Physical and Inorganic Divisions and the Biological Section will be held. In the evening a complimentary smoker will be held in the gardens of the German House.

On Thursday morning there will be meetings of the Agricultural and Food, Industrial, Organic, Pharmaceutical, and Physical and Inorganic Divisions, one of the special features being the meeting of the Pharmaceutical Division in the new Science Building of the Eli Lilly & Company, followed by a luncheon there to the pharmaceutical chemists. At the same time a complimentary luncheon will be given to the remaining chemists at the Indianapolis Brewing Company, followed by an inspection of their plant. In the afternoon all of the chemists will visit the plant of the Eli Lilly & Company.

On Thursday evening there will be a public lecture by Mr. A. D. Little at the German House on the earning power of chemistry. This lecture is one of the features of the meeting and is intended to interest chemists, business men and the general public alike. Following the lecture there will be a concert in the gardens of the German House.

On Friday there will be an early visit to the Indianapolis Water Works followed by meetings of the Fertilizer, Industrial, Physical and Inorganic Divisions and the Sections of Biological and of India Rubber Chemistry. At 12:30 these will be followed by a complimentary luncheon at the automobile factory of Nordyke & Marmon, followed by an inspection of their factory. Later in the afternoon visits will be made to the Encaustic Tile Company, to the Fairmount Glass Works and to E. C. Atkins & Company. In the evening the usual banquet of the summer meeting will be held.

On Saturday there will be visits to the Kingan & Company, Ltd., to the Polk Sanitary Milk Company and to the Diamond Chain Company; in the afternoon to the Van Camp Packing Company.

A special endeavor is also being made to see that ladies accompanying members have an enjoyable summer outing including automobile rides, receptions, theater parties and luncheons.

Over 150 papers have already been received for the divisional meetings.

Dr. Charles L. Parsons, Durham, N. H., is the secretary of the Society.

The Western Metallurgical Field.

The Miami Mill.

The Miami copper mill in Arizona is one of the large plants that recently entered the list of producers. The general line of ore treatment is not dissimilar to that adopted in the other large copper mills treating disseminated, low-grade copper ores. The following outline was given at the May meeting of the New York Section of the Mining and Metallurgical Society of America by Mr. J. Parke Channing:

The ore is crushed in gyratory crushers to 2-in. cubes and screened through cast-steel trommels having ¾-in. holes. The oversize is reduced to ½-in. cubes by 54-in. x 24-in. rolls, and is added to the undersize of the trommel. This is elevated and distributed to six 1000-ton bins, each representing a unit in the mill. The ore is automatically weighed and sampled as it leaves these bins, and then flows into a shaking launder with screen bottom, where water is added. The oversize, larger than ⅛ in., is then reduced in Burch high-speed rolls and added to the launder undersize. The mixture is then divided, one-half going to each of the two sections of the unit.

The treatment in a section follows: Over two Callow screens of a mesh of 0.024 in., oversize to a 6-ft. Chile mill, at present provided with 0.029-in. screen. The two products join and go to a drag classifier, which consists of an endless rubber belt with blades on the bottom. The coarse material from the drag classifier goes to a 10-spigot Richards hindered settling hydraulic classifier, the discharge from each spigot going to a Deister No. 2 sand table. Each table makes concentrate middling and tailing products. The middlings and certain tailings are ground in a 6-ft. Hardinge mill and classified into sand and slime, the sand being treated on two Deister sand tables, and the slime on a Deister slime table.

The overflow from the drag classifier joins the overflow from the end of the Richards classifier and goes to a large conical dewatering tank. The underflow from this is treated on Deister slime tables which make concentrates, middlings and tailings. The middlings are retreated on Deister tables. The overflow from the large settling tank flows to eight smaller conical tanks, the underflow of which is treated on Deister tables, making concentrates, middlings and tailings. The middlings join the coarser slime middlings and are treated on the two Deister slimers mentioned above.

The water recovery is accomplished as follows: The mill tailing goes to large wooden conical tanks, underflow to waste launder and overflow to 80 concrete settling tanks. Overflow water returns to the mill, underflow joins the sand tailings and goes to tailings pond. This pond is provided with a dam made of tailings, back of which the water containing slime is settled and pumped to the mill.

The mill feed has averaged about 2.6 per cent copper, which is higher by nearly 1 per cent than the ore treated by some of the other large copper mills, notably the Utah Copper Company's mills. Ratio of concentration is 20:1, and the extraction has been gradually climbing from 70 per cent to 78 per cent, and it is expected that the promised 80 per cent will be reached. The concentrate runs about 40 per cent copper, the mineral being nearly pure chalcocite with but a small amount of pyrite.

The mill consists of six sections, of which three are equipped with two 6-ft. Chile mills each. The fourth section is provided with three Burch high-speed fine rolls, and they will shortly be used for fine crushing for comparison with Chile mills. The Burch roll is provided with a fleeting movement by which one roll is moved laterally in front of the other in the direction of the axis of the roll so as to prevent grooving.

The mill was originally designed so that the six sections would have a capacity of 2000 tons per day, but it seems evident that this will reach 3000 tons per day. The power consumption is estimated by Mr. Channing to be about 1000 kw, or 1400 hp, for the treatment of 2000 tons per day in four sections. This will include the crushing and pumping, each of these operations being done for about 8 or 10 hours alternately. The mill itself will take about 720 kw, leaving 280 kw for crushing one-half of the day and for pumping the other half, so as to keep the load steadily at about 1000 kw.

Chlorination Abandoned.

It is generally understood that the chlorination plant of the Portland Gold Mining Company at Colorado Springs will be

remodeled for use as a cyanide plant. The company treats Cripple Creek ore, and is using a combination of the chlorination and cyanide processes. The raw ore is first ground and roasted, then treated by chlorination, the tailings being concentrated on tables. The table concentrates are shipped to smelters, and the table tailings classified into sand and slime. The sand is ground in tube mills in cyanide solution, and the gold solutions recovered by decantation and precipitated on zinc shavings. In addition to treating the chlorination tailings by cyanidation, the company has treated a considerable tonnage of its old accumulated tailings by the same method. The total tonnage daily treated by cyanide has been about 500 tons, equally divided between current and old tailings.

The decision to abandon the chlorination end of the treatment at the Portland will leave but one company still treating Cripple Creek ore by chlorination, viz., the United States Refining & Reduction Company. At this company's Standard Plant at Colorado Springs a combination of chlorination and cyanidation is used, on much the same order as at the Portland, with the exception that at the Standard chlorine is generated electrolytically instead of by the action of sulphuric acid on bleaching powder. Cyanide metallurgists may glean a bit of satisfaction from the announcement that chlorination is to be abandoned by one of the old companies, but it must be remembered that chlorination has had a long and honorable record in connection with Cripple Creek ores, and that cyanidation has only in recent years arrived at that state of perfection which would make it a favored rival. True, some have contended almost from the beginning that cyanide was a better agent than chlorine for treating these ores, but in the past there has been room for argument which cannot exist at the present time.

Colorado.

The complaint against the backward state of mining in Colorado, which has been heard for the last year or two, is gradually giving place to a more hopeful expression. It would be difficult to state concisely the reasons for the decline, but undoubtedly the wonderful interest in agriculture and irrigation, the restrictions against prospecting on the public domain and the high cost of equipping and handling low-grade properties have all had their effect. Now, however, the pendulum seems to be swinging back to mining, and there is a noticeable increase in interest. The commercial bodies are talking mines and mining, and public excursions are being conducted into the mining districts. Irrigation has had its sway and mining is again in a fair way to receive respectful attention from financial sources.

By way of publicly encouraging the prospector to open new fields the Denver Chamber of Commerce has raised a fund which is available to prospectors who wish to go out on a "grub stake" agreement. The idea is that a prospector will be outfitted and kept in the field during the season, and that any discoveries shall become the joint property of the Chamber and the prospector. The Chamber retains the major interest, and has the work in charge of a committee of its members. This committee consists of Messrs. James Doyle, Max Boehmer and Ernest L. Foster, all capable mining men and engineers who have had a long and active experience in mining in the State. Opinion is divided as to the practicability of the plan, but it is a worthy effort to revive interest in an industry which, though not comparable in its magnitude to that of 10 or 20 years ago, still holds a high rank in the principal industries of the State.

The Colorado School of Mines' thirty-seventh annual commencement occurred at Golden on May 26. Thirty-five young men were graduated and received degrees in mining and metallurgy. Among the theses presented as part requirement for graduation, two received prizes which are awarded annually. Mr. Roy F. Smith received the Brunton transit, and Messrs. E. J. Dittus and R. G. Bowman received the Stoiher prize of $150 for the best thesis in metallurgy. Their work was on the direct production of molybdenum steel in the electric furnace.

At the annual election of the faculty of the school there were some changes, though not as many as might have been expected in view of the persistent rumors to the effect that sweeping changes would be made. Prof. A. J. Hoskin and Assistant Prof. A. C. Smith, of the department of mining, and Assistant Prof. C. E. Smith, of the department of geology, resigned. Their places have not been filled.

The testing plant being erected at the school is under cover and will be completed before fall. The Legislature made an appropriation of $50,000 for this work and no delay will ensue if the sum proves sufficient.

The Iron and Steel Market.

The half year just ended has been an unsatisfactory one for the iron trade. The production of pig iron may be estimated at 11,750,000 tons, with a probable error of less than 250,000 tons. The three preceding half years showed heavier production, while the second half of 1905 and both halves of 1906 and 1907 showed heavier production. In other words, since the middle of 1905 production by half years has been heavier than in the half year just ended with the exception of 1908 and the first half of 1909.

This record is particularly unsatisfactory because there has been such a large increase in capacity in recent years. In the first half of 1905 there were made 11,163,175 tons of pig iron and in the second half 11,829,205 tons. These outputs represented substantially the total capacity available at the time, at any rate the capacity available with ordinary market prices, for prices were not unsatisfactory at the opening of that year and rose during the year. On the other hand, it was physically possible to make fully 5,000,000 tons more pig iron in the half year just closed than really was made, so that production was just 70 per cent of capacity.

Prices of open-market products were unsatisfactory in the half year. Pig iron, which at the opening of the year stood at a level affording only the most moderate profits to the most fortunate furnaces and represented an actual loss to a number of furnaces, particularly those in the Mahoning and Shenango valley, declined slightly, the average level being about 25 cents a ton lower on July 1 than on Jan. 1. Connellsville coke advanced and then declined, showing practically no net change, while scrap in most markets declined slightly.

The slight decline in the open-market commodities, considering that demand and production were so much below capacity, shows that the adjustment had already been made. Indeed, the year 1910 was one of steady and fairly rapid decline in prices in the open-market commodities.

In the finished steel trade there is a controlled market, and as a result a demand far below productive capacity has not produced a profitless market level. Apart from the profits involved in coke manufacture and ore production, the level has been such that there was a profit from purchased pig iron made into billets, and from purchased billets made into most finished steel products. Technically there were some advances in finished steel products early in the year, there being two of a dollar a ton each in wire products and one of 10 cents per box in tin plates. The wire advances, however, involved granting buyers large contracts at old prices, before the advances, while the advance in tin plates merely covered the advance in pig tin effected by the foreign syndicate, thus giving no benefit to the tin-plate mills. On the other hand, merchant steel bars dropped through the action of the Republic Iron & Steel Company on May 24 announcing a cut of $3 a ton in its price on steel bars, while as a result of a conference between all the important steel makers, except the Republic company, on May 29, reductions were made of $1 a ton in plates and shapes, $3

on blue-annealed sheets, $4 a ton on black and galvanized sheets and approximately $4 a ton on corrugated material. Technically, the average of all finished steel products dropped about a dollar a ton during the half year on account of these changes, but by reason of the peculiar conditions surrounding the wire and tin plate advances the effective decline was really more. Standard section rails are not included in this reckoning, as they stand in a class by themselves, the nominal price not having varied for ten years, while the quality has been materially improved.

Thus the finished steel trade suffered slightly reduced prices and materially reduced production, although its operations were still fairly profitable, and much more so than those of the merchant blast furnaces.

The trade encountered several severely adverse influences. On Feb. 22 the Interstate Commerce Commission handed down adverse decisions in the "advanced rate cases" when the general expectation had been that the railroads would be granted at least a material part of the advances in rates for which they had contended so long and earnestly, though perhaps not altogether wisely. These decisions cast a gloom upon the trade. The railroads at once curtailed purchases, and shortly afterwards a number of them suspended shipments on orders already placed.

The failure of the Sixty-first Congress to pass the Canadian reciprocity bill induced the President to call an extra session of the new Congress, which is Democratic in the House and not safely Republican in the Senate. The iron trade favors Canadian reciprocity, but became seriously disturbed over the prospect of tariff revision. May 15 the Supreme Court handed down its decision in the Standard Oil case. This was adverse to the "trust," but as the words "reasonable" and "undue" and the phrase "in the light of reason" were used in the decision there was a short-lived impression that a new and mild construction had been placed upon the Sherman law. The Tobacco decision a fortnight later, with more mature reflection upon the Standard Oil case, largely dispelled this impression, and the country became convinced that there may readily be found a number of business institutions in existence contrary to the Sherman law as interpreted.

The next adverse influence was the investigation of the United States Steel Corporation, intrusted to the Stanley committee by the House of Representatives.

In these adverse conditions the iron and steel trade has perhaps done fairly well in making the record it has in the half year. For the future, the second half of the year, the prospect is much brighter. No one can well maintain that the situation has not been quite thoroughly "liquidated." The buying trade has conducted itself with a deep impression of the adverse influences and is more likely to throw off the incubus than to yield further. It is the uniform experience that the influence of adverse developments lasts but a time, and the mental condition produced by a new condition wears away even though the condition itself may not be removed.

It is the general expectation in the trade that the second half of the year will show a much larger tonnage than the first half. There is no expectation of materially higher prices, although slight upturns in pig iron may occur in some districts. In finished steel the position is stable. While the Republic Iron & Steel Company withdrew formally from the councils of the steel manufacturers and took independent action in the matter of steel bar prices, it has not abandoned the general policy of co-operation. After the slight price cuts made in May most buyers adopted the view that other and deeper cuts would follow. This the steel makers insisted was not the case, and during the past month the expectation of buyers of lower prices has decreased. There has been a slight increase of buying of finished steel products, beginning about the second week in June, and with any further increase the stability of the finished steel price level may be regarded as reasonably assured.

Prices are quotable as follows:

Pig. iron, f.o.b. valley furnaces, 90 cents higher delivered Pittsburgh; Bessemer, $15; basic, $13 to $13.25; No. 2 foundry, $13.50 to $13.75; malleable, $13.25 to $13.50; gray forge, $13 to $13.25.

Unfinished steel, Bessemer and open-hearth billets, $21; sheet bars, $22, both f.o.b. maker's mill, Pittsburgh or Youngstown; wire rods, $29, Pittsburgh.

Finished steel products, f.o.b. Pittsburgh, except as noted:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, 1.35 cents for tank quality, ¼ in. and heavier.

Shapes, 1.35 cents for beams and channels, 3 in. to 15 in. inclusive, zees and angles 2 in. x 3 in. and larger.

Steel bars, 1.25 cents, base; iron bars, 1.35 cents, Pittsburgh; 1.20 cents to 1.25 cents Chicago.

Wire nails, $1.80, base, per keg; plain wire, 1.60 cents, base; painted barb wire, 1.80 cents; galvanized barb wire, 2.10 cents.

Black sheets, 28 gage, 2 cents; galvanized, 3 cents; blue annealed, 10 gage, 1.50 cents; painted corrugated roofing, 28 gage, $1.40 per square; galvanized, $2.55.

Tin plates, 100-lb. cokes, $3.70 per base box.

CORRESPONDENCE.

The Manufacture of "Air-Salpeter" a Well Paying Industry.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The fixation of atmospheric nitrogen for fertilizer purposes is growing rapidly in importance, and it is interesting to notice that the production of nitrates from the air for fertilizer purposes is indeed a lucrative undertaking.

Its renumerativeness is plainly shown in the report presented recently at a stockholders' meeting by the president of the Norske Hydroelektriska Aktie Sellskap, Norway. This company was formed several years ago to develop and operate the Birkeland and Eyde nitrogen fixation process. This process, which is well known, consisted in an arc spread out into the shape of a thin disk by means of a magnetic field.

Recently this process has been abandoned, and the Schönherr process, of the Badische Anilin Fabrik has been installed and is exclusively operated at Notodden, Norway, where the company's factory is located.

The Norske Hydroelektriska Aktie Sellskap is capitalized at about $2,000,000, of which $1,200,000 is preferred and the remaining $800,000 is common stock. During last year dividends amounting to 8 per cent on the preferred stock and 5 per cent on the common stock were paid.

The gross earnings during the year amounted to $1,200,000, of which $350,000 was net income. Half of this sum was put aside for use in various funds, ' $23,000 was distributed among employees, and the remainder, after the dividend was paid, was transferred to the credit of 1911, to take care of the running expenses for this year. There are certainly few new chemical industries that can show any better financial record.

The company could not begin to satisfy the demand for calcium nitrate, or "Norge Salpeter," as its product is known to the trade, and on this account they are developing, in conjunction with other financial interests, some 135,000 hp in different parts of Norway, all of these to be applied to the manufacture of nitrates from the atmosphere. Most of this power is already developed and will be taken into demand during this year for manufacturing purposes.

Extensive tests have been carried on during the past year with large furnaces taking 4000 hp, and these have been so successful that wherever possible this size will be used.

The Norwegian power conditions are somewhat different from those that most generally exist in this country, since power can be obtained there at a very low figure. This will naturally influence to some extent the financial showing.

Niagara Falls, South Ontario. John Woods Beckman.

The Problems of Tungsten Concentration.—I.

By H. C. Parmelee.

The mining and milling of tungsten ores has been a growing industry in Boulder County, Colorado, since 1900. In the early days of gold and silver mining in this district the tungsten minerals were unrecognized, and they received various names from the prospectors and miners. In general they were regarded as forms of iron, and were considered without value. In 1900, however, the first production of tungsten occurred, amounting to 40 tons of ore valued at $3,216. Since then the production of high-grade ore and concentrate has increased annually, except during a depression in 1907-8.

The output for 1909 amounted to 1100 tons of high-grade ore and concentrate, valued by the United States Geological Survey at $396,000. The total output in the United States for the same period was 1607 tons, valued at $559,500. From this it will be seen that the Boulder County production is by far the most important in this country, amounting in 1909 to about 70 per cent of the whole. In 1910 the output from Boulder was 1530 tons of high-grade ore and concentrate, valued by the State Bureau of Mines at $736,700. During the same period the output of all other metals in the county was valued at $161,589.

The tungsten minerals in the Boulder field are the three iron-manganese tungstates, ferberite, hübnerite and wolframite, and the calcium tungstate, scheelite. Ferberite predominates, but scheelite occurs in many mines, as is shown by the occurrence of lime in the analyses of ore and concentrate—there being no other source of lime worthy of consideration. These minerals are of high specific gravity, scheelite being 6 and the other three ranging from 7.1 to 7.5. They are generally soft and friable. The ferberite occurs in three rather well defined forms which, however, frequently grade into each other. These are: (1) Well-crystallized crusts and layers covering the surface of rock fragments and cementing them together; (2) massive granular ore occurring in more dense seams; and (3) the highly silicious ore in which ferberite occurs in fine grains scattered through the gangue.

In breaking ore in the mine the highest grade is sorted and shipped without preliminary milling. At present this grade must average 40 per cent or more tungstic acid. The lower grades, ranging from 3 per cent to 15 per cent tungstic acid, are concentrated by wet methods. Two grades of concentrate are recovered and shipped; the first contains 60 per cent or more tungstic acid, and the second ranges from 35 per cent to 40 per cent. The former is usually recovered as coarse concentrate and the latter as slime.

The stability of the tungsten industry depends, of course, on the uses for the metal; and as these are not extensive and the demand is limited and variable, there is always the possibility of intermittent operation of mines and mills. It is safe to say that were it not for the large companies operating in the Boulder district the industry would have a more variable career than it now enjoys. At the present writing there is a large tonnage of unused concentrates in the Eastern market, as well as at the mills, with no immediate demand in sight. The principal use of the metal is still confined to the manufacture of tungsten steel for high-speed tools. Minor quantities are used in dyeing textiles, glazing pottery, coloring glass and paper, making bronze powder and weighting silks. The manufacture of tungsten electric lamps creates a slight demand, but as 1 ton of high-grade concentrate will suffice for the manufacture of 15,000,000 to 18,000,000 lamps the quantity used is not important.

The reader who may be interested in other details of the Boulder County tungsten field, such as general and economic geology, mining, technology, ores, etc., is referred to the Colorado Geological Survey, which has published a complete report,[1] from which some of the foregoing information has been abstracted.

[1] "The Main Tungsten Area of Boulder County," R. D. George, State Geologist, Boulder, Col.

Location of Mills.

The town of Nederland is centrally located with respect to the tungsten mills of Boulder County. It is reached by stage, 18 miles from Boulder, or by railroad to Cardinal station and thence by stage for 2 miles. At Nederland is the mill of the Wolf Tongue Mining Company. At present this company is running its mill on a custom basis, sampling and paying for the tungstic acid content according to a graduated scale of prices. On ore ranging from 1 per cent to 30 per cent WO_3 the price paid per ton increases with each per cent tungstic acid contained, and above 30 per cent WO_3 the price per pound of tungstic acid also increases with each additional per cent. This system of outright purchase of ore has superseded the former custom of milling the ore at a certain price and returning the concentrate recovered and is generally more satisfactory. It insures better work on the part of the mill and should make a better return to the miner.

At Cardinal, 2 miles west of Nederland, is the Cardinal mill of the Primos Chemical Company. This plant for the past eighteen months has been retreating the tailings made during four years' previous run, when the methods of saving were not as efficient as at present. The Lakewood mill of the Primos Chemical Company is located at Lakewood, about 2½ miles northeast of Nederland. It is the newest and most attractive of the mills in the district. The company's own ore is treated at present, although in the past a great deal of custom ore has been treated.

Between Cardinal and Nederland is the mill of the Alton Mining & Milling Company, a small plant for company or custom work. On Beaver Creek, about 2 miles southeast of Nederland, are two small mills, one belonging to the Tungsten Mining & Milling Company, treating company ore, and the other owned by Smith & Ardourell, at present retreating the old tailings of the Wolf Tongue Mining Company. The Clarasdori mill on lower Middle Boulder Creek is idle. In addition to the regular milling there is an effort in a small way to roughly concentrate some of the old mine dumps, either by screening and saving the fine mineral or by hand jigging. Any material obtained in this way is sold to the mills.

Difficulties of Concentration.

The concentration of tungsten ore presents difficulties not encountered with other base minerals. This is particularly true with some of the methods now in vogue. It is believed, however, that all of these obstacles can be largely overcome by applying principles and methods that have proved successful in dressing other ores. Excessive sliming is one difficulty, the cause of which is well set forth in the report of the State geologist, previously mentioned.

"Ferberite is a rather soft mineral with one perfect cleavage, and generally one or more prominent partings. As a result the mineral is extremely friable even in the massive and massive-granular forms. Much of the ferberite was deposited as aggregates or loosely arranged crystals and crystal grains, forming crusts over the surfaces of rock fragments. One crust succeeded another until in many places the opening was filled. In other places the cavities remained open, but the walls were lined in the same manner. The crystal grains composing these crusts average not more than ⅛ in. in length and about 1/16 in. in diameter. In much of the ore where the crust is broken the crystal grains are easily separated from one another. When to this ready crumbling of the mass is added the extreme friability of the grains and crystals themselves it is easy to understand the excessive sliming. The finer parts of the slime form an almost impalpable mass which, when stirred in water, gives it an inky appearance, and the water remains turbid for ten days to two weeks. To save these slimes is one of the difficult problems with which the tungsten millman has to contend.

"Another serious problem is the successful treatment of the highly silicious ores. In almost all the tungsten mines there is a certain amount of highly silicious ore, consisting of minute

grains of ferberite in a matrix of chalcedonic quartz or hornstone. The percentage of ferberite varies widely. Outside of certain limited areas this type of ore is fortunately not very abundant and rarely amounts to 20 per cent of the product. Various methods of treatment have been tried, but none has given entirely satisfactory results. Even very fine crushing leaves a large part of the ferberite with particles of quartz attached. In concentrating, these grains consisting of quartz and ferberite will be disposed of according to their specific gravity. Those in which quartz is largely in excess will go with the tailings and ferberite will be lost, while those in which ferberite is abundant will go with the concentrates and help make a low-grade product."

Corroborative testimony on the difficulty of treating some of the ores is given by Mr. Victor G. Hills[2], who was connected with the Colorado Tungsten Corporation during 1905-7. This company treated custom ores, and at that time was doing the best work in the district. Careful records were kept and improvements were made wherever posssible. From a list of twenty-one tests on custom lots the following are given as showing the extremes and average in percentage saving:

Lot.	Mine.	Crude Ore, % WO_3	Concentration, Ratio.	Concentrates, % WO_3	Saving, %
4	D	8.07	8.69	62.17	88.90
3	C	6.07	181.81	40.37	5.03
15	E	9.51	8.93	62.59	75.11

In amount of tungstic acid in the crude ore Lot 3 compares favorably with average lots, but owing to its physical qualities it was a failure from a milling point of view. Mere assays would indicate that it was as good as any other ore, but milling tests proved its worthlessness.

The percentage of saving made in the Boulder County mills is largely a matter of conjecture in many instances. The smaller mills practise no regular control, and the larger concerns prefer to make no statement of their saving. Undoubtedly the efficiency is greater than it was four or five years ago, and as the best mill then operating made a customary saving of 75 per cent to 85 per cent, it is probable that the claims of 90 per cent saving may be realized in present practice. There is little loss in coarse tailing where that portion is allowed to go to waste, and the main loss is in the slime tailing. The statement is made that coarse tailing will assay as low as 0.1 per cent WO_3 and that slime tailings from the best mills contain as little as 0.30 per cent to 0.40 per cent WO_3.

The mills are of small tonnage capacity. Four of them can treat about 5 tons in twenty-four hours, one of them 24 tons and another 40 tons in the same period. With two exceptions they are built especially for tungsten work and are new. The two old mills are remodeled gold mills, and, while not as conveniently arranged as the newer plants, they are doing good work. A notable feature is the large table area required per ton of ore treated, which naturally reduces the tonnage capacity. In no instance is screen sizing being practised with a view to eliminating coarse material which might prove worthless. In view of the friable nature of the tungsten minerals it would seem that sizing should prove worthy of investigation, and certainly classification should be more widely practised.

The stamp is a time-honored crushing device, and finds favor in some of the tungsten mills. Some of the considerations just given, however, indicate that the stamp is out of place in crushing tungsten ore. The minerals are friable and of high specific gravity. When crushed in stamps such material tends to slime excessively, both by reason of natural properties and the fact that it remains too long in the mortar. When this preliminary step has been taken it follows that elaborate provision must be made for saving fine mineral.

Another fact that indicates the wrong use of the stamp is that much of the mineral occurs in a condition which would permit of its liberation by coarse crushing. But, as a matter of fact, a screen analysis of table concentrates made from stamped ore will show about 60 per cent passing a 150-mesh screen and almost 80 per cent finer than 100 mesh. Modern ore-dressing practice would indicate some such method as follows on the average coarse-grained ore: Crushing by jaw crusher and rolls; screen sizing and jigging; regrinding jig tailing, with subsequent classification and table concentration; regrinding table middling, followed by slime concentration on belt machines, and, finally, treatment on canvas if found necessary. Screening might be combined with the classification in such a way as to eliminate a portion of coarse stuff carrying no value.

There is but one mill in the district that is successfully using the jig, and the results are satisfactory to the operators. Other plants are considering the use of coarse concentration, and a second mill will shortly go into commission on this basis.

There are, therefore, two distinct methods of treatment in vogue in the Boulder tungsten field. The first involves comparatively fine crushing with concentration on tables, vanners and canvas plant—the latter being a very important feature and extensive in area. The second includes stage crushing, jigging, concentration on tables and vanners, with a canvas plant as a minor adjunct. The adherents of each method claim an excellent saving, which is not questioned, but the advocates of stage crushing and coarse concentration claim a less expensive plant and cheaper operation. A further claim in favor of coarse crushing is that a greater percentage of high-grade concentrate is recovered, and, since the value of the concentrate is in direct proportion to its grade, it would seem rational to recover as much mineral of high grade as possible and reduce the percentage of fine or low-grade concentrate.

But even with coarse crushing, and every effort made to reduce the quantity of slime, it is noticeable that considerable fine mineral is produced which may float away, even from the boxes receiving concentrates. One of the striking features of all the mills is the provision made for catching this fine floating mineral. Settling boxes of wood or cement are provided, and in one instance the water escaping from the settler passes through a cocoa matting filter. In this connection the idea suggests itself that the use of a coagulant might be beneficial. It is known that fine tungsten concentrate will not settle perfectly clear for several days. The simple expedient of adding a small quantity of lime water will show how quickly the solution will be clarified. On a laboratory scale the mineral thus treated will settle and leave a clear solution in a few minutes. Experiments on a large scale might show that the addition of lime solution at the time of fine grinding would be beneficial in coagulating the mineral and aiding in its recovery. Or, the addition of clear lime water to the concentrate settling boxes might prevent the loss of fine and floating mineral after it had been separated from the gangue. Other salts than lime, which are of proved value in coagulating colloid matter, might be experimented with to advantage.

Magnetic separation has been applied successfully to tungsten ores, but it is not in vogue in the Boulder field. The Boulder ores are remarkably free from sulphides of iron, lead and zinc, cassiterite, arsenopyrite, etc., which usually call for magnetic separation, and this probably accounts for the non-use of expensive magnetic treatment.

The Bingham & Garfield Railway, connecting the mines of the Utah Copper Company at Bingham with its mills at Garfield, Utah, is about 20 miles long. It is laid with 90-lb. rails, has a maximum grade of 2.5 per cent and a maximum curvature on two curves of 10 per cent. The total length of tunneling on the line is 4795 ft. in four tunnels of the following lengths: 682 ft., 754 ft., 1280 ft. and 2079 ft. There are three steel bridges of the following heights and lengths: One across Carr Fork 690 ft. long and maximum height of 190 ft., one across Markham Gulch 640 ft. long and 220 ft. high and the third across Dry Fork 670 ft. long and 185 ft. high. In addition to serving the company's own mines and millls it will haul ores from other mines at Bingham to the smelter at Garfield.

Desiccation of Air by Calcium Chloride.*

BY FELIX A. DAUBINE AND EUGEN V. ROY.

The authors have already described elsewhere the principles upon which this process is based, with special reference to the blowing of blast furnaces with dry air and their investigations have been conducted with the object of that application in view. On publicity being given to the process certain manufacturers approached the authors with the desire of putting it into practice. They yielded to these requests and undertook to make investigation of the appliances necessary for drying large volumes of air. An appliance of this nature has been installed at the Differdange Steelworks, Luxemburg, where it is now in normal working.

General Principles of the Process.

It is unnecessary to reproduce here the discussions, theories and calculations which were published in 1909 in the *Bulletin de la Société de l'Industrie Minérale* (Vol. 11, pp. 397-452, 479-541), and of which a summary has appeared in the *Journal of the Iron and Steel Institute* (1910, Vol. 1, p. 613). Nevertheless, it appears to be advisable to recapitulate briefly the general principles upon which the process is based.

It is inherent in the very nature of bodies that every substance the solutions which, when highly concentrated, possess very low vapor tensions, should be, for that very reason, a hygroscopic substance, and capable of serving for the extraction, up to a certain state of equilibrium, of the moisture contained in atmospheres possessing higher vapor tensions than those of the solutions in question. The word "solution" should, in this connection, be understood in its most general sense—a solution of a given strength of concentration may be solid or liquid, this being a matter of temperature—and it will be seen later that one of the characteristics of the process which the authors are about to describe is the maintenance of the solutions obtained in this solid "phase."

The more rapidly equilibrium is attained, the more suitable is the substance for playing its part as a desiccating agent. A highly hygroscopic body would, therefore, be one which, at a given degree of concentration, would possess very low vapor tensions, differing greatly from the vapor tensions of the air to be desiccated. This is precisely the case as regards chloride of calcium and certain of its hydrates, the very low vapor tensions of which permit of obtaining rapid desiccation. In this connection the properties of calcium chloride have been known for a very long period.

It should also be noted that every external influence which is capable of lowering the tensions of the hydrates favors, by this very fact, the desiccation; and as for any given hydrate these tensions vary with the temperature, and in the same proportion, it follows that the lowest temperature possible should always be selected. Further, as the vapor tensions increase in proportion as the molecules of water absorbed render the dilution of the hydrates greater, it becomes equally necessary always to maintain the solution at a sufficiently high degree of concentration.

Consideration of these principles, taken together with numerous experiments, has enabled the authors to determine the economic conditions of the evolution of calcium chloride during the course of its periods of hydration and regeneration. It has, to begin with, been found necessary to avoid making the concentration higher than $CaCl_2 + H_2O$ for the two following reasons: First, that the regeneration of hydrates of greater concentration than $CaCl_2 + 1\,H_2O$ requires a very large number of calories, so that, despite the very low vapor tensions of these hydrates, they are slow in coming into equilibrium for reasons which are not altogether apparent, but probably depend on a special physical condition. In other words, the $CaCl_2 +$ less than $1H_2O$ hydrates are "tardy" in their operation. Secondly, it has been found that during the absorption of water vapor a dilution of about $CaCl_2 + 8H_2O$ should not be exceeded. This hydrate becomes liquid at a temperature of 15°, whereas all hydrates of higher concentration remain solid at this temperature. Briefly, the details of the process are as follows:

A layer of broken calcium chloride, the smaller pieces at the bottom and the larger pieces at the top, rests on a sieve. Within the mass of the calcium chloride, and in its lower part, is submerged a spiral grating, consisting of pipes for the circulation of water. The volume of air to be dried is made to traverse the mass of calcium chloride from top to bottom, the draught being created by a fan. The absorption of the water by the calcium chloride leads to an evolution of heat, and this heat is carried away contemporaneously with its production by the water circulating within the spiral.

Without this indispensable precaution the temperature of the mass of calcium chloride would rise, the tensions of its hydrates would rise likewise, and the chloride mass would cease to act efficiently. The hydration of the calcium chloride should be arrested when the outside pellicle of the broken pieces commences to liquidate. If it were continued the mass of the calcium chloride would be completely melted, and it would be impossible to regenerate it on the spot.

Further, the fact of its being liquefied indicates that the calcium chloride has formed a hydrate whose dilution is already very considerable (more than eight molecules of water at 15°), and that, as a result, its very high vapor tensions render it unfit for effective desiccation.

At this point it becomes time to regenerate, and to do this it is only necessary to attain the temperatures between which that hydrate best known for this purpose is formed, namely, $CaCl_2 + 1H_2O$, which is produced between 175° and 235°. During the progress of this regeneration it is necessary gradually to raise the temperature in such a manner as constantly to maintain the hydrates in their solid phase.

Suppose, for example, that, after the passage of the air to be dried, the formula of the exterior hydrates is, at a given moment, $CaCl_2 + 4H_2O$, a hydrate which melts at about 40°. Owing to the circulation of the water, which has maintained the temperature of 15°, this hydrate has remained solid; if at the moment of regeneration the temperature be suddenly raised to above 40°, the pellicle corresponding to the above formula melts, breaks down, and is wasted.

It is necessary, therefore, to proceed progressively according to a law which has been recognized in practice and may be deduced in theory from the curve of the liquid and solid phases of the different hydrates of calcium chloride.*

It is necessary also in the course of this regeneration to be careful not to exceed the temperature of 235°, above which the "tardy" hydrate $CaCl_2 + 1H_2O$, of which mention has been made above, is formed.

It may be seen from the foregoing that it is possible to effect the regeneration of the calcium chloride with sources of heat of comparatively low grade, and that it is possible to employ with this object the waste fumes which occur plentifully in all metallurgical works.

The regeneration of the calcium chloride having been effected by this systematic warming, it is necessary in order to render it again fit for the complete absorption of water vapor to cool it completely. This cooling is quickly attained by a rapid circulation of water in the pipe system.

It goes without saying that if the air to be dried were directed on warm calcium chloride no desiccation would take place, because, with the chloride of calcium at such a temperature, the hydrates even if highly concentrated might possess very high vapor tensions. Hence the intermediate period of cooling after regeneration.

When the temperature has returned to that of the average

*A paper read before the Iron and Steel Institute on May 11; slightly abstracted.

Bulletin de la Société de l'Industrie Minérale, December, 1909, p. 497.

environment, the chloride of calcium has regained all its hygroscopic properties, and is capable of desiccating afresh the new volumes of air.

The above constitutes a qualitative summary of the different phenomena which takes place during the evolution of the desiccating substances. It may now be asked, from the commercial point of view, what figures are involved in regard to the relative volumes of air to be dried and of the drying body; to the rate of passage of this air through the body; to the efficiency of the desiccation obtained, and to the amounts of heat to be employed for the regeneration and the time required for the cooling. The replies to these different questions will show at once whether the process is one of commercial application or not. The figures are as follows:

A mass of calcium chloride of 240 kg spread out in a layer of 24 cm in depth, on a square meter of surface, will desiccate 300 cu. m of air, percolating it from above downward per hour for four hours under average conditions of 15 grams of moisture per cubic meter. Without the water circulation the temperature of the chloride of calcium mass would gradually rise to the vicinity of about 40°; the circulation of the water prevents the elevation of the temperature beyond a few degrees, such, for example, as 4 or 5.

In order to regenerate the calcium chloride from its hydrates, calculation shows that it is necessary to expend about 7,500 calories per kilogram of water deposited. In practice it suffices to circulate from below upward—that is, in the opposite direction to the air current—warm air or fumes devoid of dust at gradually increasing temperatures from about 30° to 200° during a period equal to half of the length of time of the passage of the air current—that is, for the example given above for two hours.

Naturally, the circulation of the water is arrested during the circulation of the fumes or of the warm air used for the regeneration. The cooling, owing to the water circulation, does not take any longer time than that of the regeneration. In order to be on the safe side, the authors have always allowed that, given three stages of the evolution, it is necessary to have a triplicate apparatus, so that at any given moment there should always be:

An apparatus at work (desiccation of the air);

An apparatus in regeneration (the circulation of the fumes or of warm air); and

An apparatus in process of cooling.

With regard to the percentages of desiccation obtained they have been deduced already in the calculation. The table below gives the vapor tensions of various compounds of calcium chloride, with water at a temperature of 15°, showing the lower limits which it is possible to attain:

Compounds.	Temperatures.	Pressures in Millimeters of Mercury.	Relative Tensions.
$CaCl_2 + 4$ to $6H_2O$.....	15.5	2.47	0.192
$CaCl_2 + 2$ to $4H_2O$.....	15.0	1.47	0.116
$CaCl_2 + 1$ to $2H_2O$.....	15.0	0.64	0.050

What is called relative tension in the fourth column is nothing less than the state of hygrometric equilibrium which would be attained in a case of repose with indefinite masses of chloride of calcium in presence of finite volumes of air.

Given that the instance under consideration involves a movement of volumes of air and of finite masses of the desiccating substance, these figures themselves can never be reached, although it is always possible to approximate to them. Indeed, experiment has shown that it is possible in a well-watched and carefully conducted operation to attain a degree of desiccation such that the hygrometric condition of the desiccated air will be for the average period of passage but 10 per cent to 15 per cent of its saturation at a temperature of 15°, which corresponds to tensions of water vapor of 1.2 grams to 1.9 grams per cubic meter of air. The foregoing figures have clearly demonstrated in the preliminary experiments that the commercial desiccation of air is possible by such a process. At the present moment it is an accomplished fact.

Earlier Process of the Desiccation of Air by Calcium Chloride.

Fryer Process.—The earliest process that can be mentioned is that of Fryer at Coleford, which made its appearance in 1880. It involved employing the chloride in the most simple form by making the air pass over broken pieces of calcium chloride, collecting the water which settled and regenerating partly in special boilers, and carrying it subsequently to complete igneous fusion.

The inconveniences of this process are at once apparent. If it be sought to liquefy the calcium chloride, there are at once obtained extremely high dilutions, with very high vapor tensions. The tension of the equilibrium itself rises, and finally there is left, in the air to be dried, more moisture than is desired.

This is, however, not the chief inconvenience. The Fryer process allowed for no cooling of the mass during the desiccation, so that the temperature would rise very rapidly, and the calcium chloride became gradually inefficacious.

Finally, the calcium chloride being regenerated in special appliances, a whole series of manipulations had to be provided for—the withdrawal of the liquids, concentration, pouring, solidification, cooling and breaking. The latter operations, taking place on the cold chloride of calcium, are particularly difficult, as it is necessary to take special precautions, and to operate out of contact with air. Indeed, chloride of calcium being a waste product and having in itself no value, it might be affirmed that a chloride thus regenerated would cost practically as much as calcium chloride prepared for the first time. It may be pointed out finally that Fryer, not being aware of the peculiarities of the "tardy" hydrate $CaCl_2 + O$ to $1H_2O$, carried regeneration as far as igneous fusion, which is a disadvantage from the point of view of the activity of the chloride, and requires the expenditure of a considerable amount of heat. The authors are not aware that this process was ever applied commercially.

Cremer Process.—This process dates from 1885, and is illustrated in Fig. 1, in which A is a desiccating chamber, in which are arranged the shelves upon which are placed the materials used for the desiccation, sulphuric acid, calcium chloride, or other analagous substances.

B is the air inlet; B^2 is the outlet tube. Inlet B, instead of being connected with the open air, may be connected with the discharge vent of a fan, in which case the air may be forced into B instead of being aspirated from B^2.

Regeneration can take place on the spot. For this purpose the shelves have a double bottom for the circulation of hot air, or of waste gases to heat the calcium chloride placed upon them.

This process certainly evinces considerable progress, inasmuch as it involves regeneration of the moistened calcium chloride on the spot. It is still, however, exceedingly incomplete. Cremer made the air pass above the layer of calcium chloride instead of making it traverse the layer. The contact is thus less intimate. There is formed in the upper portion an exceedingly moistened layer, the tensions of which gradually increase, as much because of the increasing dilution as because Cremer had not foreseen the necessity of cooling.

Cremer did not indicate either the temperatures of the necessary regeneration, nor the limits within which it was necessary to keep; he provided for the heating of the mass by double-bottomed chambers, which was bad, as the particles in contact absorb all the heat and have a tendency to melt, while the topmost particles are insufficiently heated. Regeneration, in order to be certain, as the authors have shown, requires to be gradual and to be easily regulated. This can be readily attained by the circulation of hot gases through the mass, as the authors have provided for.

Elsner Process.—This process is recent, and dates from 1906. Furnace gases are led on the chloride of calcium, undergoing regeneration in a lower drum. The chloride of calcium, which is assumed to have been regenerated, is raised by means of a mechanical device to an upper drum, in which the air to be dried circulates. Here again no cooling is provided, for although the method of regeneration adopted leads to the supposition that Mr. Elsner wishes to maintain the solid phase

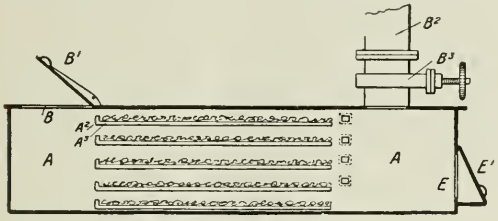

FIG. 1.—CREMER PROCESS OF DESICCATION OF AIR.

for his solutions, he has, nevertheless, neglected the safest method to attain that end—namely, the cooling during the hydration of the chloride.

To any one who has used chloride of calcium, and made it undergo many regenerations, it is a well-known fact that the lumps not only become regular sponges, which are more and more fitted to absorb moisture, but also that their cohesion becomes destroyed little by little, and that these lumps, which very readily resist the passage of air or of gases, pulverize at the slightest shock.

It is very probable that in the Elsner process it would become impossible to maintain the chloride of calcium in lumps, and that the particles would become smaller and smaller and more and more easily liquefiable.

Finally, Mr. Elsner charges his warm regenerated chloride directly into the topmost drum without first cooling it, which is absurd.

Harbord Process.—There are several Harbord processes, dating from 1907, 1908 and 1909. These processes are highly ingenious. Inert substances, such as heat, pumice-stone, all, generally speaking, porous bodies, are impregnated with a concentrated solution of calcium chloride. Regeneration likewise takes place on the spot. The principal object pursued by Mr. Harbord appears to be the retention of such chloride of calcium as might have become liquefied, and the prevention of its flow.

Granting that Mr. Harbord operates with solutions concentrated at high temperatures—above 200°, for instance—the particles retained by impregnation may well be equally active as the peculiar masses which intervene in the process described by the authors. Either one condition or the other must, however, obtain: either the volumes of air to be desiccated are large in relation to the small mass of the chloride of calcium impregnating the inert bodies, in which case there are quickly obtained liquid solutions of high vapor tension, and consequently but little effective, or else the masses of the chloride are, in relation to the volumes of air, in the proportions which the authors have themselves calculated, and the necessity arises for having appliances of enormous dimensions, the quantity of chloride being small in proportion to the quantity of inert matter.

Mr. Harbord has likewise made no provision for cooling, and this cooling would, besides, be difficult to secure, inasmuch as it would have to be carried out simultaneously on the inert bodies which serve to support the active agents. In the last resources, the presence of large masses of foreign matters would be the cause of a heavy expenditure of heat during regeneration, as it would be necessary to raise their temperature as well to the temperature of regeneration.

It would equally be a cause of embarrassment during the intermediary cooling down between regeneration and fresh hydration, as such bodies, which possess, generally speaking, a low calorific capacity, which makes them very slow in heating and causes the absorption of much heat, also require a very lengthy period during which to cool down, which would prevent the calcium chloride being put rapidly into use again.

Mr. Harbord has provided for the use of chloride of iron to prevent the formation of the oxy-chloride. This precaution is superfluous. With chloride of calcium, which had been in daily use during three months, and had undergone over a hundred successive regenerations, the insoluble residue was exactly the same as that of the same calcium chloride on its delivery from the factory.

Other patents are in existence. The bulk of those to which the authors have been able to obtain access resemble one or other of the systems referred to above.

Operation of Process at the Differdange Works.

The problem at the Differdange Works was to desiccate the whole of the air required for the blowing of the blast-furnace of 150 tons per twenty-four hours, in order to realize for this blast-furnace the economies described by Mr. Gayley in his experiments of 1904 and in those he had undertaken since.

The appliances were designed by the firm of Paul Wurth & Co., Luxemburg. Drawings showing two forms of apparatus are given in Figs. 2 to 8.

In the first design the blast is introduced by a central well and distributed in layers by means of the openings leading to different superposed reservoirs. On emerging from the latter it is collected in an annular chamber, where it is led to the place where it is to be utilized.

In a second form of appliance, on the contrary, the blast arrives by way of the annular chamber and is collected in the

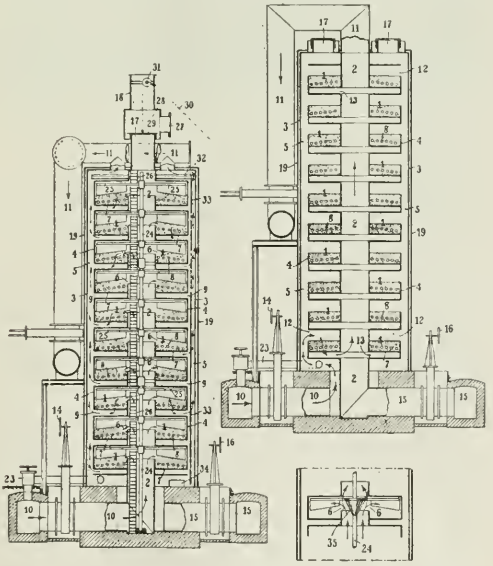

FIG. 2, 3, 8.—DETAILS OF PROCESS OF AIR DESICCATION.

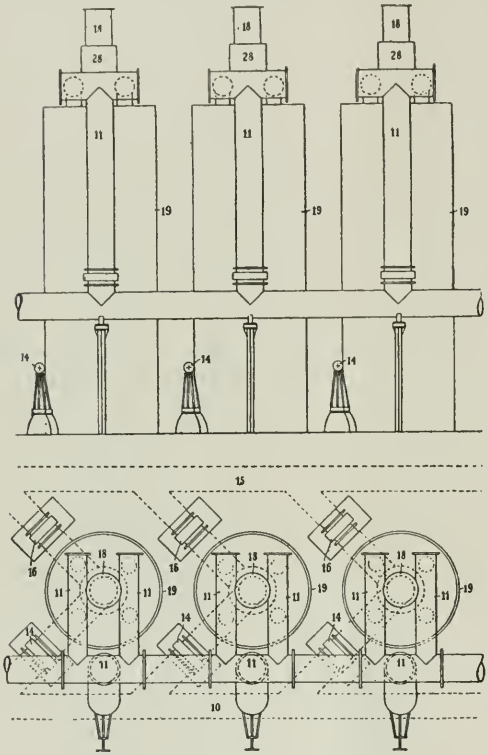
central well after traversing the layers of chloride of calcium and is led thence to the place of utilization.

In order to be able to regenerate the chloride of calcium on the spot, the central well (or the annular chamber) is connected with a second pipe, admitting air or hot gases. The arrangement of the fans is such that it is possible, at will, either to pass the air to be dried, or the gases which are to serve for the regeneration, through the apparatus, or else to isolate it completely during the cooling down.

Figs. 2 to 8 show the two forms of design. Fig. 2 shows, diagrammatically and in longitudinal section, the first type of design, and Fig. 3 the second type. Figs. 4 and 5 show in elevation and in plan an installation composed of several drying apparatus; while Figs 6 and 7 show, in longitudinal section and in plan, the details of the spiral cooling arrangement. Fig. 8 shows details of the means for distributing the air current.

According to Figs. 2 and 3, the apparatus, which has a cylin-



FIGS. 4 AND 5.—DETAILS OF PROCESS OF AIR DESICCATION.

drical shape, is composed of a certain number of compartments identical with each other (1), a central shaft (2), a cover (3), which forms, with the external shell (4), a number of compartments, and the annular chamber (5).

Each compartment (1) has a circular inlet orifice (6) and a grid (7), on which the chloride of calcium rests. An outlet (9) is provided below the grid.

Towards the end of the desiccation the air is drawn by means of the fan across the main lead (10) into the central shaft (2), and distributed to all the compartments. It traverses the chloride of calcium from above downwards, depositing its moisture; it then escapes into the annular chamber and reaches the conduit pipe (11), which takes it to the place of utilization.

As is well known, the chloride of calcium warms during the desiccation, and this must be rectified by the cooling. It is with this object that water is made to circulate in the spirals provided in each compartment. These spirals are arranged to have a certain inclination to provide for their being rapidly emptied. The joints are effected in a special box securing a water-tight separation for the chloride of calcium, with a discharge vent in case the joint becomes defective. The chloride is thus completely protected against such an event occurring.

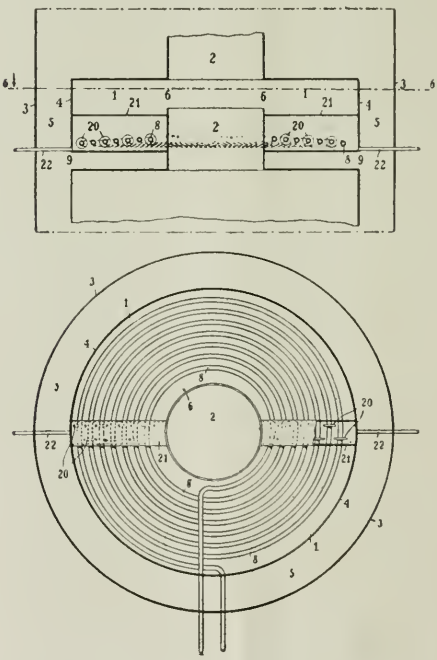
When the chloride of calcium has absorbed the requisite amount of moisture, the apparatus is cut off from the inlet and outlet of air by the slide valve (14), and communication is made by means of the slide valve (16) with the main (15) which conducts air or warm gases.

As the temperature should only be increased gradually, the fan aspirates cold air at the same time as it takes in the gases, to allow the temperature being regulated. By diminishing the amount of air admitted and increasing that of gas the temperature is gradually raised to 235°.

When the calcium chloride has been regenerated the apparatus is first cooled by means of a cold current of air entering the chamber (5) by the conduit pipe (23) and escaping by the outlet orifice (17) and then water is introduced in the spiral cooling coils until the temperature has been sufficiently lowered. The apparatus is then ready to desiccate the air-blast anew.

In the installation shown in Figs. 4 and 5 three apparatus have been assumed to be employed, of which one dries the blast, while in the second the chloride of calcium is being regenerated and the third is undergoing cooling. During the period of the passage of the blast, or at the end of the period of cooling, it is possible to obtain access to the appliance, either by the central shaft by means of the ladder shown in Fig. 2 or to the annular chamber by the ladder (33), running on rails at the top (32).

In the application of the process at Differdange, which is shown on Fig. 9, the conditions require the drying of 30,000



FIGS. 6 AND 7.—DETAILS OF PROCESS OF AIR DESICCATION.

cubic meters of air hourly. The apparatus, constructed in accordance with Figs. 2 to 8, possess the following features:

Total area presented to the passage of the blast, 100 square meters per apparatus.

Number of compartments, 10.

Depth of the layer of calcium chloride in each compartment, 24 centimeters.

Apparent density of the chloride of calcium, 1.0.

Weight of chloride of calcium contained in each apparatus, 24,000 kilograms.

Weight of chloride of calcium contained in all three appliances, 72,000 kilograms.

Cooling surface of the spirals in each apparatus, 170 square meters.

These appliances have been designed to work in the most unfavorable conditions—that is to say, to remove, during the summer months, 15 grams of moisture per cubic meter of air during a period of four hours.

At the time of writing this paper the appliances have been working normally for six weeks, but as the season is the end of winter and as the moisture in the air is not very large, it has been found unnecessary to make as many reversals as were contemplated.

Each apparatus receives the blast for 6 to 8 hours. The air which contains 6 to 8 grams of moisture before its passage only contains 1 to 1.5 grams per cubic meter on emerging from the apparatus, and this figure remains practically constant from the commencement to the conclusion of the period.

Regeneration requires four hours for its completion and is carried out by means of the waste smoke gases from boilers and from Cowper stoves. These gases, cleaned to the extent of 0.4 gram per cubic meter, pass directly through the mass of chloride. The temperature is regulated at 30° to commence with, and thereafter gradually raised in conformity with a certain ascertained law up to about 200°. In the summer the temperature will be carried to 275°.

Cooling takes three hours.

It is interesting to compare these results of drying the blast with those which are capable of being given by the freezing method used by Mr. Gayley.

The authors reproduce below a table of the vapor tensions of ice and the amounts of moisture which saturate a kilogram of dry air at temperatures below 0°:

Temperatures. Degrees.	Vapor Tensions in Millimeters of Mercury. Per Cent.	Weight of Water Vapor in Grams in Saturated Air per Kilogram of Dry Air. Per Cent.
0	4.60	3.80
—1	4.27	3.50
—2	3.95	3.20
—3	3.66	3.00
—4	3.39	2.80
—5	3.13	2.60
—6	2.89	2.40
—7	2.67	2.20
—8	2.46	2.00
—9	2.27	1.85
—10	2.09	1.70

From the above table may be seen to what temperature the air must be cooled to obtain results identical with those obtained at the Differdange Steel Works.

At 15° an amount of humidity of 1.5 gram per cubic meter corresponds with the content of 1.22 gram per kilogram of dry air. This figure, as may be seen, is well within the limits of the foregoing table. To obtain this result, calculation shows that it is necessary to cool the air effectively to —15°, which requires even considerably lower temperatures in the refrigerating tubes.

This shows the advantage which the employment of calcium chloride has over that of refrigerating machines. While with the latter system cooling to —5° leaves a minimum of 2.60 grams per kilogram of dry air, the use of the calcium chloride regenerated under the form $CaCl_2 + 1$ to $2H_2O$ and maintained in sufficient excess at 15° allows of a degree of moisture as low as 0.5 gram per kilogram of dry air being attained.

During the winter months, during which the refrigerating system is practically inoperative, particularly in Continental European localities, chloride of calcium allows of exceedingly low figures being attained—that is, distinctly less than 1 gram per cubic meter of air.

With regard to the blowing tests on dry air now being undertaken at the Differdange blast furnace it is impossible for the authors to give any details at present. The installation is too recent for the true value of the economies realized to be stated, but it is now quite established that the manufacture of dry air need present no difficulty whatever.

The installation has cost a little less than one-quarter of what would have been the cost of an installation for desiccation by means of refrigerating machines. One man for the day shift and one for the night shift are sufficient to handle the apparatus, which is of the most simple description. The expenses of working are thus greatly reduced.

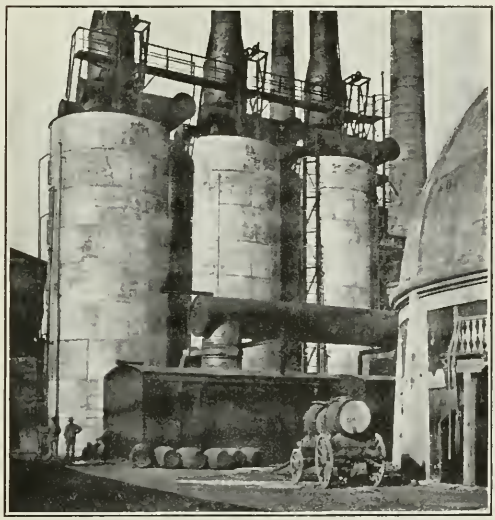


FIG. 9.—AIR DRYING BY CALCIUM CARBIDE AT THE BLAST FURNACE PLANT OF DIFFERDANGE STEEL WORKS IN LUXEMBURG.

The authors state, in conclusion, that similar apparatus are under investigation, not only for other metallurgical works, but also with a view to their application in other industries that require drying operations carried out at low temperatures, as, for example, for the desiccation of chemical or pharmaceutical products, india rubber, resins, gums, gelatin, albumen, glue, aniline colors and various organic bodies. It may thus be seen that there is a vast field open for the commercial production of dry air.

Aubone, France.

The Detection of Willemite by Ultra-Violet Light is used at Franklin Furnace by the New Jersey Zinc Company for the examination of tailings. It has been found that ultra-violet rays cause willemite to show a peculiar luminous glow, which enables one to examine in broad daylight tailings containing this mineral. The method used was described by Mr. George C. Stone, chairman of the New York Section of the Mining and Metallurgical Society of America, as follows: The apparatus consists of an arrangement to produce an arc between iron electrodes, which is rich in ultra-violet rays. Every barrowful of tailings is examined by the foreman, and if he believes that the material contains more than 2 per cent zinc it is returned for retreatment. The mill foreman becomes quite expert in examining material in this manner, but he is checked by assays. The discovery that willemite could be detected in this manner was made in 1896 and is due to Dr. Baskerville and Dr. Kunz.

The Melting Point in Its Relation to Alloying Capacity.

By Dr. Hans Goldschmidt.

The opinion is often expressed that if a metal has a high melting point it is difficult to produce with it an alloy of uniform composition. When scrutinized, however, this opinion is found to be unwarranted. When I first introduced the

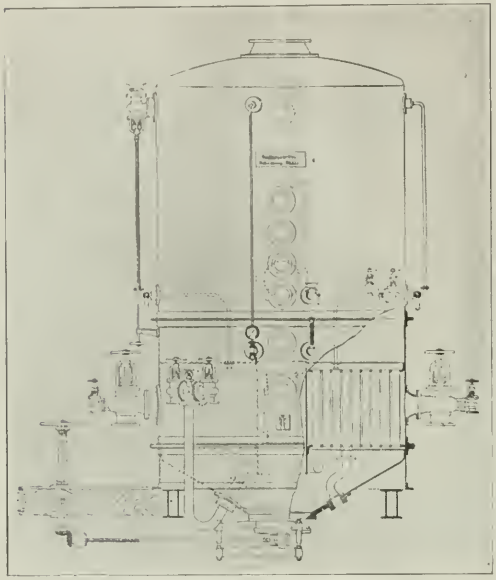

FIG. 36.—GERMAN VACUUM PAN WITH SHORT VERTICAL HEATING TUBES.

aluminothermic metals, such as chromium, manganese, ferrotitanium, etc., into commercial practice, I had to overcome considerable trouble, since metallurgists would tell me that the melting point of these carbon-free metals or alloys was higher than that of the usual brands then on the market which contained carbon, and that the higher melting point of my metals would interfere with their use.

Meanwhile, practice has long shown that carbon-free chromium, in spite of its melting point of 1550° C. (2822° Fahr.) alloys easily with molten steel. The same is true for carbon-free manganese with a melting point of 1245° C. (2273° Fahr.) and this manganese alloys especially easily with copper; in fact, more easily than manganese containing carbon.

In recent years titanium is often added to steel. Ferrotitanium made for this purpose by the aluminothermic process has a melting point of 1330° C. (2426° Fahr.) and alloys easily with liquid steel.

In the preceding paragraphs I have stated the melting points although they are not of practical but only of scientific interest. The following notes will make this clear:

An alloy is nothing but a solution. For instance, an alloy of zinc and copper is called a "solid solution." Zinc has a melting point of 419° C. (786° Fahr.), copper a melting point of 1098° C. (2008° Fahr.). Now let us try to alloy lead instead of zinc with copper; lead has a melting point of 330° C. (626° Fahr.), hence much lower than zinc, yet our efforts of producing an alloy of copper and lead will not be successful. It is simply a fact that lead does not dissolve in copper.

Among the most refractory metals known we have platinum with a melting point of 1775° C. (3227° Fahr.). Yet platinum alloys with tin and lead at a temperature of the melting points of these two metals. Many a young chemist has been sorry to make the experience that when by accident a small amount of these metals got into his beautiful new platinum crucible a hole was formed when it was heated. The fact is simply that the high melting point of platinum does not protect the crucible from the dissolving action of the metals mentioned.

Since, as stated before, an alloy of two metals is nothing else but a solution of one in the other, we are justified from a scientific standpoint to consider it as analogous to the solution of common salt in water. We know that common salt dissolves easily in water; the melting point of common salt, which is at 820° C. (1508° Fahr.) is without any significance for the process of solution.

From what has been said it is clear that for their practical purposes metallurgists have simply to take care that they employ metals or alloys which will dissolve. And it may become necessary to use intermediary alloys which dissolve more easily in the metallic bath. For instance, a high-percentage manganese-copper alloy is made from pure manganese, while instead of pure titanium ferrotitanium is used.

This carbon-free ferrotitanium, containing 25 per cent of titanium, is used now quite extensively as an addition to steel for making rails and rolls. This ferrotitanium made by the aluminothermic process dissolves very easily and uniformly in the molten steel. It has a small intentional content of aluminium, as this increases its solubility.

The experience of metallurgists has shown that as a rule carbon-free metals dissolve more easily than metals containing

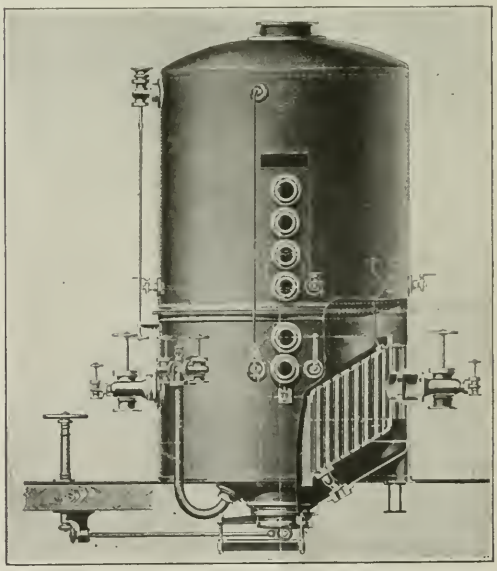

FIG. 37.—GERMAN VACUUM PAN, WITH INCLINED REMOVABLE HEATING SYSTEM AND VERTICAL TUBES.

carbon, since the latter contain carbides—that is, chemical compounds with carbon. It is true that the melting point of the carbides is lower, but as was shown before, this has nothing to do with the solubility, or what is the same, the alloying capacity. The situation is practically the same with ferrovanadium as it is with titanium. For titanium and vanadium it is advantageous to use an intermediary alloy, because only very small quantities of these metals are used.

When a metallurgist has the choice between metals made by different processes the main point of importance is to use starting materials of absolutely uniform composition. Only if he is sure that they will not vary in composition he can get good reliable results. This requirement is fulfilled for metals made by the aluminothermic process on account of their method of production, since they are not made in small quantities, drop by drop, as is the case in the arc or melting zone of electric furnaces, but are produced from a uniformly fused charge. Uniform products are obtained as a result of the uniform composition of the thermit mixture. On the other hand it is very difficult to maintain uniformly the melting zone in an electric furnace, and for this reason it is practically impossible to obtain an absolutely uniform composition in electric furnace alloys, such as ferrochromium, ferrotitanium and ferrotungsten, as especially the carbon content varies considerably.

Essen-Ruhr, Germany.

Evaporators and Vacuum Pans.

By B. Viola, M.E.,
Member American Society of Mechanical Engineers.
(*Continued from page* 311.)

Already in many German vacuum pans short heating pipes have been adopted, but if so arranged the belt or frame of the pipes are generally inclined and the heating tubes are in a

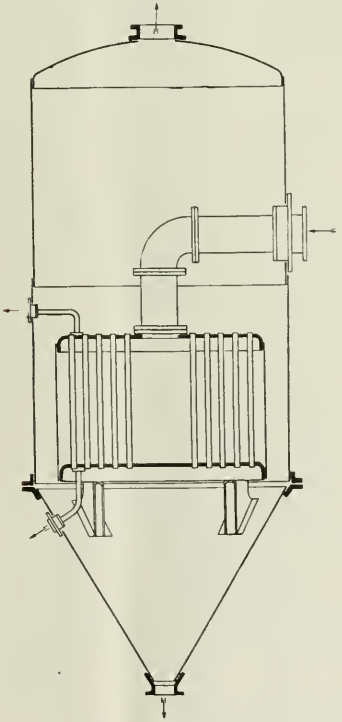

FIG. 37*a*.—PASSBURG VACUUM PAN, WITH REMOVABLE HEATING CHEST.

vertical position. These heating systems can be made steady or removable; the last ones being only hooked in and can be exchanged any time (Figs. 36 and 37). An American-made vacuum pan with removable heating chest can be seen in Fig. 37a of the Passburg system. This is another specialty, in so far as the heating steam does not enter on the side of the heating tubes, but on the top of the heating chest, which gives the steam a better opportunity to heat the pipe surfaces more equally and by that a better evaporation can be effected. The main point is, however, that the steam pipe carrying the steam into the steam chest should always be immersed in the liquor.

The most highly recommended shape for the inclined heat-

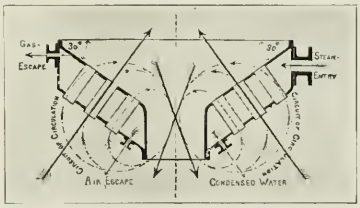

FIG. 38.—PRINCIPAL OF THE INCLINED HEATING TUBE SYSTEM.

ing tube system is shown in Figs. 38 and 39, and is the foundation of Stade's express vacuum pan. This most modern pan consists of one or more heating systems which are arranged in the following manner. The calandria consists of conical parallel plates, which are fixed like a double funnel and contain a central circulation pipe inside and a cylindrical ring outside. The heating tubes are fixed at such an angle that their central lines form a kind of parallel or central radiatiform (Fig. 38).

The steam enters at the upper part of the calandria, the condensed water escapes at the lowest point, while for air and gas separate pipes are arranged to insure highest efficiency of the system. The tubes are short and wide. They deliver even the most concentrated masses up to 5 per cent water to the top. The tubes being set inclined, the masses have to get out sideways and are forced to circulate sideways in or outside of the system.

There are only about three or four supports required for one system, consequently there are no complicated stays to hinder

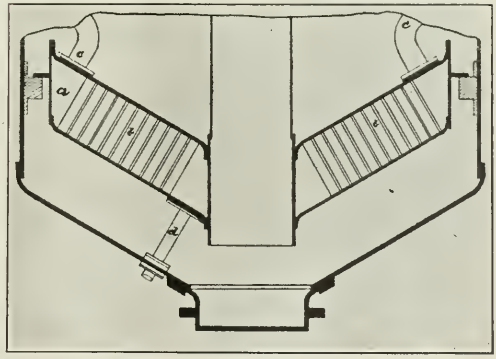

FIG. 39.—REMOVABLE INCLINED HEATING-TUBE SYSTEM.

the full circulation which is bound to take place in a methodical forced system. (Fig. 39.)

One of the chief points of the express vacuum for practical engineers is the easy access to all parts of the system. The tubes can be reached from outside and inside, so that in case of any leakage repairs can be effected in the most simple manner.

The fundamental principle on which the circulation system in general use now (in combination with short inclined express tubes) is based upon may be explained as follows:

The construction consists of a double or false shell fixed at certain intervals over the calandria (Fig. 40). The shells separate the large interior space of the pans in such a manner that a forced but natural circulation takes place from inside up (through the inclined express tube system) to outside down (the space between false shell and pan shell). All the superheat taken up through the tubes goes in form of vapor straight to the condenser and the so cooled masses possess again the necessary low temperature to get the highest transmission of heat when coming again into contact with the calandria tubes.

The natural law states that in two communicating tubes filled with liquids of different specific gravities the levels must be of different height. Now the express circulating system contains inside above the express heating system a mass-cuite mixed with the vapor generated. Outside, however, between the inner and the outer shells the mass-cuite remains free of any vapor as by action of the vacuum pump the vapor generating from the masses escapes at once to the surface and goes to the condenser. Consequently the specific gravity of the mass-cuite outside is higher than the specific gravity of the masses above the calandria. This causes the inside masses to overflow over the inner shells.

In addition to this circulation, however, the action of the heating tubes of the calandria has to be taken into account. These tubes serve as a powerful suction pump, drawing the mass-cuite from the bottom and delivering it through the express tubes to the inside shells system, helping in this way to form a strong circulation in the most simple way, doing away with all stirring and all movable parts inside the pan.

All kinds of steam can be used with the new express circulation pan, and a pressure of 7½ lbs. is sufficient even for large pans with high heads of mass-cuite. With steam of 10 lbs. pressure careful experiments with a large pan gave an evaporation of 15 lbs. water per square foot heating surface.

The materials used for the construction of vacuum pans are copper, iron, lead or lead-lined sheet iron. The heating coils or tubes are copper in most cases on account of its better heat-conducting power, or lead and lead-lined copper, according to the materials which has to be concentrated.

Pans made of copper are usually round, while those of iron are cylindrical or half cylindrical with flat bottoms.

Each vacuum pan, similar to the last effect of the evaporators, is provided with a foam catcher, juice catcher, and has an amply large diameter connection pipe with the condenser.

For the evaporation of certain acid liquors, lead or lead-lined sheet iron is

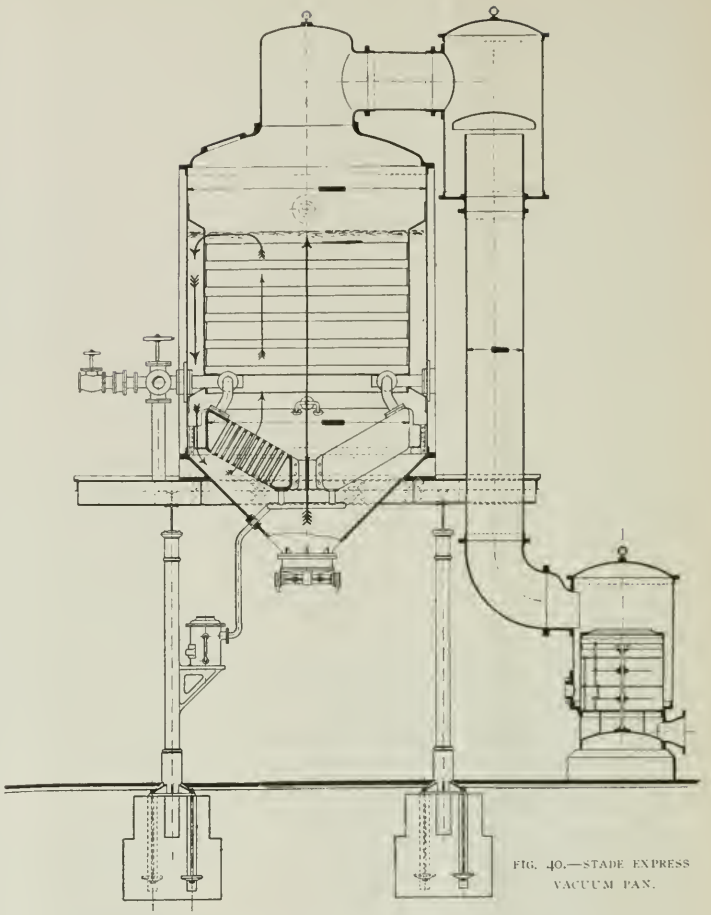

FIG. 40.—STADE EXPRESS VACUUM PAN.

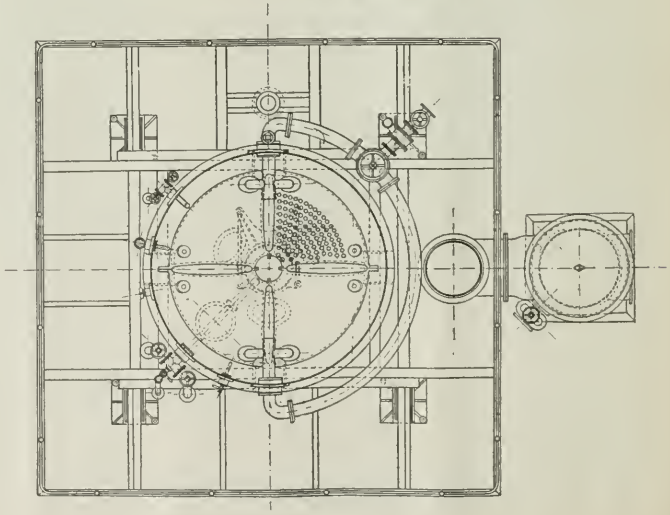

the material mostly used for vacuum pans. If lead is used, then on account of the thickness, the whole pan has to be made of lead casting. Naturally the heating coils were made of lead also, in spite of their poor heating capacity, because no other material can stand certain acids. An entire lead vacuum pan with lead heating coils can be seen in Fig. 41.

Lead vacuum pans had neither foam nor juice catchers, and so it proved necessary to catch the acid particles, which were carried along with the vapors. For this purpose cylindrical cast-iron vessels or so-called overflows were connected with the vapor discharge of the vacuum pans, so that the acid particles could settle there and only the vapors passed on to the condenser. In order that the iron should not be destroyed by the acid particles some neutralizing material had to be used. A complete equipment of such a plant is shown in Fig. 42 vacuum pan, overflow and condenser. However, these overflows were destroyed very quickly and after a while were given up entirely and foam and juice catchers were used.

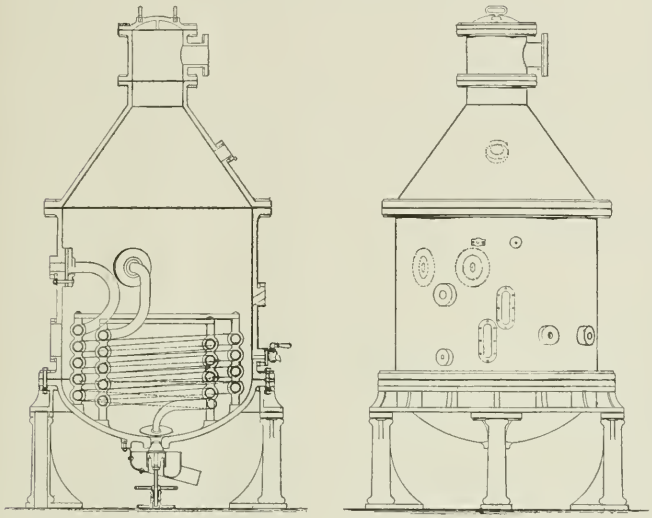

FIG. 41.—CAST-LEAD VACUUM PAN, WITH HARD-LEAD HEATING COILS.

Lead-lined sheet iron for vacuum pans and lead-lined copper coils for heating the acid liquids can be used with great success. Lead-lined sheet iron can be handled more easily than lead casting and be made much lighter in weight, which makes it preferable for the construction of vacuum pans. Lead-lined copper coils have a larger heating efficiency than lead; higher steam pressure can be used and little repair is required.

Fig. 43 shows the top of a lead-lined vacuum pan with foam catcher in the dome and a juice catcher in the vapor line, connected to the condenser.

Fig. 44 shows a complete disposition plant of a homogeneous lead-lined double vacuum pan, provided with single lead-lined copper heating coils and catch-all in the dome, through which the vapors pass to the condenser.

For the evaporation of acids the following constructions have to be mentioned also, which are built by the "Kuehnle-Kopp-Kausch" or homogeneous lead-lined system. Very often two separate evaporators are connected with one juice catcher and one condenser. Such an installation is represented in Fig. 45. These two evaporators are equipped with two homogeneous lead-lined copper coils, about 100 ft. long each and 2¾-3 in. diameter, having an evaporating capacity of about 16 to 20 lbs. water per minute. Both evaporators are working together, but as shown any of them can be cut out occasionally.

A very interesting homogeneous lead-lined evaporator is Fig. 46, which in fact is a double effect. Between the first and second effect we see a catch-all, where all the drops carried over from the first pan by the vapors, are caught and the vapor passes to the second effect, where a higher vacuum is obtained. This second effect has a catch-all in the dome, so that as few drops as possible should be carried over into the overflow, which is inserted between the pan and the plainly seen counter-current condenser.

These heating coils have in the first effect 3⅜-in. diameter by 300 ft. length and a heating surface of about 323 sq. ft. A homogeneous lead-lined copper coil for about 85 lbs. working pressure is followed by a lead-coil in the second effect with 3⅝-in. diameter and 323 ft. length. About 17 gal. of sulphate-alum solution are evaporated per minute. The liquor is in the first effect boiled and the vapors from there are used for the second effect, where the cooking process is finished. In this case both effects have to work together.

Another arrangement for an acid vacuum-evaporating plant, something similar to Fig. 45 is shown in the two homogeneous lead-line vacuum pans of Fig. 47. However, each pan has its own overflow and condenser, but both condensers are connected with one water separator and vacuum pump. This arrangement makes it possible that each vacuum pan can work independently from the other. The necessary valves are inserted between the condensers and tail pipe, cooling-water inlet and in the connections of the condensers and water separator.

Each apparatus is provided with a homogeneous lead-lined copper coil and each has a heating capacity of about 162 sq. ft. and concentrates per minute 10 gal. liquor to 2¾ gal. of acid.

It is always preferred to use above-mentioned equipments, because if two vacuum pans are connected to one condenser bronze or lead valves have to be used to cut out one pan. However, bronze is destroyed too quickly by the influence of acids and lead valves also do not last long enough; they get untight in a very short time.

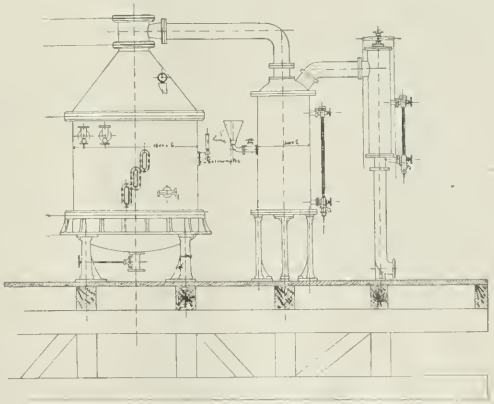

FIG. 42.—VACUUM PAN WITH OVERFLOW AND CONDENSER.

Fig. 48 is a homogeneous lead-lined vacuum evaporator with vertical heating pipes. The steam chamber encloses the outer surfaces of the pipes and the liquor circulates through them

exactly the same way as already mentioned in another part of this paper. To give the liquor a more lively movement and thereby enforce the evaporation, a propeller mixer is equipped in the center of the evaporator, which drives the cooler layers of the bottom always upward, making 150 rev. per minute. The setting of these mixers caused the change of the situation of the vapor outlet. This evaporator has about 280 sq. ft. heating surface and evaporates about 13 gal. of acid liquor per minute. It can be heated with steam from about 65 lbs. pressure.

A very simple construction of a homogeneous lead-lined evaporator with jacket is shown in Fig. 49, having 4 ft. 3 in. diameter, about 52 sq. ft. heating surface and when heated by live steam of about 80 lbs. pressure it evaporates around 4 gal. of liquor per minute. On the top in the center, the vapors are escaping to a condenser.

[*This serial is to be concluded in our next issue when vacuum dryers will be dealt with.*]

The Control of Thermal Operations and the Bureau of Standards. *

By George K. Burgess, D. Sc.

The name that is generally recognized as standing foremost in the determination of the thermal properties of materials is that of Regnault, but it is perhaps not as generally known that the experimental investigations in heat carried out by him over an interval of some thirty years, beginning in 1840, were initiated and supported by the French Government. The problem that Regnault first attacked was that of the properties of steam, a particularly opportune subject at that epoch, and the title page of his first memoir on the subject reads as follows:

"Account of the Experiments undertaken by order of the Minister of Public Works, and on the proposition of the Central Committee on Steam Engines to Determine the Principal Laws and the Numerical Data which enter into the Calculation of Steam Engines."

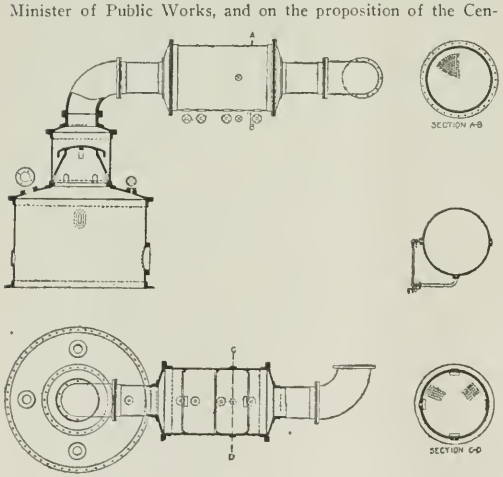

FIG. 43.—TOP OF VACUUM PAN WITH FOAM CATCHER AND JUICE CATCHER.

This was published in 1847, or seven years after the granting of the government subsidy. This delay was in part due to the necessity Regnault labored under of carrying on many researches, fundamental and subsidiary to his main problem, including, for example, the construction of both a temperature and pressure scale, as well as determinations of absolute densities and of specific and latent heats.

The example thus set by France in giving sustained governmental aid for the determination of thermal constants of fundamental importance has been appreciated and followed after many years, it is true, by other countries, several of which have established government laboratories for the carrying out of investigations, not only on the fundamental thermal properties of materials but also, in some instances, with activities covering

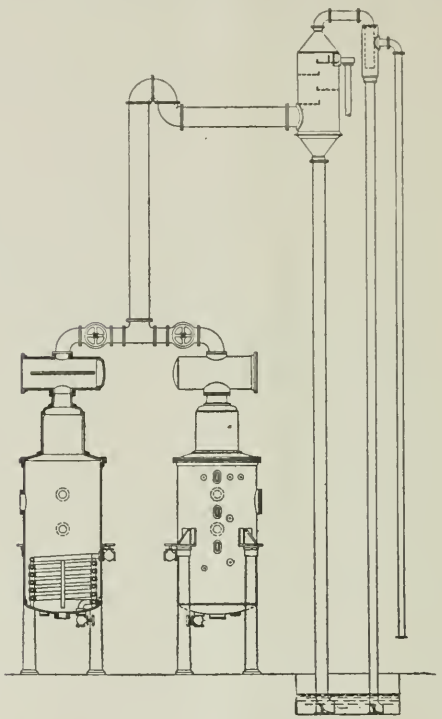

FIG. 44.—HOMOGENEOUS LEAD-LINED DOUBLE VACUUM PAN WITH SINGLE LEAD-LINED COPPER COIL.

the whole range of the physical sciences, including the testing of instruments and materials submitted by the public. Of this type are the German Imperial Physico-Technical Institution (P. T. Reichsanstalt), established in 1887, the National Physical Laboratory of Great Britain, organized in 1899, and the Bureau of Standards founded only ten years ago.

It would take us too far afield to endeavor to cover the whole subject of standardization and its relation to industry, and it will serve our purpose to limit ourselves to the consideration of a domain, that of heat, in which the development of standards has been less rapid and less exact than in many other lines. We shall sketch in some detail the part taken by the Bureau of Standards in the control of thermal operations, with the object of calling attention to an aspect of the question of economic efficiency that is of fundamental importance, namely, the rôle of common units and standards, their establishment, maintenance and availability.

It is a most painstaking matter to set up and maintain a temperature scale, in fact the textbooks state that temperatures cannot be measured and that we can only recognize or locate a given temperature in terms of some other phenomenon that we can recognize or measure. For such reasons, in great contrast to the certainty and permanence of our standards of

*A paper read at the Congress of Technology, April 11, 1911, in celebration of the fiftieth anniversary of the granting of the charter to the Massachusetts Institute of Technology.

length, mass, time, and more recently the electrical quantities, we have had and still have great discrepancies in our temperature scales and all the varied quantitative relations and thermal constants depending on them.

It is eminently fitting, therefore, and particularly necessary that there be a central authority for the establishment, maintenance and distribution of a single temperature scale and the

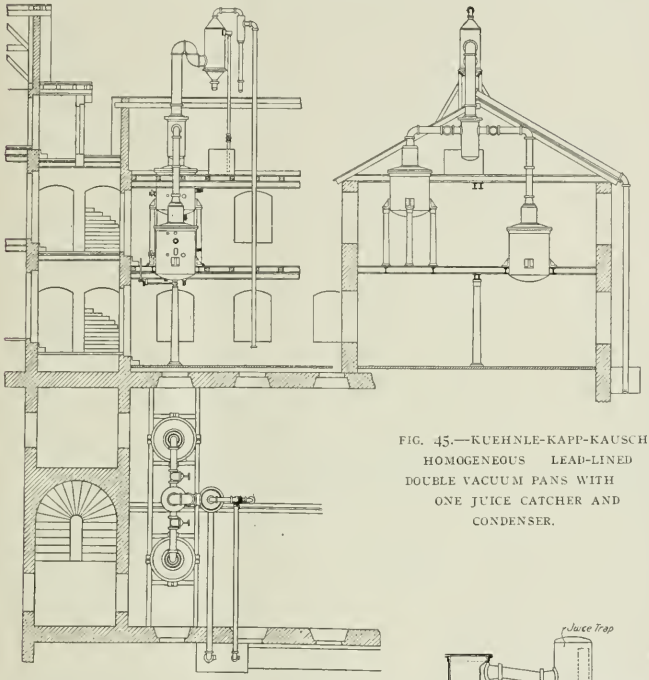

FIG. 45.—KUEHNLE-KAPP-KAUSCH HOMOGENEOUS LEAD-LINED DOUBLE VACUUM PANS WITH ONE JUICE CATCHER AND CONDENSER.

derived heat units. The International Bureau of Weights and Measures, established in 1871 at Sèvres near Paris revising the work of Regnault and others, performs this function in the first instance for the fundamental thermometric interval 0-100° C, while the higher and lower temperature ranges and derived quantities have been left mainly to the various national laboratories since their establishment, as they were previously left entirely to individual initiative. Among the most brilliant examples of the latter are those of Barus in the early eighties, when he was physicist of the Geological Survey, Rowland at the Johns Hopkins, and our own Holman.

Experience has shown, however, that it is quite impracticable for any individual working alone, and engaged in other pursuits as he must be, to maintain and disseminate a temperature scale. Indeed, progress in exact measurements in thermal constants and in all physical constants depending on temperature has often been greatly hampered in the past by the unavailability of any common temperature scale in terms of which results might be expressed. Each investigator was speaking a different temperature language which he could translate into no other. It required, for example, several elaborate, subsequent researches to express the results of Rowland's magnificent work on the mechanical equivalent of heat in terms of the hydrogen scale of the International Bureau. To-day it is neither necessary nor desirable for an independent investigator to try and set up his own temperature scale. Continuity and permanence of thermal standards can only be maintained to advantage by laboratories especially equipped for the purpose, the organization and working of which are not dependent on any individual and the equipment and staff of which are adequate to meet the demands of the public.

Since its creation in 1901, the Bureau of Standards has been actively engaged, in so far as its resources would permit while developing many other lines of work, in serving the United States in the capacity of an advisor on best values and available methods in the many lines of thermal measurements. This activity has necessitated the undertaking of a considerable number of experimental investigations, the carrying on of a very extended correspondence and the execution of many tests of instruments and materials. The bureau does not impose its authority in thermal standards on anyone, and any prestige in this field it may possess must rest on the reasonableness of its suggestions.

The temperature scale of the International Bureau has been reproduced here

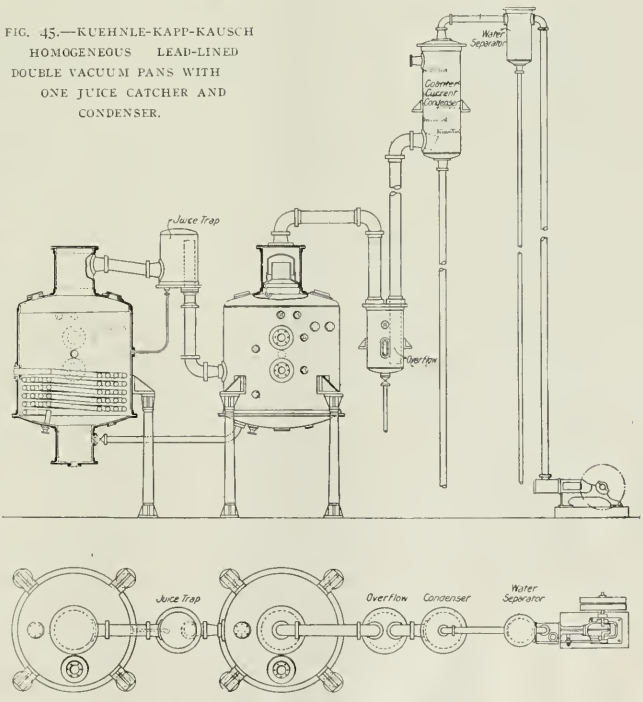

FIG. 46.—HOMOGENEOUS LEAD-LINED DOUBLE VACUUM PANS FOR SULPHATE ALUM SOLUTION.

to 0.°002 C in the interval 0 to 100° C, or to as close as temperatures are known within this interval; and for the remainder of the temperature range, for which there is no international authority, a temperature scale has been constructed which, except perhaps for the very highest temperatures, is in substantial agreement with those maintained

by the German and British laboratories. This temperature scale of the Bureau of Standards is reproducible to about 0.°03 at 500°, 1° at 1000° and 10° at 2000° C and has required for its establishment a great deal of experimental work, and advantage has of course been taken also of similar work elsewhere.

It may be of some interest to consider the relation of this bureau to some of the various bodies with which it comes in contact and mention in particular some of the thermal problems to the solution of which it has contributed.

The bureau is by law constituted the custodian of the standards and is authorized by the organic act creating it to exercise such functions as "the comparison of the standards used in scientific investigations, engineering, manufacturing, commerce and educational institutions with the standards adopted or recognized by the government; the construction, when necessary, of standards, their multiples and subdivisions; the testing and calibration of standard measuring apparatus; the solution of problems which arise in connection with standards; the determination of physical constants and the properties of materials when such data are of great importance to scientific or manufacturing interests and are not to be obtained with sufficient accuracy elsewhere."

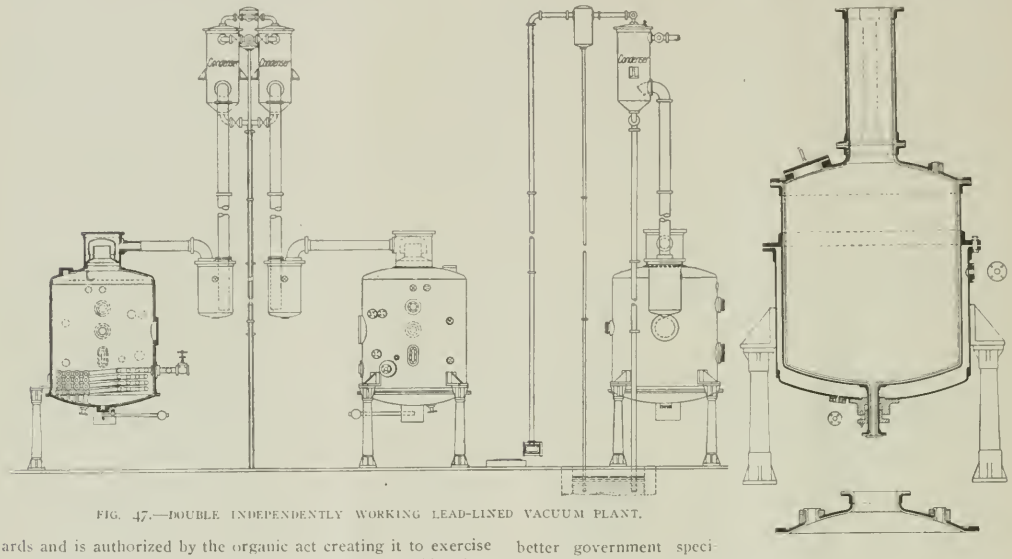

FIG. 47.—DOUBLE INDEPENDENTLY WORKING LEAD-LINED VACUUM PLANT.

Questions arising in the departments of the government requiring advice or decisions on the physical properties of materials are usually referred for solution to the bureau, and this demand for its services and advice is growing at a greatly accelerated rate for tests of various kinds of temperature measuring instruments, for the formulation of specifications, for the purchase of thermal apparatus and of materials on which thermal tests may be made to control their quality, and for the carrying out of specific experimental investigations on materials, processes or methods involved in the solution of some problem in which one or another department of the government is interested.

To mention a few examples among many of the control thus exercised, the purchase of clinical thermometers for two of the departments as well as of the various kinds of thermometers of several of the scientific bureaus is based on specifications drawn up by the bureau and its testing of the instruments before their acceptance, and the knowledge on the part of manufacturers that a bid may be rejected due to the findings of a disinterested, competent authority is not detrimental to the class of instrument submitted in competition for purchase in this way. Experience has proven this practice effective.

The purchase of refractory brick by the Panama Canal Commission is also based on such tests, as well as that of many other materials.

The decision as to whether contested materials are inflammable and, therefore, to be barred from carriage on passenger steamers, is left to the bureau, and such decision sometimes entails an unexpected amount of experimentation.

Investigations of lubricating and illuminating oils and of the types of apparatus used in the testing of them are being carried out with several objects in view, such as the drawing of better government specifications, the furnishing of data for better and more uniform testing methods both in this country and by international agreement. The tests of viscosity, for example, are now on a purely empirical basis, different countries use different instruments and in the United States there are several incommensurable instruments in common use. It is hoped to reduce all such measurements to a common basis.

FIG. 49.—HOMOGENEOUS LEAD-LINED EVAPORATOR WITH JACKET.

The bureau has been asked to take part in the work of several international and national societies or committees, usually with the object of establishing by experimentation the necessary conditions or specifications for the carrying out of some method of testing or standardizing materials, methods or instruments. We have not been able to meet all the demands of this kind in the field of thermal operations, but have limited ourselves to some of the problems that are in the most unsatisfactory condition. Besides the oil question, which is very troublesome, the subject of combustion and gas calorimetry has been attacked from the foundation, and although less than two years have been spent on this, we not infrequently receive praiseworthy letters of a slightly ironic cast asking for our final results on this or that phase of the problem. Accepting Regnault's standard, we still have five years to make good on this problem,

however. An outsider does not always realize that no one is more impatient to finish his problem than the worker himself, but where fundamental standards are concerned the worker is bound to be more conservative than his severest critics.

In this calorimetric work it has been necessary, for example, to design and install a complete plant for the production of pure oxygen, new calorimeters, resistance thermometers and accessory apparatus capable of giving results of the highest accuracy attainable at the present time, and the thermal constants must be determined with different sets of apparatus and checked by several methods.

This calorimetric investigation is very far-reaching and involves, for example, the heat values to be accepted as standard in this country for the constituent components of gas burned in every city and town and, therefore, the ultimate basis on which the price of gas as a fuel should be fixed. The heats of combustion which are being determined of those substances suitable for calibrating bomb calorimeters, in a similar way, will define the ultimate units on the basis of which coal and oil fuels should be bought and sold. Concrete calorimetric standards are realized in the form of certified samples of pure materials of known heat value, which are distributed to interested parties. The various types of calorimeter are also being compared, and incidentally to the whole investigation, improved methods of measurement and new instruments have been developed.

To the refrigerating industries we have furnished after elaborate experimentation the correct values of the specific heat of brine at low temperatures, a constant of very great importance to them. There is great need for further systemization of units in this field as well as the better determination of other constants fundamental to refrigeration. The question of these units will be gone over very carefully at the next International Congress of Refrigeration, which meets in this country next autumn.

The relation of the bureau to the manufacturers of precision instruments is very close, manifold, and in general most cordial. When it is remembered that previous to 1901 there was no generally recognized standardizing authority in this country for thermometers and that each manufacturer had his own scale tied up in one or more long cherished instruments, the breakage of which was a real calamity for him and his clients, the necessity for the establishment of a standards bureau is self-evident.

Besides the testing of thermometric instruments, and thereby furnishing all manufacturers with a single scale, uniform everywhere, the bureau, in certain cases, loans its own standards. It has also taken a very active part in the improvement of specifications and the methods and materials of manufacture as well as in testing methods. The resulting improvements in American thermometer manufacture have been such that in 1906 Gehr. Wiebe, the chief of the thermometer department of the Reichsanstalt, published the statement that the German thermometer manufacturers were complaining more and more of the loss of the American market.

The manufacturers of instruments for the measurement of high temperatures have also been aided greatly, and the condition in this field may be described as having been chaotic before the benefits of uniformity of calibration could be realized. Opportunity is also given for trying out and developing new types of instruments, and a great many suggestions have been given manufacturers which have been incorporated in their instruments. The standards of practically every pyrometer and thermometer manufacturer in the country have been tested at the bureau.

The past ten years has witnessed great strides in the development of the manufacture and use of pyrometers. Formerly the question usually asked by an engineer responsible for the control of some process involving change of product or output with varying temperature was "Do I need a pyrometer and is there a reliable one?" To-day he knows he needs one and asks which is the best for his purpose. The bureau carries on a very heavy correspondence with the users of such instruments, endeavoring to furnish them with the information best adapted to each case, although no pretense is made of replying to the often asked question, which is the best pyrometer?

In a similar way, advice has been furnished to universities

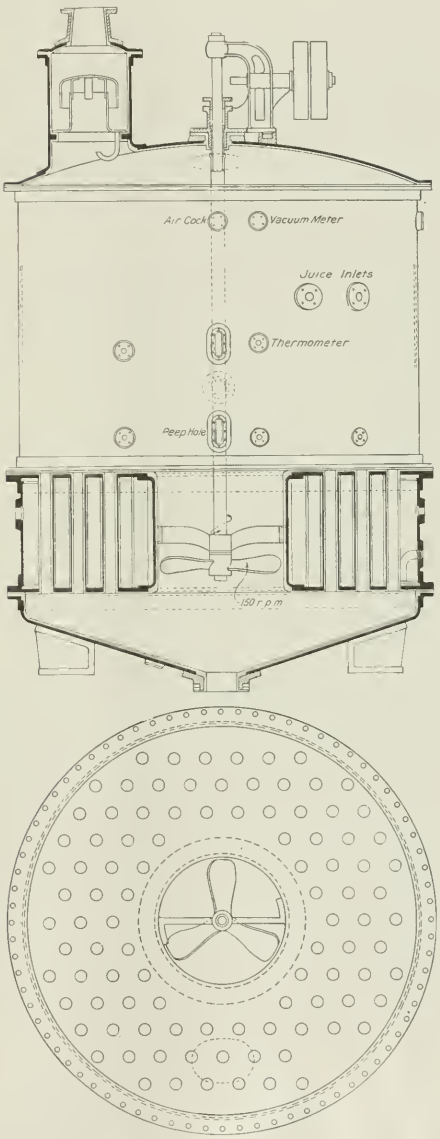

FIG. 48.—HOMOGENEOUS LEAD-LINED VACUUM EVAPORATOR WITH VERTICAL HEATING PIPES.

and technical schools regarding the formation of courses of instruction in heat measurements, the installation and design of new apparatus, and the testing with the highest possible accuracy of instruments to be used by them in numerous experimental investigations.

To still further aid in the dissemination of a uniform tem-

perature scale, preparations are being made for the distribution of samples of pure metals and salts of certified melting points, thus permitting any one to check his own thermometric or pyrometric apparatus in place. As a preliminary to this a careful survey of the reproducibility of the thermal behavior of such materials from several sources of supply has been made.

Among the other investigations under way or in immediate contemplation that have a bearing on the control of thermal operations may be mentioned studies of thermal properties of steels and refractories, including in both instances the purest obtainable materials and the commercial products; the properties of steam with respect to turbine design; the melting points of the elements and of some pure salts and alloys; gas thermometry; the temperatures of incandescent lamps; the corrections to be applied to optical and radiation pyrometers when sighting on steels, bronzes, clays, and so forth; and the comparison of the laws of radiation.

Some of these experimental problems have been undertaken at the suggestion of one or more interested individuals or corporations who often are in a position to furnish materials that may sometimes be difficult to obtain otherwise. Indeed, we are at times in the position of being offered a great many more opportunities of this kind than we can embrace.

Still another function the bureau has occasionally exercised, and one that will probably develop, is to act as referee or court of appeals in case of disputes involving standards, physical properties of materials and the like, and for the interpretation of contracts involving testing methods.

The testing activity of the heat division of the bureau for the past four years ending June 30, 1910, was as follows:

	1906-7	1907-8	1908-9	1909-10
Clinical thermometers.....	8,444	8,395	10,955	13,082
Various thermometers.....	577	798	1,791	1,508
Pyrometers	46	60	31	39
Calorimetric tests.....	....	....	41	58
Oils: Flash and viscosity.....	42	17	159	17
Miscellaneous	9	99	6	45

Several of these miscellaneous tests were of the nature of quite elaborate investigations and most of the pyrometers were manufacturers' standards. Nominal fees are charged for all tests except for the United States or State governments. About one-third of this testing is for the United States government. The bureau makes known the results of its investigations by means of its Bulletin, and its testing methods and specifications are described in Circulars of Information.

With the ever-increasing economic competition and the improvement of scientific methods and instruments as applied to the arts and sciences, the demand for higher accuracy of calibration is also constantly growing. Where, for instance, 0.°01 C was considered an ample precision a short while ago in combustion calorimetry, and 0.°001 C sufficed yesterday, the demand is now for a certainty of 0.°0001 C in temperature differences at 25° C. The meeting of such rigid requirements necessitates oftentimes the application of entirely new methods and instruments, and we are witnessing in consequence the passing of some familiar types, such as the mercury-in-glass thermometer, from the list of instruments of precision.

A most important step is yet to be taken in the unifying of the temperature scales and the values assigned to the various thermal constants in use in the several countries. To-day a pyrometer manufactured in France, calibrated in England and used in the United States comes in competition with a German-made and certified instrument and with one of American make and certification. They will each give a different temperature for a furnace of say 1500° C. We have the example of the unification of the standards of weights and measures as well as those of electricity and photometry, and it is to be hoped that ere long the standards of heat may also be rendered universal.

Washington, March 21, 1911.

The Methods of the United States Steel Corporation for the Technical Sampling and Analysis of Gases.

Copyright, 1911, by J. M. Camp, Chairman Chemists' Committee.

(*Concluded from page 306.*)

2. Blast Furnace Gas.—Before the analysis is commenced, the solutions in the pipettes are brought flush with the capillary tube, while the latter and burette are filled with water. The petcock on either end of the sample tube containing the gas sample (No. 2, analytical apparatus), is filled with water and attached to the rubber tubing, also full of water, leading from the shelf bottle (No. 1), while the other end of the sample tube is attached to the rubber tubing at the end of the main capillary and the sample tube is placed in its rack on the side of the apparatus. The leveling bottle is then placed on top of the apparatus, the pinchcock on the water supply, the lower, then the upper cock on the sample tube, and the three way cock on the capillary tube are opened; the water from the shelf bottle forces the gas into the burette against the pressure from the leveling bottle, which is lowered if necessary, the gas being always maintained under pressure.

About 25 cc of gas are thus forced into the burette, and then expelled through the stem of the three-way cock, all connections remaining as they are. This sample is rejected because it contains the air that was in the rubber connection between the capillary and sample tube. A second sample is forced in until it reaches the base of the burette and about one minute is allowed for the burette to drain and the temperatures to equalize; during this period the sample tube may be disconnected from the apparatus. With the leveling bottle on top of the apparatus, the tube leading from it is pinched between the thumb and finger and the three-way cock opened, the pressure of the gas being thus released. The remaining portion is slowly forced out by releasing the pressure until the meniscus just reaches the zero mark in the burette, then the three-way cock is closed. If the water in the leveling bottle is brought to the same level as that in the burette, the meniscus of the latter should be exactly at zero.

Determination of Carbon Dioxide. The leveling bottle is slowly raised after the cock in the first reagent pipette containing the solution of potassium hydrate has been turned so that the gas will bubble through the solution. If the leveling bottle should not be raised slowly the bubbles which first appear may be lost by being carried into the other compartment of the pipette. When all but about 5 cc of the gas has passed into the pipette the cock is turned to a position for drawing the gas back into the burette, keeping the leveling bottle raised, and the instant the reagent has been expelled from the side capillary of the pipette by the remaining gas the leveling bottle is lowered and the gas drawn back. Thus the gas is forced in and drawn out of the pipette at least three times, the reagent finally being drawn to its initial point in the stem of the capillary. The burette is allowed to drain for about one minute and the reading taken. The difference between this and the initial reading represents the percentage of carbon dioxide in the gas. If the percentage of carbon dioxide is high, to make certain that it has all been removed, the gas should again be passed into the solution of potassium hydrate and a reading taken as before.

Determination of Oxygen. The passing of the residue from the absorption of carbon dioxide into the fuming sulphuric acid for the absorption of the illuminants or olefiant gases is usually omitted with blast furnace gas, as these are either entirely absent or present only in such small quantities that they can scarcely be detected in the usual way. Therefore the residue is at once passed into the second pipette containing stick phosphorus and left there for about one minute to remove the small amount, if any, of oxygen found in blast furnace gas. The difference between the burette reading obtained and that after the absorption of carbon dioxide represent the percentage of oxygen present.

Determination of Carbon Monoxide, Hydrogen and Methane. One-half the above residue is used for the determination of these gases. The last reading when substracted from 100 shows the volume of the residual gases remaining in the burette. One-half this residue substracted from 100 shows the point on the burette the meniscus must reach to reserve one-half the residue. If it is desired to duplicate the explosion, one-half of the residue is reserved in the phosphorus pipette. If not, the leveling bottle is placed on top of the apparatus, the connecting rubber tubing pinched, and the residue to be rejected is slowly forced out through the stem of the three-way cock until the meniscus just reaches the calculated point. The three-way cock is closed and by the application of the leveling bottle the calculated reading should be obtained.

Approximately 45 cc of the oxygen and nitrogen mixture are now passed into the burette, through the permanent rubber tubing connection, and an exact reading is made. If the carbonic acid in the absence of oxygen is low in the sample it indicates a gas rich in combustibles, in such case a proportional increase is made in the amount added of the oxygen and nitrogen mixture. The leveling bottle is raised, the cock leading to the explosion pipette opened, and the gases are passed over and back two or more times to insure a thorough mixture; the gases are exploded, drawn back into the burette and after the lapse of one minute Contraction I is noted.

The residual gas is passed through the potassium hydrate pipette at least three times to remove the carbon dioxide. After the burette has drained a reading is made, which, less the preceding reading, gives Contraction II. The residual gas consists of nitrogen and oxygen, and for the purpose of calculation, the oxygen must be known. About 35 cc of hydrogen are added, an exact reading is taken, and the gases are passed back and forth into the explosion pipette until a thorough mixture is effected. The gases are exploded, drawn back into the burette, allowed to drain and cool and a reading again taken. This reading, less the former, represents the contraction due to the combustion of hydrogen and oxygen. This is known as Contraction III, and one-third of it represents the oxygen present prior to the last explosion.

In the analysis of all gases there should be an excess of hydrogen after Contraction III, hence two-thirds of Contraction III should be less than the hydrogen added; if it is not less oxygen still remains, this is removed by passing the residue into the phosphorus pipette until the oxygen is removed. The contraction is noted, multiplied by three and added to Contraction III; one-third of this total is the oxygen present prior to the last explosion.

The remaining gas consists of nitrogen and hydrogen, which do not enter into the subsequent calculations, as all the necessary data has been obtained for calculating the amounts of carbon monoxide, hydrogen, methane and nitrogen that existed in the original mixture. The reactions which take place in the combustions are as follows: $2CO+O_2=2CO_2$, or two volumes of carbon monoxide unite with one volume of oxygen, forming two volumes of carbon dioxide, there being a contraction of one volume. Therefore, the contraction and the oxygen used are each one-half the carbon monoxide, and the carbon dioxide formed has the same volume as the monoxide. $2H_2+O_2=2H_2O$, or two volumes of hydrogen unite with one volume of oxygen forming water vapor which condenses, the contraction being three volumes. The contraction is then three-halves the hydrogen, and the oxygen consumed is one-half the hydrogen. $CH_4+2O_2=CO_2+2H_2O$, or one volume of methane unites with two volumes of oxygen, forming one volume of carbon dioxide, the water condensing and the contraction being two volumes. The contraction and the oxygen used are each twice the methane and the carbon dioxide has the same volume as the methane.

From these facts the following equations are formed:

Contraction I=½ carbon monoxide+3/2 hydrogen+2 methane.

Carbon dioxide formed=carbon monoxide+methane.

Oxygen consumed=½ carbon monoxide+½ hydrogen+2 methane.

From these three equations a variety of formulæ may be derived for calculating the components of the original mixture. The simplest are:

Oxygen consumed = oxygen added — ⅓ Contraction III.

Hydrogen=Contraction I—oxygen consumed.

$$\text{Carbon monoxide}=\frac{\text{Con. I}+(4\times\text{Con. II})+\text{Con. III}}{3}-\text{oxygen added.}$$

Methane = Contraction II — carbon monoxide present.

As the analysis by explosion was performed on half portion the results must be doubled for expression of percentage. Nitrogen in all cases is obtained by difference, i. e., it is equal to 100 minus the sum of the percentage of the other constituents of the gas.

Example—Data.

an insufficient amount of oxygen remains after the first explosion. In such case the gas is drawn back into the burette and the oxygen and nitrogen mixture is added until the volume approaches 100 c. c.; the gases are again mixed, exploded and the analysis completed as usual, the oxygen added being found from the sum of the two additions. If, in the first explosion of any analysis, the ratio of inert to combining gases is not sufficiently high, and doubt exists as to the formation of oxides of nitrogen, the explosion and resulting determinations may be duplicated, using a larger amount of oxygen and nitrogen mixture and the portion of the residue which has been reserved in the phosphorus pipette, or the residue from a new portion obtained in the following manner. One hundred cubic centimeters are taken from the original sample and the carbon dioxide, oxygen, and illuminants if present, are removed in the usual manner. The remaining residue will not be the same as that obtained on the first sample on account of the reduction in volume of the carbonic acid, due to its solubility in the water in the sample tube, but a part of the residue is taken equal in volume to the gas used in the first explosion, and the analysis is continued as usual.

3. **Producer Gas.**—For the analysis of producer gas the method as described under Blast Furnace Gas is used with one or two modifications as subsequently described.

Determination of Carbon Dioxide and Illuminants. A sample of exactly 100 c. c. is measured and the carbon dioxide removed in the usual manner. Next the gas is bubbled twice through the fuming sulphuric acid pipette to remove

the unsaturated hydrocarbons, composed chiefly of ethylene and commonly called illuminants. Care must be exercised not to allow any water to enter the pipette. After the acid has been drawn to its initial point in the stem of the pipette, the gas is passed into the solution of potassium hydrate two or three times to remove the white acid fumes. A reading is taken and the decrease in volume noted indicates the percentage of illuminants present.

Determination of Oxygen. Next the oxygen is removed, and since the presence of illuminants entirely or partially inhibits the desired reaction with stick phosphorus, it is essential that they be removed before this is attempted.

Determination of Carbon Monoxide, Hydrogen and Methane. Producer gas is much richer in combustible gases than blast furnace gas; therefore the extent of dilution of the residue taken for the explosion should be such as to reduce to the minimum the temperature of the latter, and thereby the error due to formation of oxides of nitrogen. It is also desired that the maximum amount of the original residue practicable enter the explosion, in order that multiplying errors due to fractionation of the sample may be reduced to the minimum. The method to be used for the determination of these constituents is dependent upon the percentage of combustible gases in the sample. This percentage usually varies inversely with that of the carbon dioxide present.

Method "A" is used when less than seven per cent of carbon dioxide is present in the sample. One-half of the residue remaining after the oxygen content has been determined is rejected or reserved in the phosphorus pipette. The remaining half is passed into the explosion pipette, the stem of the latter being completely filled with water. Approximately 70 c. c. of oxygen and nitrogen mixture are added, the mixture in the intervening capillary being swept into the burette by the water remaining in the stem of the explosion pipette. Then the oxygen and nitrogen mixture is accurately measured, mixed with the above residue and exploded; the gases are returned to the burette, allowed to cool and a reading is taken. Contraction I is found by subtracting the residue left after the explosion from the sum of the residue taken for the explosion and the auxiliary gas added. Contraction II, the amount of carbonic acid formed during the explosion, is next determined in the regular manner and the residue is passed into the explosion pipette. Approximately 70 c. c. of hydrogen are added, as just described with the oxygen and nitrogen mixture, and accurately measured, mixed with the above residue and exploded, the resulting gases being returned to the burette and measured in the usual way. Contraction III is found in the same manner as was Contraction I.

The expected amount of combustibles may not be present in the gas portion taken for the explosion, and the residue after the first or second explosion may be greater than can be measured in the burette. In case this should occur, the residue is measured in two portions, the sum of which plus 0.1 cc, the capillary space, equals the total residue.

Example—Data.

Nitrogen	54.1
	100.0

Explosion Ratios: I, 2.58; II, 1.68.

Method "B" is used when the carbon dioxide of the sample is above 7 per cent. The method of analysis calculation is identical with those described under Blast Furnace Gas, with the exception that oxygen and nitrogen mixture is added to the portion of the residue reserved for the explosion until the volume approaches 100 cc. If the carbon dioxide value is between 8.0 and 9.0 per cent the amount of oxygen and nitrogen mixture to be added should be diminished by about 10 cc or difficulty may be encountered in removing the excess oxygen in the second explosion.

4. **Flue Gas.**—The repeated determination of large quantities of oxygen by stick phosphorus or pyrogallol solution introduces undesirable features with the use of either reagent. In the former case, unless care is exercised, the heat of reaction causes fusion, with consequent disarrangement of the phosphorus sticks; with the use of the latter reagent there is a liability of the incomplete removal of all the oxygen. In such a case it would be absorbed in the cuprous chloride solution with the carbon monoxide, if this reagent were used for the purpose, thus giving erroneous values to the carbon monoxide found. To overcome these difficulties the following method has been devised whereby the oxygen and carbon monoxide are determined by explosion, and it has been proven superior to the absorption method, which is the method usually followed in the analysis of flue gases.

Determination of Carbon Dioxide. This constituent is determined on exactly 100 cc, measured in the usual way, as under blast furnace gas.

Determination of Oxygen and Carbon Monoxide. One-half the volume of the residual gases is computed and rejected. The oxygen present in the sample varies inversely with the carbon dioxide content, consequently the hydrogen to be added for its combustion is dependent upon this factor. If the sample contains less than 10 per cent of carbon dioxide, approximately 20 cc of hydrogen and 30 cc of oxygen and nitrogen mixture are added to the reserved portion of the residue. If the sample contains more than 10 per cent of carbon dioxide, 15 cc of hydrogen and 35 cc of oxygen and nitrogen mixture are added The gases are thoroughly mixed, exploded, and after the proper interval Contraction I is noted. They are then passed through the solution of potassium hydrate to remove the carbon dioxide that has been formed from the burning of the carbon monoxide that may have been present, and Contraction II is noted.

To the residue hydrogen is added until the volume of the mixture approaches 100 cc. The gases are thoroughly mixed and exploded, drawn back into the burrette, and after the proper interval a reading is taken and Contraction III is noted.

The data necessary for the calculation of the percentage of oxygen and carbon monoxide in the sample has thus been obtained. From the reactions given under the determination of carbon monoxide, hydrogen and methane in blast furnace gas it is seen that when one volume of oxygen unites with two volumes carbon monoxide there is a contraction of one volume and the formation of two volumes of carbon dioxide, which on absorption cause a further contraction of two volumes; the total contraction is, therefore, three volumes for one volume of oxygen, or the oxygen is one-third the total contraction. The carbon monoxide was also shown to have the same volume as the dioxide formed. In the combustion of hydrogen and oxygen it was shown that the oxygen is one-third the contraction. Then the oxygen entering the two explosions, or the total oxygen, is one-third the sum of the three contractions and the oxygen in the sample is found by subtracting the oxygen added from this total oxygen. These facts are expressed in the following equations:

$$\text{Carbon monoxide} = \text{Contraction II.}$$

$$\text{Oxygen in sample} = \frac{\text{Con. I} + \text{Con. II} + \text{Con. III}}{3} - \text{Oxygen added.}$$

Explosive ratios. I, 2.20; II, 2.96.

The absence of methane and hydrogen in a flue gas may be proven by the application of this formula:

$$H_2+CH_4=\frac{2(\text{Con. I})-\text{Con. II}}{3}-H_2 \text{ added for the first explosion.}$$

This is usually found to be zero.

Thermal Values.—If a calorimeter is used for determining the thermal value of a gas, the Junkers instrument is recommended for this purpose. The results so obtained must be expressed in b.t.u. under the standard conditions of dry gas at 62° Fahr. and 30 in. mercury.

When a calorimeter is not available it is customary to calculate the calorific value of a gas from the analytical results. Considerable discrepancies exist among the values commonly given as heats of combustion for the different gases; but it is believed that the following figures, being means of published values of several well-known investigators, will give results which are sufficiently reliable for all technical purposes.

In the following table, showing the b.t.u. developed in the combustion of 1 cu. ft. of the different gases, measured at 62° Fahr. and 30 in. mercury, two values are given—the gross and the net, the difference between them being the latent heat of the water formed, which is not included in the latter. The products of combustion in both cases are assumed to be at 62° Fahr. For the purpose of comparison all Corporation results should be expressed in terms of net b.t.u.

	Gross.	Net.
Ethylene (illuminants)	1591	1491
Carbon monoxide	324	324
Methane	1012	912
Hydrogen	328	278

In the calculation of the thermal value of a gas the percentage of each combustible present is multiplied by its value in the above table, and the sum of the products will represent the b.t.u. evolved in the combustion of 1 cu. ft. of the gas.

Specific Gravity and Percentage by Weight.—When suitable apparatus is not available for determining the specific gravity of gas, it may be calculated from the volumetric analysis by means of the following table compiled by the Bureau of Standards, showing the specific gravity of various gases compared with air:

Air	1.0000
Carbon dioxide	1.5290
Ethylene (illuminants)	.9684
Oxygen	1.1054
Carbon monoxide	.9670
Methane	.5545
Hydrogen	.06951
Nitrogen	.9674
Water vapor	.6222

The calculated specific gravity of a gas is found by adding the products obtained by multiplying the percentage by volume of each constituent gas by its specific gravity. The respective products thus obtained divided by the specific gravity of the gas yield the percentages by weight of the constituent gases:

The specific gravity of moist gas is found by adding the product of the specific gravity and the percentage of water vapor accompanying dry gas to the specific gravity of the dry gas, and dividing the sum by one plus the percentage of water vapor. This latter value is found by multiplying the grains per cubic foot dry gas by .3012, the volume occupied by 1 grain water vapor, or by dividing the vapor pressure by the difference of the gas pressure and the vapor pressure.

Weight of a Cubic Foot of Gas.—The following table, calculated from the most recent values given by the Bureau of Standards, shows the weight in pounds of 1 cu. ft. of the constituent gases at 62° and 30-in. pressure. The weight of 1 cu. ft. of gas is the sum of the values found by multiplying the weight per cubic foot of each of the constituent gases by its percentage by volume.

Air	.07626
Carbon dioxide	.11660
Ethylene	.07386
Oxygen	.08430
Carbon monoxide	.07375
Methane	.04228
Hydrogen	.005302
Nitrogen	.07377
Water vapor	.04745

The weight of 1 cu. ft. of moist gas is found by adding the product of the weight of a cu. ft. of water vapor and the percentage of water vapor accompanying dry gas to the weight of dry gas, and dividing the sum by one plus the percentage of water vapor.

Correction for Temperature and Pressure.—All metered gas shall be corrected to dry gas at 62° Fahr. and 30 in. of mercury pressure as the standard conditions for comparison.

When T = Temperature of gas at meter plus 459°.

T_s= Temperature sought plus 459°.

P = Pressure found by barometer + manometer reading at meter — vapor pressure at temperature of gas, and

P_s= Pressure sought.

Then a factor may be found by calculation, or from the table on page 358, equal to $\frac{T_s P}{P_s T}$ and applied as follows: The volume at standard conditions equals the volume observed times the factor. The b.t.u. at standard conditions equal the b.t.u. observed divided by the factor.

Vanadium in Cast Iron.*

By George L. Norris.

The use of vanadium in gray iron castings has been limited when compared to its use in steel castings, although the past year has shown a marked increase and its use in certain classes of castings has become well established. We have in the case of cast iron a material the cost of producing which from the crude pig iron has been slight. The price at which iron castings in general are sold precludes the use of any alloy for affecting the quality of the material, except in the case of certain classes of castings where unusual strength or some special quality in the iron is desired. In such cases even a very material increase in the cost of the castings is readily accepted.

In the case of vanadium we are dealing with a metal of fairly high price and its use in the manufacture of cast iron naturally will be confined to the classes of work that can stand a material increase in cost in return for the special qualities obtained. The addition of 1/10 per cent of vanadium to cast iron at the present price of $5 per pound means an increase of ½ cent a pound for the iron in the ladle and necessitates an increase in selling price of ¾ cent to 1 cent a pound at least to cover losses due to scrap, gates, spruces, etc.

While vanadium has a strong affinity for oxygen and nitrogen and is partly used up by combining with these elements, the primary purpose of adding vanadium to cast iron is not the removal of oxygen and nitrogen. The removal of oxygen can be effected sufficiently well by cheaper means and as the injurious effect of small amounts of nitrogen on a refined metal, such as steel, is still an open question, the harmfulness of this element on a metallurgically crude metal like cast iron is open to still greater doubt.

Vanadium increases the strength of the cast iron to which it is added from 10 per cent to 25 per cent, depending, of course, upon the initial strength of the iron. This increase of strength is due directly to the intensifying effect of the vana-

*Abstract of a paper presented before the American Foundrymen's Association at the Pittsburgh Convention.

dium on the metals present in the cast-iron alloy, such as silicon and manganese and also by combination with the chemically combined carbon.

It exercises a very strong effect on the grain of the iron, causing a more even distribution of the graphite with consequent greater freedom from both hard and porous spots. This effect is very apparent, vanadium cast-iron fractures showing a finer and more uniform grain. In the case of chilled iron, vanadium produces a deeper, stronger and tougher chill, and one less liable to spall or flake. This chill, however, is not as hard apparently as the more brittle chill of ordinary chilling iron, and can be filed and machined more readily than the latter.

Vanadium also gives an element of toughness to cast iron which is very apparent in machining the castings. This toughening effect, together with the uniform fineness of grain or texture due to even distribution of graphite in small flakes, makes vanadium cast iron very superior for such purposes as gas and steam-engine cylinders, glass-bottle molds, gears, castings to withstand heat and internal pressures of fluids and gases without leakage.

Three or four years ago the New York Central lines equipped one of its locomotives with a pair of vanadium cast-iron cylinders. The performance of this pair of cylinders over a test period of about two years was so satisfactory that 500 or more locomotives on these lines are now equipped with vanadium cylinders. The test of the original pair demonstrated that over twice the normal mileage of ordinary cast-iron cylinders could be obtained from vanadium cylinders before reboring. The loss in casting these cylinders was extremely low, no cylinders being scrapped at all for the first 183 locomotives ordered.

The same sort of results have been reported by a builder of large gasoline engines for marine use. In his particular case the number of cylinders formerly lost when tested after machining was excessive, due to porousness of certain sections.

Piston rings and cylinder and valve bushings of vanadium cast iron have been thoroughly tried out and adopted by a number of leading railroads on account of the greatly increased length of service obtained. A very interesting application of vanadium has been for glass-bottle molds. These are chill castings and are usually covered with engraving. The iron has to be clean, close and uniform in grain, machineable and take a good polish. The first vanadium cast-iron bottle molds were made a little over a year ago and proved not only to have a longer life, but it was found possible to increase the speed of the bottle machines as the glass did not appear to stick to these molds to any extent. This can be readily accounted for by the uniformity of the grain and freedom from mottled spots.

One of the first applications of vanadium to cast iron was in chilled iron rolls for sheet mills. A number of these were made and gave excellent results, some of them showing 50 per cent greater tonnage with one-half of the dressing against the regular chilled roll. The question of cost, however, entered in here in an unusual manner. Fully 65 per cent to 70 per cent of the roll breakages are due to accidental causes and no amount of vanadium would insure, for instance, against a roller letting a pair of tongs pass through the rolls.

We have had opportunity from time to time to make comparative tests of the strength of cast iron with and without vanadium extending over a considerable period, and believe that these comparisons are more nearly representative than single tests, as they represent average conditions.

The following tests are the average for ten consecutive days' work on locomotive cylinders. The transverse tests were made on bars 1 in. square, 12 in. between supports; the bars were machined all over and consequently were absolutely comparable, which is not always the case with bars only brushed or cleaned.

	Transverse.	Tensile
Plain cast iron	2,130 lb.	24,225 lb.
Vanadium cast iron	2,318 "	28,728 "

This iron has stood 750-lb. water pressure for sections ¼ in. thick. The average chemical analysis of this iron is about as follows:

Combined carbon	0.50
Silicon	1.50
Manganese	0.45
Phosphorous	0.600
Sulphur	0.095

I endeavored to get together a series of tests on irons of various compositions to show the effect of vanadium both on the strength and on the chilling qualities, but owing to various delays I am not able to present this in complete form. The following tests were supposed to be from iron from the same ladle, before and after adding vanadium, but the chemical analysis shows that such could not have been the case. The difference in composition, however, so far as it influences the physical qualities of the iron are all in favor of the iron without vanadium. In addition to the bars for tensile test, chill blocks were cast to show the effect of vanadium on the depth of the chill.

CHEMICAL COMPOSITION.

	Without Vanadium.	With Vanadium.
Graphitic carbon	2.34	2.48
Combined carbon	0.79	0.71
Silicon	1.83	2.21
Manganese	0.43	0.424
Phosphorus	0.508	0.546
Sulphur	0.102	0.071
Vanadium		0.056

PHYSICAL TESTS.

	Without Vanadium.	With Vanadium.
Tensile strength	34,560	35,600
Depth of chill	No white chill	1/16 in. white chill

Size of chill test block 4½ in. square by 1½ in. thick.

The difference in the machining quality of the two irons was decidedly in favor of the vanadium iron. I need hardly mention that the cast iron treated with vanadium should be at least approximately of the proper composition for the particular class of work to which it is intended.

The usual amount of vanadium added to cast iron is 1 10 per cent for cupola melted iron, equivalent to about 5 ounces of ferro-vanadium for each 100 lb. Some foundries advocate the use of a higher percentage, up to 15 per cent, which is about as much as can be conveniently added in the ladle. As low a percentage as 0.05 per cent will produce distinctive effects.

Owing to the high melting point of vanadium and the limited reserve heat available in a ladle of iron it is advisable to use the alloy in a finely crushed condition, or even powdered, when the amount of iron treated is small, and to use an alloy of low melting point. The iron should be tapped out as hot as possible and a ladle used that has just been emptied in order to conserve as much heat as possible.

After the bottom of the ladle is covered with a few inches of iron the finely crushed or powdered ferro-vanadium is added by sprinkling on the stream as it flows down the spout to the ladle; in this way advantage is taken of all the available heat and also of the mixing effect of the stream as it strikes the iron in the ladle. After the vanadium is added the contents of the ladle should be well stirred and allowed to stand a few moments in order to insure thorough incorporation and complete reaction.

In the case of the higher-grade air-furnace iron, with its reserve of available furnace heat, the procedure is very simple. After the charge is melted and 15 to 20 minutes before tapping the ferrovanadium is added and the bath well stirred or

rabbled. The addition of 0.18 per cent to 0.20 per cent vanadium is recommended in this case, equivalent to 10 ounces to 11 ounces of 35 per cent ferrovanadium per 100 lb. of metal.

The American Vanadium Company has lately developed a ferrovanadium containing about 30 per cent to 35 per cent vanadium, 10 per cent to 15 per cent silicon, 5 per cent to 10 per cent manganese and 2 per cent to 5 per cent aluminium, which melts and dissolves readily in molten cast iron and has been giving very satisfactory results. In distinction from standard low silicon "Amervan" ferrovanadium this new alloy is called "Masvan."

Melting Non-Ferrous Metals in an Electric Furnace.

By CHAS. A. WEEKS, M. E.

In an address by Dr. J. W. Richards, of Lehigh University, at the convention of the American Brass Foundrymen's Association, held at Detroit, June, 1910, the possibilities of melting bronze and brass in an electric furnace were compared in a theoretical way with the present methods of melting these metals in oil-direct-fired and crucible coke or oil-heated furnaces.

For several years I have been investigating the use of an electric furnace for melting copper, monel metal, bronze, brass and zinc refining, in large units and on a commercial scale, comparing the costs of melting in my electric furnace with other methods of melting now in use, along the lines of Dr. Richards' address.

In order that this work be done in a large and original way, I designed and built an electric furnace with a crucible capacity of three tons of copper. My knowledge of non-ferrous metals melting caused me to take rather radical steps to prevent the copper and other volatilizable metal from being volatized as they would be in the general arc type of furnace. To prevent this burning of metal I designed a furnace which may be classified under the arc type, but in which the heat is transferred to the metal by radiation from the arc, together with some reflection and conduction from walls and roof of furnace. The furnace is entirely enclosed and the atmosphere is neutral, the furnace works very smoothly, heating any size of charge up to furnace capacity; it is built economically and with no lining complications, it is as simple as an open-hearth furnace.

The furnace used in making these runs was also provided with a condensing system for the treatment and recovery of zinc from zinc dross and zinc ores containing copper, iron, lead, etc. While unfortunately I was not able to treat ores at the time of running the furnace during July and August, 1910, yet at that time I made a very good zinc from impure zinc dross, and during the run made some 1600 lb. of zinc and no blue powder. Some zinc oxide was produced at vent of condenser, but this was wanted and expected. It is my belief that this is the largest amount of zinc produced in an electric furnace, without making blue powder, made at a commercial cost. The run was stopped at that time by reason of making more zinc than the condenser could handle.

Copper Melting.

A number of runs were made melting copper scrap in which charges of about 2000 lb. were melted. To melt and superheat to a temperature above 1600° C. from cold furnace required 600 kw-hours, and the metal was poured in 3½ hours. This temperature was considerably in excess of copper melting, using more power and longer time. The loss of copper with new lining was less than 1 per cent.

Melting another charge of 2000 lb. to temperature of 1200° C. required from cold furnace about 500 kw-hours, time three hours. Under operating conditions, that is, with a hot furnace and using charges of two tons or more, this figure would undoubtedly be cut down to 300 kw-hours or less per ton, metal heated to pouring temperature of 1200° C., with melting time about 2½ hours.

As no slag complications are involved, the furnace can be tapped into as many receptacles as wanted without power interruption; the copper can be poled at will and resulting tough pitch copper can be rested in the furnace indefinitely without becoming oxidized, since a blanket of charcoal may be kept floating on the metal to protect it from such slight amounts of air as do enter a practically tight furnace.

This furnace is entirely free from the very objectionable vaporization of copper as experienced with those furnaces in which the current arcs from the electrodes to the bath, with resultant danger to the operator, as noticed in the letter of Mr. C. A. Hansen in the February, 1911, number of this journal.

The above figures will apply to melting monel metal, the proper pouring temperature of which is around 1400° C. The melting of monel metal in an open-hearth or reverberatory furnace or in crucibles allows a very serious oxidation of the metal; as a general result the castings made are porous for high-pressure work. It is only necessary to say that melting this metal in a non-oxidizing furnace, such as my electric furnace, where the metal cannot be burnt or oxidized, the making ing large sound castings from this metal will be accomplished.

Bronze and Brass Melting.

In his address Dr. Richards gave 1 lb. of coke = 0.67 lb. of oil = 1.8 hp-hours or coke at $4 per ton = oil at $6 = power at $12.25 per hp-year. I have taken power at 1 cent per kw-hour and would say that while this cost seems low a well-known oil-engine concern will guarantee a cost of about ½ cent per hp-hour. Any large electric plant can sell power at this price at a profit for day load. In order to obtain some idea of the causes controlling oxidation and cost comparative runs on gas, coke and oil-fired furnaces show that oxidation varies approximately as the length of time required to melt; also in proportion to the square of the temperature. On this basis, comparing the electric furnace with direct oil-fired and coke-fired crucible furnaces, I have assumed for the former an oxidation of 0.7 per cent (actually 0.5 per cent should be taken).

Taking the amount of power necessary to melt one ton of bronze or brass at 150 kw-hours, I find a reasonable figure to be 190 kw-hours per ton in 1½ hours time.

For comparison with the above figures I will take figures given in a test of rival direct-heating oil furnaces. This test was made under the direct supervision of one of the best-known brass foundry superintendents, who is in charge of one of the largest foundries in the country.

This test was fair and the figures are presumably correct. The metal mixture was 66 parts of copper, zinc 34 parts, part scrap, gates, etc. Pouring temperature, 2135° F.; loss of metal through oxidation, 1 1/3 per cent; fuel, 36 gal. of oil per ton metal melted, at 3 cents per gal.; cost of lining, taken at 10 cents per ton.

Coke-fired furnace; coke $4 per ton; melting 8 lb. of metal to 1 lb. of coke, with oxidation 1 per cent; cost of crucibles $3 per ton metal melted, with copper at 13 cents per lb., zinc 5 cents per lb.

We thus get the following:

	Electric furnace.	Direct oil-fired furnace.	Coke-heated crucible furnace.
Cost of heat	$1.90	$1.08*	$0.50*
Oxidation	1.44	2.68	2.05
Linings	0.10	0.10	0.10
Crucible	0.00	0.00	3.00
	$3.44	$3.86	$5.65
Time of melting	1½ hours	2 to 2½ hours	2½ to 3 hours

While the electric furnace shows a lower cost and larger output, as above, melting in two-ton charges, the power cost

*Furnace builders' claim.

would be cut to 150 kw-hours or $1.50 per ton metal melted in 1½ hours.

Interest, depreciation or labor are not taken into consideration in above.

As is well known, copper, monel metal, bronze or brass cannot be melted in any type of fuel-fired furnace without oxidation, as the average crucible at red heat is metal-tight, but not gas-tight, gases readily finding their way through the pores of the crucible material. We also know that carbon dioxide gives up oxygen very readily to many metals, especially to zinc, being reduced to carbon monoxide, so that the fact of my electric furnace being sealed and non-oxidizing, makes it particularly valuable in melting non-ferrous metals.

The best furnace is the one that produces the best metal, from which the greater number of perfect castings can be made, in which the temperature is easily controlled, and in which a neutral atmosphere can be maintained for any length of time at required temperature without oxidizing and little loss of metal, in which metal can be treated or alloyed with large output without the production of deleterious fumes and with perfect safety to operator, I believe there can be no question as to the superiority of my arc-heat radiating furnace for the melting of non-ferrous metals in these respects. Compared with the direct oil-fired, coke or oil-heated crucible furnaces, it certainly makes better metal at a cost much less than was thought possible commercially. I here quote a paper of Dr. Richards and discussion as to actual present cost of melting yellow brass.

Efficiencies of Furnaces.

In a paper presented by Dr. J. W. Richards at the Pittsburgh meeting of the American Brass Founders' Association in May, 1911, the author explained what was meant by efficiency of industrial appliances, and cited examples of carelessness in describing the efficiencies of various products. Applied to furnaces, efficiency often means ratio of fuel to output.

Mr. Webster asked for information relative to the melting ratio of brass furnaces and stated that in using anthracite coal the usual ratio was from 2½ to 3 lb. of metal melted per pound of fuel. The question was then asked how this compared with regular practice, and Mr. W. M. Corse stated that with coke the average is 45 lb. per 100 lb. of metal = 2.25 lb. of metal per pound of coke.

Mr. H. P. MacKinnon, of the Hersey Manufacturing Company, South Boston, Mass., stated that he had melted 900,000 lb. of bronze for light castings, at an average consumption of 3¾ gal. of oil per 100 lb. of metal in a tilting furnace, and that approximately one-ninth of the metal was in form of borings. The cost of oil averaged 18 cents for 4½ gal., 75 gal. of oil melted 2000 lb. of metal at cost of 4 cents per gallon.

Mr. John A. Smith, of the American Air Brake Company, stated his fuel consumption was 3 gal. of oil per 100 lb. of metal in an open-flame furnace or 60 gal. per ton.

Fuel cost of melting 2000 lb. brass as above:

Coke, 900 lb., at $4 per ton	$1.80
Oil tilting crucible furnace, 75 gal., at 4 cents	3.00
Oil, open-flame furnace, 60 gal., at 4 cents	2.40
C. A. Weeks electric furnace, 1 cent per kw-hour, 190 or 150 kw-hours	$1.90 or $1.50

Temperature of yellow brass ready for pouring, 2000° F.

Refining of Zinc from Impure Zinc Dross in an Electric Furnace.

Some years ago several plants were erected, using methods and furnaces from my designs, for the work of recovering a pure zinc from impure zinc dross, purchased in open market, without selection.

The requirements of these plants were that the zinc recovered should be equal to the well-known horse-head brand of zinc in every way. The cost of refining to be low, production regular and furnaces of long life. I am glad to say that these conditions were met in every way, particularly as to furnace upkeep. The repair account in some five years has been less than 1 per cent of the first cost. As these furnaces have been under fire with heat high enough to volatize zinc, through retorts for a year at a time, they show fair construction. While the above is not under discussion I state it to show that I have some knowledge of this subject.

The greatest cost and uncertainty of the above process are the retorts, which are of small capacity, the largest size of retort holding 1000 lb. The cost of retorts per ton of dross charged is from $5 to $8 and in some cases where retorts are not properly treated the cost is greatly increased.

With a view of obtaining, if possible, a better product with larger charges, and in some cases to use a more impure dross and do away with retorts, I was led to design an electric furnace for this work, in which I could charge two to three tons, with an output of not less than 200 lb. of refined zinc per hour.

When I took up the construction of this furnace, which is of the arc type, from which heat is transferred to the charge by radiation from the arc, with some reflection and conduction from the furnace walls and roof, at that time (1905-6) the statement was made that all attempts to refine zinc metal from either zinc ores or zinc dross in presence of an electric arc had been failures, as the vapors were so superheated by the intense heat of the arc that it had been impossible to condense them; further, that when the zinc vapors did condense they produced blue powder. In this relation I would say that from the very first attempts I made to refine zinc dross, some ten years ago, I have never made during this entire period more than 5 lb. of blue powder in actual working.

As I was not particularly interested in blue powder and did want zinc metal, I was not interested in the failure of others. I built the furnace for this work, arranged to use a condenser, which I had having a capacity of 35 to 50 lb. metal per hour, intending to build a larger condenser later, with capacity of 300 lb. metal per hour.

After preliminary heating to dry out the lining and testing the working of furnace, which was found to operate very smoothly, we made several runs on zinc dross, and in the last run obtained over 1000 lb. of zinc metal. But owing to insufficient condensing capacity with an average output of 35 lb. per hour, and zinc being made so fast that metallic zinc jammed everything up, the run was stopped.

During the run no blue powder was made, liquid zinc coming off regularly for some 36 hours; during this time there was no adjustment or appreciable loss of electrodes.

To give some idea of the furnace working, I would say that with 80 kw input 35 lb. of zinc was obtained per hour; of this, by reason of the excessive overheating of the furnace, due to the small amount of zinc taken off, about 65 kw was lost by radiation and water cooling, leaving 15 kw available for distillation.

The cost of zinc production compares more than favorably with the present methods of zinc distillation, with the great advantage of treating dross on ores containing iron, copper, lead and other metals in large amount. While no attempt was made to obtain a great purity of zinc during these runs, nor using methods of refining as in my retort system, the zinc produced from the most impure zinc dross I have ever seen was more than good, as the following analysis shows:

Electric Furnace.

Charged Zinc Dross.		Refined Zinc Output.	
Lead	2.00%	Iron	.024%
Iron	6.50%	Lead	.666%
Zinc	85.50%	Cadmium	.105%
Undetermined	6.00%	Zinc by difference	99.205%

Retort Furnace.

Average Zinc Dross.		
Lead	.52%	Average zinc produced by my other process; zinc by difference 99.75 to 99.90.
Cadmium	.22%	
Iron	3.36%	
Zinc	95.90%	

From these analyses it will be seen that refining of zinc dross

into high-grade zinc in an electric furnace is a success. I believe that these runs made during July and August of 1910 produced the greatest amount of zinc metal made in an electric furnace without blue powder. As there was no change in the furnaces or condensers from their first design in 1905, there is no reason why these results could not have been obtained at that time.

Philadelphia, Pa.

The Phase Rule in Cyanidation.

BY H. B. LOWDEN.

It is not the purpose of this article to enter upon a scientific discussion of the phase rule as applied to the reactions occurring in the cyanide process, but rather to point in a general way to its bearing upon the conduct of operations in practical work. The object will be served by a consideration of the reactions between gold and an alkali cyanide if it is borne in mind that the influences at work in the treatment of silver ores by cyanidation are governed by the same laws.

Gold in ores when in contact with cyanide solution dissolves at a rate which decreases as the solution increases in precious metal content and becomes reduced in free cyanide. This decreasing rate of dissolution, analogous to the diminishing rate at which a salt dissolves in water as the point of saturation is approached, is well known, but if viewed in the light of the phase rule the reason for it is made clearer and the application of cyanide solutions to ores might in many cases be made more efficient.

Bearing in mind that dissolution will proceed until an equilibrium is reached between the undissolved metal, the metal in the solution and the free cyanide, and that as this equilibrium is approached the velocity of the reaction becomes reduced, it is easy to account for the relatively slight increase in extraction secured by prolonging treatment, as well as by the addition of fresh cyanide to solutions after being for some time in contact with the ores: the latter by reason of the fact that although the free cyanide is increased thereby, the alkali auricyanide remaining in the solution continues to exert an important influence on the velocity of dissolution. Were the alkali auricyanide removed from the field of the reaction, the velocity of dissolution would be increased by reason of the removal of that phase which, from its tendency to undergo the reverse reaction, exerts a detrimental effect by keeping the whole system near the point of equilibrium. An immeasurably small concentration of auric cyanide would suffice to bring the dissolution to a standstill were it not removed as rapidly as formed, by dissolution in the excess of alkali cyanide present with formation of the complex alkali auricyanide. Although this removal of auric cyanide is what renders the cyanide process possible, the fact should not be lost sight of that we have in the formation of alkali auricyanide only a system in which the permissible concentration is relatively large, and that while the tendency to the reverse reaction is, from a commercial standpoint, often negligible, there are nevertheless instances in which it should be given serious consideration.

A discussion of all the influences affecting these reactions, including those brought about as a result of working with such impure substances as ores, is unnecessary, and nothing would be gained by introducing complications which would only befog a clear view of the subject. The application of the phase rule points to the separation of ore from solution when the velocity of dissolution becomes low and the application of fresh solution in which the concentration of alkali auricyanide is small, and to the eventual attainment of a continuous cyanide process based on the principle of counter currents, in which the richest solution is in contact with the richest ore and the solution most free from alkali auricyanide is in contact with the ore after the dissolution of the greater portion of the values.

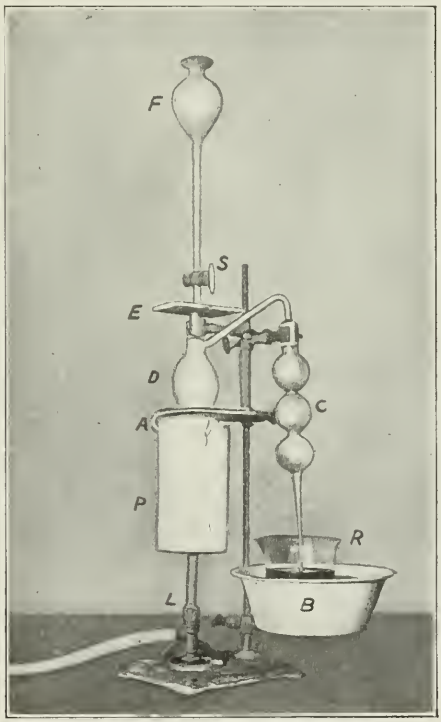
Denver, Col.

Determination of Arsenic and Antimony in Anode and Cathode Copper.

BY EDWARD F. KERN AND CHING YU WEN

In reviewing the literature on this subject, several methods were found and tried but none were sufficiently accurate for the separation and determination of arsenic and antimony in cathode copper of high purity. Some of these methods, which are in more general use, accomplish the separation of the arsenic and the antimony by distillation of the arsenic as arsenious chloride, which begins to distill at about 110° C.

These methods are in brief as follows: A sample of the copper is dissolved in concentrated nitric acid, after which about 1 gram of ferrous sulphate crystals is added, the nitrous fumes boiled off and the solution diluted. The iron, arsenic and antimony is precipitated with the addition of an excess



DISTILLATION APPARATUS.

of ammonia; thus, the arsenic and antimony is separated from the large quantity of copper, and are then separated from each other by distilling the arsenic as arsenious chloride.

These methods differ principally in the treatment of the iron precipitate, in the reducing agent used for the reduction of the arsenic, and in the procedure of the distillation.

Of these methods, the first that may be mentioned, was that which practically got rid of all the copper in the ferric hydroxide precipitate, first, by dissolving the iron precipitate with 50 c.c. of hot dilute solution of hydrochloric acid (1 acid to 5 water) through the filter, and precipitating it with concentrated NH_4OH while hot. The re-precipitated precipitate was dissolved with 20 c.c. of concentrated hydrochloric acid through the filter, and filter paper was washed with the same amount and kind of acid. This was then transferred into

the distilling flask which had previously contained 15 grams of ferrous sulphate, and distillation was made according to the method given by E. H. Miller,[1] which consisted of three intermittent distillations, using 50 c.c. concentrated hydrochloric acid each time.

The results obtained varied and were always low and showed that ferrous sulphate did not appear in this case to be a satisfactory reducing agent. Besides, the distillation, with ferrous sulphate as reducing agent, was difficult to control, because, as the solution became concentrated, it often happened that violent bumping was inevitable, sometimes so violent as to cause the distilling flask to crack

The combined reducing agents, composed of stannous chloride and ferrous sulphate, were next employed, and the object of using the former salt was to decrease the amount of the latter. The solution containing iron, arsenic and antimony was first reduced by adding, drop by drop, a saturated solution of stannous chloride in concentrated hydrochloric acid until it became colorless, and then transferred into the distilling flask containing 7 grams of ferrous sulphate crystals. The distillation was made as before. But this also proved unsatisfactory in that the results were low, varying from 15 per cent to even 50 per cent.

The unsatisfactory results in this case were, perhaps, due to the excess and strong action of stannous chloride, which caused over-reduction of the compounds to their metallic state and these reduced metals remained undissolved even in a concentrated solution of hydrochloric acid, as black particles were observed in the flask during and after the distillation. Another objection to the use of stannous chloride was that it complicated the determination of antimony. A. E. Knorr[2] thinks that stannous chloride is not a good reducing agent to use for the determination of arsenic, because of the volatility of chloride of tin.

Both sodium thiosulphate and ferrous sulphate were also tried, singly and combined. The iron precipitate with the filter papers, in this case, was treated with 20 c.c. of concentrated nitric acid in a 350 c.c. casserole covered with a watch-glass. It was digested and evaporated on a hot plate until it became a pasty mass. After addition of 3 grams of potassium bisulphate ($KHSO_4$) and 10 c.c. of concentrated sulphuric acid, it was carefully heated over a free flame until fume of sulphuric anhydride was strongly given off. The solid mass, after being cooled, was taken up with 30 c.c. of concentrated hydrochloric acid and distilled as before, using either 1 gram of sodium thiosulphate, or a mixture of 0.7 gram of sodium thiosulphate and 7 grams of ferrous sulphate crystals.

The low result obtained by this method might be due partly to the loss of solution by spattering during evaporation to dryness and partly to the interference of the sulphur dioxide which was liberated by the decomposition of the sodium thiosulphate. A saturated solution of sodium thiosulphate, instead of solid sodium thiosulphate, was also tried and the reduced solution in the distilling flask was boiled for a few minutes before addition of the hydrochlorous acid, in order to expel any sulphur dioxide that might be present. But this procedure also failed to give satisfactory results, they being low, and varying from 20 per cent to 60 per cent.

Thus it is seen that the methods mentioned above did not give satisfactory results, so other reducing agents were tried, with the outcome that the following modified method, which proved to give accurate results, was finally adopted. It is as follows

A sample of about 10 grams, in the case of anode copper, and from 30 grams to 10 grams, in the case of cathode copper, depending upon the amount of arsenic it contained, was weighed out and dissolved in a No. 6 beaker with concentrated nitric acid (45 c.c. for 10 grams of copper). The beaker was covered with a watch glass and warmed on a hot plate in order to hasten the dissolution of copper. When the solution was complete the beaker was removed from the hot plate and about 1 gram of ferrous sulphate added. The beaker was again heated to expel the red fume. The solution was then diluted to 400 c.c. or 500 c.c. and warmed. The iron, arsenic and antimony was precipitated with strong ammonium hydroxide. Sufficient excess was added to dissolve all the copper compounds.

The precipitate was allowed to settle, decanted, filtered while still warm and finally washed with a hot solution of ammonia (10 water to 1 ammonium hydroxide, sp. gr. 0.9). The precipitate, together with the filter paper was transferred into a No. 1 beaker covered with a watch glass, and digested gently on the hot plate with 20 c.c. of concentrated nitric acid, until practically all the red fume was driven off. (Care should be taken not to heat the solution vigorously lest some of it would be lost by spattering.)

After cooling the solution 10 c.c. of concentrated sulphuric acid was added and the beaker was re-heated on the hot plate till fume of sulphuric anhydride freely evolved. It was then allowed to cool and about 5 c.c. of a 10-per cent solution of hypophosphorous acid, or 6 c.c. of a 20-per cent solution of potassium hypophosphite was added (provided the solution did not contain more than 0.3 of a gram of arsenic).

The solution was again heated on the hot plate until all the excess of the hypophosporous acid, or potassium hypophosphite was destroyed; this was indicated by the evolution of strong fume of sulphuric anhydride. (In order to be sure of destroying the excess of the reducing agent let it fume for at least one-half an hour.)

The content in the beaker after cooling was transferred into the distilling flask (*D*, Fig. 1), the beaker was then rinsed twice with only 10 c.c. of water. The distilling flask was gently heated to boiling, with a smoky flame, in order to expel any sulphurous-acid gas that might be present in the solution. Bumping of the solution sometimes occurred and was prevented by imparting a rotary motion to the solution. It was then allowed to cool. After cooling any solution that was left in the beaker was rinsed into the distilling flask twice or three times with 30 c.c. of concentrated hydrochloric acid, making a total of not over 10 c.c. water and 40 c.c. concentrated HCl.

The apparatus, as is shown in Fig. 1, was now connected and adjusted: the receiver *R* (a No. 4 beaker), containing about 250 c.c. of water, was placed in a bath of cold water, *B*, and under the condenser, *C*, the tip of which was immersed into the water to a depth of about ⅛ in. Ten c.c. of concentrated hydrochloric acid was poured into the funnel, *F*, and allowed to run slowly into the distilling flask, *D*, through the stop-cock, *S*, in order to drive off the air in the lower part of the stem of the funnel, which would disturb the regularity of the acid feed. The stop cock was closed and the funnel filled with 80 c.c. of concentrated hydrochloric acid. Now heat was applied, first with a smoky flame, and when the solution began to boil was gradually increased until a proper flame was adjusted.

The hydrochloric acid in the funnel, *F*, was now allowed to run into the flask, drop by drop, at such a rate that the liquid volume in the flask might be during the entire distillation, maintained approximately constant. (The rate was, usually, three drops per two seconds.) When the acid in the funnel, *F*, was nearly exhausted, the distillation was complete. The receiver, *R*, containing the distillate was carefully removed and then the flame was turned off. The content in the distilling flask was left in place to cool and reserved for the determination of antimony.

The distillate was transferred into a No. 6 beaker and nearly

[1] "Quantitative Analysis for Mining Engineers," E. H. Miller, ed. 1904, p. 116.
[2] Private communication.

neutralized with a strong (30 per cent) solution of potassium hydroxide and the neutralization completed with a saturated solution of sodium bicarbonate, the addition of an excess of 70 to 80 c.c. being necessary. The neutralization was done by placing the beaker in a bath of cold water, in order to keep the solution cool while the neutralization was taking place. The neutralized solution was then titrated with a standardized solution of iodine (N 10.) Starch solution was used as indicator.

Precautions in the Distillation Method of Arsenic.

The analysis of arsenic by the above method requires careful manipulation. In order to do it successfully it is of much importance that the quantity of hypophosphorous acid, or potassium hypophosphite, added for the reduction should be limited to as small amount, as given in the above procedure; otherwise it reduces not only the compounds of arsenic and antimony to their metallic state, but also those of other metals, such as iron, copper, etc.

Over-reduction, according to A. E. Knorr[3], would fail to give satisfactory results, even though the metallic arsenic and antimony would afterwards re-dissolve in the concentrated hydrochloric acid solution. It is also important that complete destruction of the excess of hypophosphorous acid, or potassium hypophosphite, should be accomplished before the transference of the reduced content (solid salts and solution) into the distilling flask takes place. Any of either reducing agent remaining undestroyed will interfere with the determination and the result will in all cases be low.

The advantages of having a continuous acid-feed, during the entire distillation, are great and manifold. In the first place, the temperature may be properly regulated, secondly, the strength of the hydrochloric acid in the distilling flask may be maintained to prevent the reversible action, which may be shown by the following chemical equation:

$$As_2O_3 + 6HCl \leftrightarrow 2AsCl_3 + 3H_2O.$$

and, finally, a more rapid and effective distillation may result and, therefore, much time may be saved.

In order to secure a steady flow of the acid-feed, a grooved rectangular board of asbestos, *E*, is placed on the mouth of the distilling flask, so as to prevent the heating of the stop-cock, which would, otherwise, cause irregularity of the flow. Back-suction is the chief cause of failure. It is caused either by draught or by variation in the flame, which supplies insufficient heat. To prevent the former it becomes necessary to protect the flame from draught by suspending under the ring, *A*, an asbestos cylinder, *P*, 4½ in. high and of the same diameter of the ring. To prevent the latter, the flame should be carefully regulated from time to time. In this way back-suction is less liable to occur and success may be insured. If the distillate is once sucked into the flask, re-distillation proves absolutely fruitless, because arsenous chloride refuses to distill in such dilute solution.

The distillation apparatus was made by E. Machlett and Sons, glass-blowers, at 143 East 23rd Street, New York City. It is known as the Knorr Arsenic Distillation Apparatus.

Test of the Above Methods.

The accuracy of the above method was tested according to the following procedure: A weighed sample of about 0.1 gram of c.p. arsenous oxide was dissolved in 10 c.c. of sodium hydroxide. When the solution was complete 50 c.c. of concentrated nitric acid was added and then 20 c.c. of saturated bromine water in order to oxidize the arsenic to the higher state. The solution after an addition of about 1 gram of ferrous sulphate was heated to expel the excess of bromine, and after adding 15 grams cupric sulphate to the solution it was diluted to about 300 c.c. and heated to boiling. The iron and arsenic was precipitated with concentrated ammonium hydroxide and the red precipitate was treated in the same way as above described.

[3] Private communication.

In testing this method both potassium hypophosphite and hypophosphorous acid were employed as reducing agents. In the case in which potassium hypophosphite was used the amounts of arsenous oxide taken for analysis were 0.1004 gram and 0.1014 gram, which corresponded to 0.076 gram and 0.077 gram of arsenic respectively, and the analyses gave 0.070 gram and 0.072 gram of arsenic. In the case where hydrophosphorous acid was used the amounts of arsenous oxide were 0.1027 gram and 0.1014 gram which corresponded to 0.078 gram and 0.077 gram arsenic while the analyses gave 0.070 gram and 0.071 gram of arsenic. The values in both cases approximated the calculated values of arsenic.

Determination of Antimony.

For the determination of antimony Weller's[4] method was adopted. After the separation of arsenic by distillation the content in the distilling flask was transferred into a No. 5 beaker and diluted to about 400 c.c. The antimony, together with the copper, was precipitated in warm solution with a stream of hydrogen sulphide which continued to pass until the precipitate settled down and the solution became clear. The precipitate was separated first by decantation and then by filtration, and washed three times with hydrogen-sulphide water. It was placed with the filter paper in a No. 2 beaker and treated for an hour at room temperature with 40 c.c. of potassium sulphide (10 per cent) solution. The copper sulphide was filtered off, washed three or four times with hydrogen-sulphide water and discarded. To the filtrate now contained in a No. 5 beaker 50 c.c. of dilute sulphuric acid (1 acid to 4 water) was added to precipitate the antimony. The yellow precipitate was filtered off and washed with hydrogen-sulphide water three times.

The antimony sulphide, together with the filter paper, was placed in No. 2 beaker, treated with 40 c.c. of concentrated hydrochloric acid and oxidized to the pentad state by adding, little by little, about one gram of potassium chlorate, and the solution was heated to expel the free chlorine. (During the heating, should the solution show a dark coloration, more potassium chloride should be added.)

After oxidation and the complete solution of the antimony sulphide, the filter paper was filtered off and washed three or four times with a hot dilute solution by hydrochloric acid (1 part acid to 3 parts water). The filtrate was evaporated to 50 c.c. so as to make the solution to contain a constant quantity of hydrochloric acid. Twenty c.c. of concentrated hydrochloric acid was added and the solution diluted from 600 c.c. to 700 c.c. After the addition of 3 grams of potassium iodide crystals the solution was thoroughly stirred until the potassium iodide completely dissolved. It was then titrated at room temperature with a standardized (N 10) solution of sodium thiosulphate, starch solution being used as indicator.

As the liberation of all iodine does not take place instantaneously it is, therefore, necessary to titrate the solution slowly, that is, the thiosulphate solution should be run into the solution drop by drop until the blue color disappeared at least for one minute. Should, in any case, the blue color return immediately, more thiosulphate solution should be added. *Metallurgical Laboratory, School of Mines, Columbia University, New York City.*

Metallurgy at Cobalt.—In the sixth annual report of the Nipissing Mines Company it is stated that the company has erected a small plant at the mine to test on a working scale a process devised by Mr. Charles Butters for the treatment of high-grade cobalt ores. This is in accordance with the desire of the company to find some means of reducing to bullion the silver in the high-grade ores without the expense incidental to a regular smelting plant. The present experiment is said to be satisfactory as far as tested and bullion is being shipped.

The Electric Iron Reduction Plant at Trollhättan, Sweden—I.

At the meeting of the Jernkontoret (the Swedish Association of Iron Masters) at Stockholm on May 31 a report was submitted by the engineers in charge of the electric iron smelting plant at Trollhättan, Messrs. J. A. Leffler and E. Odelberg; this report being the first official publication in regard to the construction of the plant, its operation and the results obtained during the first six months of operation.

The following abstract of this report will give an account of the construction of the plant and will in part cover the operation. In our next issue the report of the operation will be concluded and the results of the operation will be given.

There is no necessity to give here an account of the former work done in Sweden on electric iron ore reduction by the Grönwall, Lindblad and Stalhane (A. B. Elektrometall) process, as this has been fully covered in former issues and volumes of this journal. A concise historical review of the process, for which the British, United States, Mexican and other rights have been acquired by Electro-Metals, Ltd., 9½ Union Court, Old Broad Street, London, was given in our March issue (this volume, page 163). In the following we give simply from Mr. Leffler's paper an account of the experience with this process at the Jernkontoret plant at Trollhättan.

The most important points to be investigated at this plant were the folllowing:

The proper height of the furnace and other dimensions most suitable for different purposes and different charges; the most suitable design and way of building; consumption of electrodes and the shape and arrangement of electrodes; energy consumption per ton of iron of certain composition; coal consumption per ton of iron of certain composition; circulation of gas, its significance for the economy and means to accomplish circulation in case of choking charges; manufacturing of iron of different composition; conduct of various charges and concentrates and the influence of same on the economy; value of escaping gases; efficiency of the furnace; maintenance cost at the furnace.

Naturally, certain of the above questions cannot be answered definitely after six months of operation, but the experiments are to be carried on and questions which are now vague will undoubtedly have their final solution within a not far distant future. The observations made so far will greatly serve the industry as they have been made under almost ideal conditions, with greatest care and accuracy, by aid of the best instruments, and under the supervision of a highly efficient staff of engineers.

Location of the Plant.

The plant is located at Trolhättan on grounds owned by the Swedish government by agreement with the Royal Water Power Commission and will be retained until Oct. 1, 1912.

The distance from Trollhättan railway station is about 1 mile, the works being connected with this station with a normal-gage railroad track. Two sidetracks are laid to the site, one being for transport of fuel to the fuel storage house and the other for transport of other materials to the works and of iron from the works.

The fuel is charcoal, which is conveyed from the railroad trucks into the storage house by two band conveyors of cold-rolled steel. From the storage house the charcoal is elevated to the furnace top in suspended baskets running on a wire rope.

The ore is barrowed in the usual manner from ore heaps to the crusher plant, from which it is elevated to the furnace top in a truck running on an inclined track.

A narrow-gage track has been constructed for transport of iron and slag to the iron storage and slag tip respectively.

The *coal-storage house* has the following dimensions: Length, 48 m; width, 21 m, and height to the eaves, 10 m. It has a capacity of about 7000 cu. m, which approximately corresponds to six months' consumption. The charcoal is shoveled from the railroad cars into wooden hoppers under which the band conveyors run, conveying the charcoal into the storage house. The band conveyors from the hoppers to the storage house have an inclination of 1:4.4 (13°) and run in wooden troughs, the sides of which are removable so that the charcoal can be unloaded by means of a scraper at any desired point.

The steel bands are 400 mm broad and 0.95 mm thick. Each conveyor is made of three lengths of such steel bands riveted together and has a total length of about 170 m. A 16-hp motor is provided for driving, but the actual power required for one conveyor is about 7 hp and about 10 hp for both conveyors working simultaneously. The speed is 0.45 m per second, and the average carrying capacity of each conveyor is about 20 cu. m per hour.

Crushing Plant.—The dimensions of the jaws of the crusher are 550 mm x 300 mm. The machine is placed on a concrete foundation, so that the working floor is about 2.75 m above the ground level. The barrows are dumped outside the house into an elevator truck, which brings the ore up to an incline along which it slides into the crusher. The crushed material falls into a sheet-iron hopper. In this hopper a sufficient quantity is collected to fill the elevating truck to the furnace top. The door at the bottom of this hopper is operated from the working floor, and the man in charge of the crusher also regulates the elevator to the furnace top. A 40-hp electric motor is provided for driving the crusher and its elevator.

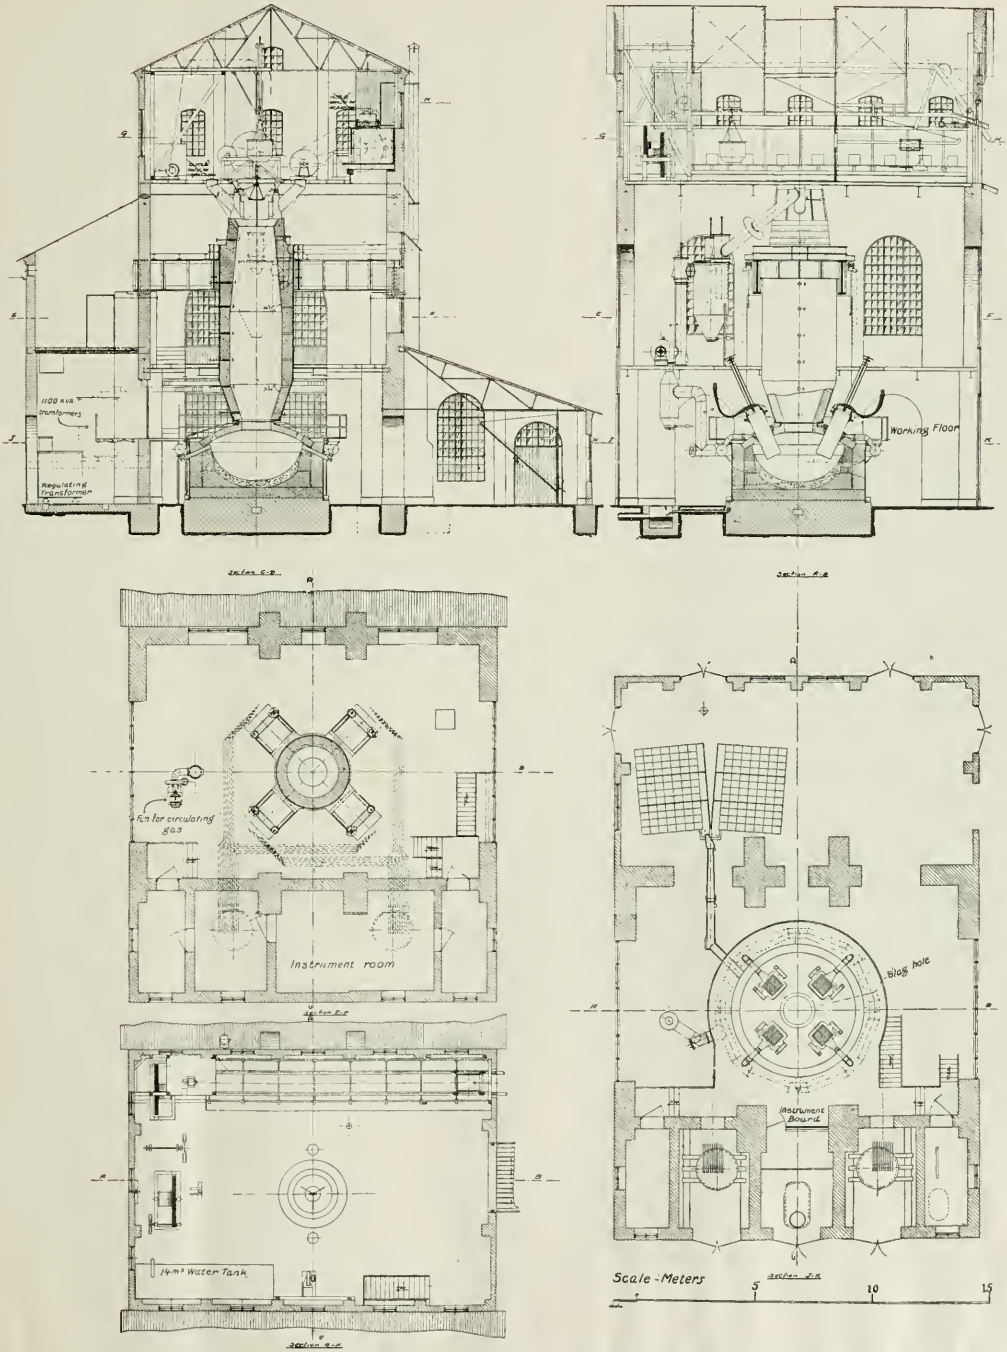
The *furnace house* has a floor space of 24 m x 15.5 m. The height from the ground floor to the furnace top is 13.7 m, and the total height to the eaves is 21 m. With regard to the electric installation, the high-tension apparatus and transformers are placed in a separate section of the building. From the two transformers for the furnace the low-tension conductors enter the furnace house proper through two openings in the wall.

The construction of the furnace is shown in Fig. 1. In this construction of furnace two separate portions are to be distinguished—that is, the shaft and the crucible or hearth. The shaft consists of a shell of steel plates 10 mm thick around the stack and 12 mm around the bosh. At the top it is riveted to an octagonal supporting ring of channel iron, on which the shaft is supported. The walls of the house on both sides of the furnace are built out at four places as suporting pillars. At a height of 9 m from the ground level they support two built-up beams, 1300 mm high, with a free length of 10.6 m. Around the furnace these are joined to form an octagon on which rests the channel-iron ring mentioned above.

The shaft is lined with Höganäs firebrick to a thickness of 360 mm in the bosh and 450 mm in the stack. At the top of the shaft is placed a Tholander charging bell and cone, which is raised and lowered by means of a capstan driven by a 2½-hp reversible three-phase motor. The cone is connected to the capstan by a 12-mm wire rope provided with a hook, which is removed between the charges so as to be out of the way of the coal baskets which pass close to the center line of the furnace.

The crucible rests on a concrete foundation. Like the shaft, it is surrounded by a sheet-iron shell 15 mm thick. At the top this shell is reinforced by a 200-mm x 18-mm iron band to take up the pressure of the arched roof. The lining of the hearth is of Höganäs and Stabbarp firebrick next to the shell and foundation with an inner lining of magnesite brick, while the dish-shaped bottom is formed of a mixture of magnesite and pitch rammed in so as to extend for some distance up along the walls. The roof is constructed of Ifö firebrick. The hearth and shaft are joined by means of a sand seal.

The four electrodes project through the roof in a slanting position at an angle of 65° to the horizontal. Each electrode is built up of four carbons of square total section of 660 mm x 660 mm. At the openings in the roof the electrodes are surrounded by cooling jackets of copper provided at the top with asbestos packing to prevent the leakage of gas. The connections to the electrodes are arranged at their upper ends and



ELECTRIC FURNACE PLANT FOR IRON ORE SMELTING AT TROLLHÄTTAN.

wedged between the electrodes and a holder of cast steel. This holder is supported on a frame movable up and down between two guides placed on each side of the electrode.

In this process gas is drawn by means of a fan from the gas outlets and blown into the crucible. Consequently the quantity of gas passing any given section of the shaft can be varied within certain limits by varying the speed of the fan.

This circulation of gas has two special objects:

a.—The gas blown into the crucible is there heated and gives off its heat to the charge in the shaft in passing up through it. Through this heating of the charge in the shaft a reduction of the ore by CO is facilitated, so that this gas is utilized to some extent for the process.

b.—The second purpose of the circulation of the gas is connected with the construction of the crucible, as the gas cools the roof and thus protects it from overheating. This cooling action of the gas is due in part to the absorption of heat, raising its temperature, and in part to the decomposition of CO_2 and H_2O in the gas in contact with the incandescent carbon in the crucible.

The arrangement of the gas pipes is shown in Fig. 1. From two gas outlets at the top of the shell the gas passes into a large dust-collecting chamber and from this chamber the circulating gas is drawn by the fan, which blows it into a circular pipe surrounding the furnace. From this pipe it finally enters the furnace through four tuyeres. The volume of gas corresponding to the gas formed escapes from the dust-collecting chamber through a pipe extending above the roof of the building and burns there.

In Fig. 1 four gas pipes are shown leading into the cooling jackets around the electrodes. These pipes were, however, soon disconnected, as it was found that the electrodes were attacked too strongly by the carbonic acid in the gas blown through them. The original intention of introducing the gas around the electrodes was to cool them as well as the surrounding brickwork.

The fan was designed for a speed of 2500 r.p.m. and a consumption of 8 hp and to deliver 70 cu. m of gas per minute against a back pressure of 325 mm of water, the temperature of the gas being assumed at 200° C. and its composition to be equal volumes of CO and CO_2.

The arrangement of tap hole, feeders and pig beds is also shown in Fig. 1. The iron is conducted in trenches of a total length of about 6 m to a small swinging spout in the foundry. There are six beds arranged in two rows of three beds each containing twenty-eight pigs. Each section is provided with its distributing feeder, to which the iron is conducted through the swinging spout. For tapping of the slag the crucible is provided with a slag hole from which the slag is tapped into slag bogies of ordinary construction. During a large part of the time the charge has, however, been high in iron and the quantity of slag correspondingly small. Under these conditions separate tappings of slag have not been made, but the slag which has accompanied the iron has been skimmed off and allowed to flow into a sand trench.

Among the arrangements at the furnace top the charging arrangement and provision for lifting the ore have already been mentioned.

The ore boxes are constructed of 2-in. boards. They are eight in number, and each has a capacity of 3.8 cu. m. Their total capacity is, therefore, about 70 tons of ore. A tipping wagon runs on a track above the ore boxes and into this wagon the elevator truck discharges the ore.

Two capstans are placed on the top platform, one for elevating the ore truck from the crusher and the second for bringing up the charcoal baskets. Both are driven by one 16-hp motor.

In one corner of the top floor is a water tank of 14 cu. m capacity. Water is pumped from the Stallbacka canal close to the works. The pumping plant contains two centrifugal pumps (one as a standby), each having a capacity of 1500 liters per minute. Of this quantity 625 liters per minute are for the requirements of the plant and the remainder is at the disposal of the adjoining works of the Trollhattan Elektrothermiska Aktiebolag.

The office building is located at the south corner of the site and also comprises the watchman's room, laboratory and storerooms. On the other side of the furnace house is a smaller building which contains a small repair shop and a shop for storing and fitting the electrodes. A grinding mill is also placed there.

The electric energy for the plant is obtained from the government's power station at Trollhattan and is three-phase alternating current of 25 cycles and 10,000 volts tension.

The two furnace transformers are each of 1100 kva with a guaranteed overload capacity of up to 1375 kva under one hour. They are coupled according to the well-known Scott method, giving secondary two-phase currents. Regulation is possible between 50 volts and 90 volts in eight stages and by different connections of the secondary coils, also from 100 volts to 180 volts. The voltage can be regulated during operation.

When the plans were first made for this installation there was some doubt whether such regulation should prove satisfactory and a special three-phase regulating transformer was installed to be coupled direct before the furnace transformers and thus giving these varying voltages. As soon as this plant commenced operations it was shown that the simple regulation direct on the furnace transformers was very satisfactory and the regulating transformer has never been used. This transformer has lately been exchanged for an 1100-kva single phase transformer designed to serve as reserve for both main transformers.

The low-tension conduits from the transformers are taken through the wall into the furnace-room. These conduits consist of six copper bars, 8 mm x 200 mm, for each electrode. These bars are supported on insulated clamps of brass. The energy is conducted to the four electrodes through 192 flexible cables (forty-eight per electrode). Each cable has an area of 185 sq. mm.

The instruments required for observing and regulating the working of the furnace and electrodes, together with all handles and hand-wheels for regulating the current, are placed on an instrument board on the working floor. In the so-called furnace office on the floor above are placed the self-recording kilowatt meter (showing the power consumption for the *furnace* only) and two kw-hour meters with a maximum indicator.

In the same room are placed two galvanometers for the eight thermoelectric pyrometers which measure the temperature in the furnace at the places indicated in Fig. 1.

At the side of each pyrometer hole on the furnace is a smaller opening which was used for observing the gas pressure and for collecting samples of gas.

Ordinary U gages with colored water are permanently connected to the furnace top, the discharge side of the fan and to a hole on the roof of the crucible. A "Mono" apparatus for a maximum of 60 per cent CO_2 records the percentage of CO_2 in the gas taken from the discharge side of the fan and the pressure is registered by a recording gage. The pressure due to the speed of the gas returning to the furnace is measured at an opening on the suction side of the fan, where the temperature of the gas is also determined by a mercury thermometer. The "Mono" apparatus, the gas calorimeter, the recording gas pressure gage, the speed gage and a gas-analysis apparatus of Sonden's type are placed in the room close to the furnace office, and are there easily accessible for the engineer in charge, who usually remains on the operating floor.

In electric pyrometers platinum-platinum-rhodium elements and silver-constant elements are used, the former in the lower and the latter in the upper part of the furnace. They are arranged to record the temperature every ten minutes. For

determining the temperature of the iron and slag on flowing from the hearth an optical pyrometer of Siemens & Halske's make is used. For the direct determination of the calorific value of the gas a gas calorimeter of Dr. H. Strache's, Vienna, construction is used. The quantity of gas passing through the gas pipes is determined by means of Krell's pneumometer and micromanometer. It has so far been impossible to use the recording instrument for determining the speed of the gas owing to the soot and dust carried over by it.

Cost of Construction.—In the estimate of Oct. 16, 1909, the total cost of the works was estimated at $60,700, and the association appropriated a sum of $69,000 for the installation.

The accounts show, however, that the actual cost amounted to $88,500. The excess in cost was caused by the whole construction being carried out in a more elaborate and substantial manner than was at first contemplated. The furnace house, for instance, was first intended to be constructed partly of wood, but has been built entirely of brick and steel construction, and the furnace shaft instead of being supported on a steel framework from the ground is supported on heavy beams resting on the brick walls.

Management of the Works.—The management of the plant is in the hands of a committee appointed by the association and consists of Major-General G. Geijer, Mr. Aug. Herlenius, chamberlain to H. M. the King, and Messrs. J. A. Brinell, chief engineer of "Jern-Kontoret," Axel Wahlberg and E. Odelberg, the last named acting as managing director for the committee.

At the works the management has been in the hands of Messrs. J. A. Leffler and E. Nyström, both engineers on the staff of "Jern-Kontoret," the former acting as general manager and the latter as superintendent.

The employees at the furnace consist of three men for charging, two for bringing up charcoal, four for crushing and bringing up ore, five furnacemen, three men for fitting electrodes, two for weighing iron and slag, one blacksmith, one blacksmith's helper, one electrician, five men for loading and unloading, one carpenter and one watchman and messenger.

The report will be concluded in our next issue, when the following subjects will be taken up: The principles of the reduction furnace; principles employed for calculating the form and dimensions of the shaft; charcoal, ore and limestone; electrodes and electrode consumption; the charges; the durability of the crucible and roof; iron and slag; composition and pressure of the furnace gas, and notes relating to working results.

Electric Furnaces for Molten Materials.

BY CARL HERING.

To design an apparatus as perfectly as possible one should first find what the desired ideals are and then endeavor to reach them as closely as practicable and in proportion to their importance.

The chief desirable ideal features of a commercial electric furnace for molten charges seem to be the following: Greatest possible economy in power; greatest possible rapidity of treatment, hence greatest tonnage per day for a given furnace; heating from the bottom instead of from the top; no higher temperature than that actually required; rapid and uniform distribution of the heat; rapid circulation to produce greatest possible homogeneity of product; largest possible surface of contact between the metal and the slag when the treatment is dependent upon the chemical action of the slag; heat transmitted from the metal to the slag rather than the reverse; greatest possible reduction of the troubles, cost and power losses due to the electrodes possibility of adding fuel heat; ease of control; reliability of operation; simplicity and cheapness of construction and operation.

The economy of power involves numerous features. The ideal method of heating is to generate the heat in the material itself, where it is wanted, as distinguished from generating it elsewhere and transmitting it to the material by radiation or conduction. There will then be no waste, as the efficiency of the utilization of the heat will be 100 per cent—that is, theoretically perfect. It is done in this way in the induction furnace, as also in all other resistance furnaces in which the material treated is itself the resistor. In the arc furnace whatever heat is generated in the arc itself and in the electrode can reach the material only by radiation and then only when the temperature is higher than that of the material.

To always pass the current through the whole charge means either a constant depth of bath, which excludes feeding with solid material, or else it means a provision for the regulation of the current through very wide limits, hence large and expensive machinery. For these reasons it seems preferable to pass the current through only a small portion of the charge, which portion is always constant and is independent of the depth of the bath. But this becomes practicable only when this small heated portion is continually and rapidly removed as soon as it is heated and is replaced by cooler material, otherwise it would soon be volatilized, which would break the circuit, injure most linings and possibly produce explosions. In other words, this is operative only when there is a circulation through the channels containing the portion of the charge which is being heated, and if such circulation is not very rapid, the furnace will necessarily either be a large slow-acting one, or the heated material will get too hot for the lining; circulation by gravity due to the heated material rising would be far too slow for a commercial furnace. The lack of means for producing a rapid circulation through such restricted resistor channels seems to have been the reason why this very desirable method had not come into more general use.

To further increase the heat economy the top surface of the charge and that exposed to the walls should be as small as possible for a given charge, as the losses of heat from an internally heated charge are due entirely to these surfaces and to the electrodes; they are less the smaller these surfaces are The ideal shape of the charge would therefore be a sphere; this, of course, is not practicable, but the shape should approximate to it as closely as possible, say, by making the charge the shape of a hemisphere if practicable instead of having the hearth large, flat and shallow.

These losses from the surfaces of the charge seem to be far greater than is generally supposed, hence in addition to reducing these surfaces as much as possible the wall thicknesses should be made as great as practicable, and of the best heat insulating material; bricks are cheaper than kilowatts, and they represent only a first cost, while the kilowatts lost are a continuous cost. There should also be as many joints between bricks as possible, transversely to the direction of the flow of heat, as joints seem to be excellent and cheap heat insulators and take up practically no space. The usual heat insulation of combustion furnace is very crude and wasteful and would be very inadequate for electrical furnaces in which those constant losses have a far greater money value.

Still further heat economies will be obtained the more rapid the treatment; these losses through the walls and electrodes evidently continue during the whole time of treatment, hence if its duration is reduced these important losses will be reduced in the same proportion. Hence it is very important that the heating should be done as quickly as possible and that everything possible should be done to hasten the various actions which bring about the melting and refining. If, for instance, it takes 50 kw merely to keep a ton of steel at the desired temperature during refining, which means that these losses amount to 50 kw per ton, then if the time necessary for treatment could be hastened so as to be only half as long, for instance, the energy required (in kw-*hours*, not in kilowatts) would evidently be only half as great. It is in this increase in rapidity of treatment that probably the greatest improvements in the reduction in power will be made in the future. It increases the

tonnage *per day* delivered by a given furnace. A small, rapidly acting furnace could produce the same tonnage per day as a large slow acting one, and the leakage losses of heat will be less per ton.

Attention need hardly be called to the fact that, as most hot materials rise it is far better, more rational and much more rapid to heat from the bottom instead of from the top whenever practicable. Heating a liquid by means of the arc, or by means of directly impinging gases, as in the open-hearth furnaces, must necessarily always be done from the top, hence the rapidity of the heating is then limited by the necessarily slow conduction of heat from the top to the bottom. Cases have occurred in which pieces of metal in the bottom of the charge were still unmelted, although the refining of the top of the charge had been completed. The ideal method is unquestionably to heat from the bottom. This becomes possible with some types of resistance furnaces.

Owing to these continuous losses, which are by no means small, the temperature ought not to be any higher than that required for the desired reactions, as these losses increase when the temperature rises. In the resistance furnace the temperature is generally within one's control, while with the arc it is the boiling point of the electrode material, hence generally far higher than required and the radiation is also to the sides and roof, where it is not only not wanted and is lost, but where it sometimes even acts destructively.

The more rapidly and uniformly the heat is distributed throughout the mass the more rapid will be the treatment and the less will be the leakage losses, as the temperature will be lower and the time of treatment less.

Homogeneity of the product is often of prime importance, particularly in steel refining. Complaints have been made that the metal at the bottom of a hearth of an arc furnace sometimes has a very different composition than that at the top. Moreover, an overtreatment of the metal at the top in order that after mixture with that at the bottom it will have the right composition, is a makeshift, and involves the element of chance to a great degree. Hence, circulation is very desirable.

Moreover, materials are already in use which when introduced into molten steel cause some particular refining action, and it is quite likely that more such materials will be forthcoming. When quickly and thoroughly mixed throughout the whole mass the time necessary for the reactions should be proportionately reduced, thereby decreasing the losses of heat, increasing the tonnage of a furnace per day (or reducing the size of a furnace for a required daily tonnage) and delivering a more uniform product.

The same applies to the alloying materials which are sometimes introduced into the molten metal; some of these tend to float and others tend to sink, hence circulation is very important.

When the refining is dependent upon the chemical action of the slag, as in steel refining, it is evident that such an action can take place only at the surface of the contact of the metal and the slag. Hence, the time necessary for such refining would be less the greater this surface. To have such large surfaces in a bath in which the renewing of this surface is accomplished chiefly or only by gravity would mean that the continuous losses of heat would be relatively very large. It would, therefore, be far more desirable to have the dimensions of this chemically active surface small and then increase the actual and effective surface by continually renewing it as, for instance, by circulating the metal rapidly in a more or less vertical direction up against the blanket of slag.

Rapid circulation is, therefore, of the very greatest importance in such electric furnaces for numerous different reasons.

It is claimed by steel makers that steel must be left standing in a quiescent state for quite a time while in a molten condition; this is called "killing" the steel. It is, therefore, alleged that circulation would be bad. The writer believes, however, that what is accomplished by this killing is to give the lighter impurities, such as gases, slag, oxides, etc., an opportunity to rise to the surface by gravity. If this is correct, the same ends ought to be accomplished far more rapidly and, therefore, more cheaply, by a forced systematic circulation from the bottom to the top (as distinguished from a mere agitation) during which all the impurities and gases would in turn be brought to the top into contact with the slag and when they have once gotten there it is presumable that they will stay there. Hence it is believed that, even though circulation is the direct opposite to resting, it will probably be found to accomplish the same object and do it far more quickly, thoroughly and cheaply.

Slag reactions require at least a certain temperature of the contact surface. This temperature is more easily maintained if the heat travels from the good conductor, the metal, to the poorer conductor, the slag, than the reverse, and the maintenance of this temperature is no doubt a very important factor in reducing the time of treatment, which in turn reduces the losses of heat per ton and increases the tonnage per day. Hence the metal should be hotter than the slag, which again becomes possible in the resistance furnace. This also reduces the maximum temperature required to maintain this necessary temperature at the surface of contact of metal and slag. If the slag is hotter than the metal, as in arc, open-hearth, or other furnaces heated from the top, the cooler good conducting metal will more quickly abstract heat from the layer of slag immediately in contact with it, forming a cooler layer of slag just where the heat is most needed; and as slag is a poorer heat conductor, it will take longer time for heat to pass down to reheat this cooler layer; hence, the action would be slower, or else the temperature of the slag must be made very much higher so as to hasten this downward flow of heat through a poor conductor. Moreover, most hot liquids are less dense than when cooler, and therefore heated liquids rise naturally by gravity. To cause heat to flow downward from a hotter to a cooler layer one must rely entirely on the very slow process of conduction, as gravity will not aid such transmission the way it does in the other direction. Rapid circulation, of course, will hasten such a transmission of heat.

The ideal way of overcoming the troubles, cost and loss of power due to the electrodes is, of course, to dispense with them entirely, as in the older forms of induction furnaces. But this also has its disadvantages, and it is significant that in what appears to be the most successful form of induction furnaces electrodes have been added.

If, therefore, these electrodes cannot be dispensed with, the next best thing to do is to make them as unobjectionable as possible. If made of the metal to be treated, their size and the losses in them become considerably less than if made of carbon or graphite, as the writer showed by actual tests some years ago. This becomes possible with resistance furnaces, but not with those using the arc. Moreover, when thus made of metal, if they are immersed under the liquid metal they cannot be consumed, or break off; they then require no adjusting and do not contaminate the molten charge. Hence in such furnaces the cost of electrodes consumed, which in arc furnaces is quite large per ton, would be entirely eliminated.

The possibility of adding fuel heat is often very desirable, especially when cold materials are charged, as the lower temperature heat is generally more economically obtained from fuel. Such heat would also reduce the loss of heat from the top surface of the electrically heated metal, would assist in melting the slag forming materials, and would lessen the amount of heat which would otherwise have to flow from the metal into the slag. The ideal form of furnace would, therefore, seem to be one in which gaseous fuel heat is supplied over the top and electric heat in the charge itself.

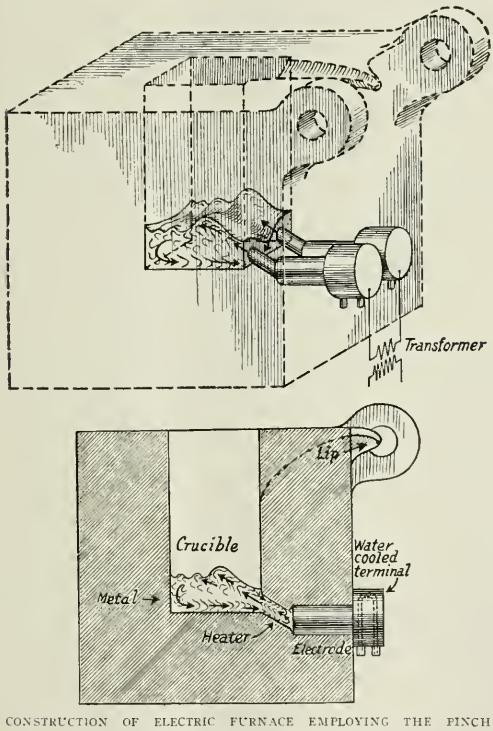
The control of resistance furnaces may generally be accomplished by the simple process of regulating the voltage of the transformer, and this can be done, within reasonable limits,

without appreciable losses of energy; hence it also approaches the ideal.

The reliability of operation, and the cheapness and simplicity of construction and operation, depend, of course, on the particular design, and, of course, the designer will approach the ideals in these features as closely as he can. In general, however, it may be said that resistance furnaces are simpler in their operation than arc furnaces, and that cheapness of first cost and of operation are good properties only when not purchased at too high a sacrifice of other desirable features.

When electric furnaces are designed so as to approach these ideal conditions more closely it is not unreasonable to predict that relatively large furnaces may become available even when the electric current must be purchased from the city mains, when all the accompanying advantages are duly considered.

With the above mentioned desirable features in mind the writer has endeavored to devise a form of furnace which



CONSTRUCTION OF ELECTRIC FURNACE EMPLOYING THE PINCH PHENOMENON FOR AGITATION OF THE CHARGE.

would embody as many of them as possible. To do this some radical departures had to be made from existing forms and types. The underlying principles of a type of furnace whose properties seem to approach some of these ideal features, especially that of rapid circulation, were described by the writer in a recent paper.[1]

Furnaces of this type are now being developed and will soon be undergoing commercial tests. The general form is shown in outline in the accompanying sketches, which represent, in its elements only, a small crucible tilting furnace.

The underlying principle, in which it differs from the usual types, is a new electromagnetic phenomenon which might be called a valveless pump. It follows as a consequence from the now well-known "pinch phenomenon" described by the writer some years ago, that when an electric current of suitable amount is passed lengthwise through a column of a liquid conductor confined in a submerged hole or tube the liquid will be ejected from the middle of this tube quite forcibly by this peculiar electromagnetic action, and at the same time will be sucked in around its circumference.

If, therefore, these holes or tubes are so proportioned that the necessary heat for the furnace will be generated in the metal in them due to its resistance, and that the ejecting force will be great enough to eject it as fast as it is heated, it will be seen that the metal in the crucible above the tubes will not only be duly and rapidly heated, but will at the same time be projected upward against the blanket of slag and be thoroughly and very actively circulated as it passes repeatedly into and out of the heating tube or resistor.

The sketches explain themselves. The heaters or resistors are the short, small tubes in which this electromagnetic force acts and in which all the heat is generated. The arrows show the circulation approximately. The electrodes, preferably made of the same metal, are the larger embedded cylinders, and are provided at their outer ends with water-cooled terminals, to which the leads from the transformer are attached. The direction of this squirting action is independent of the direction of the current, hence either direct or alternating currents may be used. The actions in this furnace have been described in the paper above referred to and need, therefore, not be repeated here.

It may, however, be of interest to add here that the ejecting force, even in a small furnace to which this principle is less well adapted than to larger ones, is great enough to cause considerable agitation, about as shown in the sketches. The suction in one case was even great enough to suck in air with a whistling noise, through a leaky tap hole at the bottom of one of the resistors against a hydraulic head of about 6 in. to 8 in. of molten lead. In another case, when the level of the liquid in the crucible had gotten too low, being nearly down to the top edge of the tubes, pieces of floating charcoal were sucked into the tubes accompanied by a snorting sound due to air being sucked in with it. When the depth of metal is sufficiently great, as it should be when operating normally, the action is entirely noiseless.

Each particle of metal is in the tube apparently for only about a second or two, judging from the velocity of the circulation. By using two tubes for each electrode the metal may be caused to pass into one and out of the other, instead of flowing in both directions in one tube.

The transformer may be directly attached to the furnace, so that the furnace as a whole may be arranged to tilt. The one shown tilts around the nose as a center, so as to enable the metal to be poured directly into the molds, thereby avoiding the use of pots.

[1] A New Type of Electric Furnace. Read at the meeting of the Amer. Electrochem. Soc., in April; abstracted briefly in this Journal for May, p. 277.

A Continuous Cyanide Treatment Method for Gold and Silver Ores.

BY JOHN E. ROTHWELL.

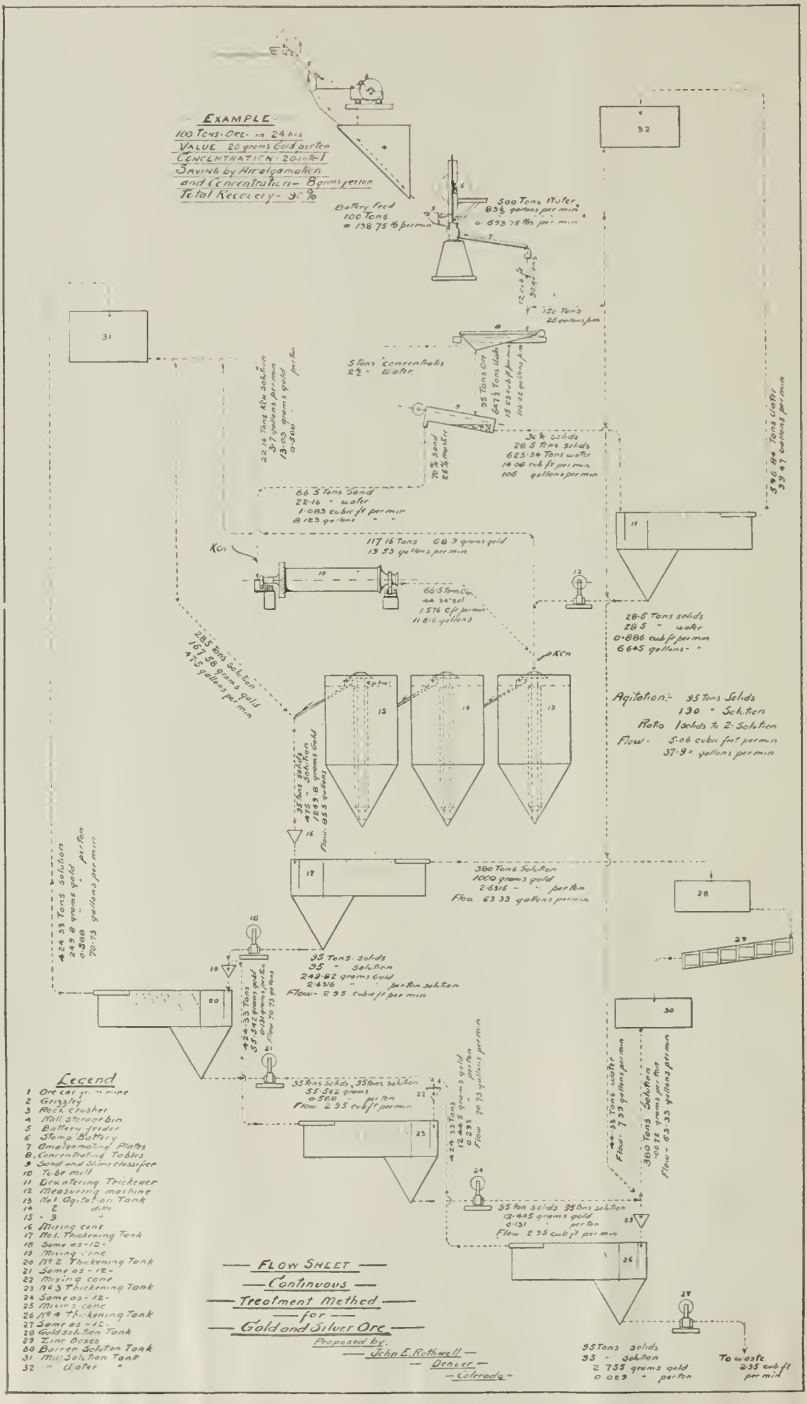
The method of continuous treatment outlined in the following is suggested as a means of operation along lines that will tend to eliminate as much as possible the personal equation which always plays such an important part in all milling operations, and bring the whole treatment to a nearly automatic operation.

Reference is made to the flow sheet that accompanies this paper, on which is shown the general machinery and equipment of a milling plant and the flow of the ore through same. Certain arbitrary conditions are assumed in the illustration, but these conditions are well within the limits of ordinary practice.

The example of milling treatment is taken at 100 tons per day, so the conditions prevailing at different points during the flow can be carefully noted in cubic feet and gallons per minute flow during the daily operation. Thus we get an idea of the volume passing certain points in a given time and the requirements in equipment necessary to handle these amounts. The mechanical automatic regulation and control are matters on which I will not go into the detail, but will say that equipment designed to perform the necessary functions, and register, by record, the actual conditions prevailing at the different points throughout the operation, is entirely a matter for the mechanical and electrical engineer, and presents no serious obstacle in either field.

The mechanical operations outlined in the flow sheet for the preliminary mechanical treatment of the ore down to the continuous agitation tanks, shown as 13-14-15 in flow sheet, are based on common practice. Some of the features shown may not be required on certain classes of ore, the leaving out of any one of which will not affect the general flow.

At the agitation tanks, it will be noted that the continuous flow is carried on through a sampling vane located *above* the pulp level in the tank The object of this is that these tanks also may act as an equalizer for the flow of the ore through the plant. Thus, for illustration, in event of a stoppage of the milling end of the plant for a short period of time, the tank 13 can be drawn on for about one-third of its capacity and maintain a constant flow through the others; similarly the other storage tanks can be drawn



on for a part of their contents and deliver a constant flow to the cycle of operations following.

The flow of the solids after leaving the agitation tanks and the recovery of the dissolved value is based on the idea of a countercurrent flow of diluent against the downward flow of the solids and accompanying dissolved values.

The critical point in this whole operation requires the absolute control of the ratio of the two currents in order that dilutions may be positive. The slight variations of value in gold and silver to be recovered due to the change in the grade of the ore being treated will not require any radical change in the flow in either direction.

The value of the countercurrent lies in the constant change of solvent as well as diluent, the tendency of which is to avoid reaching the chemical equilibrium between the solvent and the metal to be dissolved and obtain for the solvent its highest efficiency.

The recovery of the dissolving chemical (the cyanide) when, due to economic features, a solution is used that requires this recovery, is not shown in the flow sheet; but if we follow out the general features of the recovery of the gold values, in a subsidiary treatment, this recovery can be made to any degree required for economical practice. Absolute accuracy is not claimed for the figures shown in the flow sheet, but they are well within the lines of general practice and are given to show the possibilities of the method of treatment carried out in a continuous manner.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

The Iron and Steel Institute

The spring meeting of the Iron and Steel Institute was held at the Institution of Civil Engineers, London, on May 11 and 12.

The discussion on the paper by MM. F. A. Daubiné and E. V. Roy entitled "A Process for the Desiccation of Air by Calcium Chloride" (which is printed in full elsewhere in this issue) was opened by Mr. J. H. Harrison, who said that the value of the paper lay in its being a practical contribution dealing with iron and steel manufacture. Some six or seven years ago while the principle propounded by Mr. Gayley's paper on desiccation of furnace-blast air met with some degree of acceptance, his conclusions were received with incredulity if not with ridicule, but now it was recognized that dessication effected a saving of from 10 per cent to 20 per cent in coke. The author's method seemed to be a distinct improvement on the processes previously employed.

Mr. H. Hawdon remarked that in England very few works were equipped with apparatus for washing the waste gases used for drying the calcium chloride, and the heat required would involve considerable cost; and as to cooling apparatus, he thought that a large proportion of the chloride would not come into contact with the water at all.

Mr. J. E. Stead said the desiccation of blast by calcium chloride was first tried fully twenty-five years ago, but there was not then any provision for the obviously necessary cooling of the chloride after it had been dried. The hot blast was sent through the chloride to dry it, and was immediately followed by the passage of the cold blast. That process was, of course, ineffectual, but the author seemed to have met the difficulty.

Mr. F. W. Harbord doubted if the process would in practice do what the authors claimed in keeping surface temperature low. It was probable that as the surface of the chloride liquefied the resulting mass would greatly impede the passage of air through the grids, but if the process were really adaptable to the conditions of every-day work it would be better than the freezing process.

Mr. Lawrence Sterne expressed a desire for definite figures of working costs. The results obtained by refrigeration were known, and simplification of the apparatus with reduction of prime cost and upkeep were progressing favorably.

The balance of the report of the Iron and Steel Institute meeting will be given in our next issue.

"The Times" on Steel Prices

A special article on American Steel Prices and the effect of cutting on British Trade in *The Times* of May 31st is apparently written by an English optimist. The writer discusses the effect of the breakdown of the price maintenance understanding in the United States Iron & Steel trade, and commences by pointing out that "In the United States there are plenty of blast furnaces and rolling mills to undertake about nine-tenths of the world's export business in iron and steel, in addition to meeting home demands. If our United States rivals are able and willing to cut their export prices low enough—just a little below British and German figures—they can easily secure the supreme position in neutral markets, almost wipe out all competitors, and, besides practically destroying nearly all their rivals' export trade, they can make very serious inroads upon the purely domestic business of British steel manufacturers.

"There is a world's export trade in iron and steel of something like 13,000,000 tons a year. Of this total Britain and Germany between them are dividing nearly 10,000,000 tons; America is taking only one and a half million tons. But America has plant enough to do an export trade larger than that of Britain and Germany put together. In minerals, mills and men the United States producers are equal to the task. The only difficulty is that of price. Can our American rivals sell cheaply enough to beat us in the race?"

After offering explanations of the non-fulfilment of the repeated intimations during the last ten or fifteen years of a great export campaign by American steel manufacturers, he proceeds:

"Given the collapse of the American understanding and the prospect of an all-round reduction to the lowest profitable level, involving something like free international competition, how would matters shape themselves? On this point it is impossible to appeal with much confidence to past history. It is known that in the past American competition has been more imaginary than real. Our United States rivals have never approached us in the exportation race. . . . Is America at last about to make her long-threatened bid for the lion's share of the world's export trade in steel?

"This brings us to the root question. Can America produce at a sufficiently low cost to conduct a big export business for any great length of time? Are the costs of production really lower in the United States than they are in Britain or Germany? Twelve years ago it was authoritatively estimated that the cost of producing steel-making pig iron was less in America than in this country by very nearly 20s. per ton, and that in the case of steel rails the difference was 29s. . . . But it is a remarkable fact that since that time productive costs have gone up more substantially in the American iron and steel group of trades than in any other important branch of industry anywhere. The latest reliable figures are those supplied to the Ways and Means Committee two-and-a-half years ago, and they show that between 1899 and 1908 the net cost of producing pig iron increased by 24s. per ton, and of steel rails, 27s. per ton. This in spite of the mechanical and metallurgical improvements effected. Since the late nineties mining royalties have risen; mining costs have increased, while the yield of the ore has declined; cost of coal and coke has gone up; transit charges on water and rail have increased, so that it is not now possible to produce iron and steel with anything like the economy of a dozen years ago. There has been no corresponding rise in our costs of production for the rise in prices of some raw materials has been just about offset by improvements in processes."

One has got so used in this country to depreciation of our industrial potentialities that this article is quite a refreshing change to the much advised British manufacturer. But whether it will be safe for the lion to emulate the ostrich and hide his head in the sand in another matter. Wolf has been cried so often that the sheer novelty of a whisper of safety may have the same effect as the first of the alarms which disturbed our equanimity and make us more wary than we have recently been.

Market Prices.

May, 1911.

Copper was lower during the first part of the month, reaching £53.15.0 by the 10th, and remaining there till the 15th. It then rose steadily to the 23d, when £55 was reached. Closes at £55.

Tin was nervous at the beginning of the month, going between £195.10.0 to £192.10.0 before rising, which commenced on the 10th whence it soared pretty steadily up to its present price of £203.

Lead is slightly stronger at £13.7.6, rising on the 8th.

Haematite is down, having fallen away from 8th to 12th, and now standing at 61/9.

Scotch Pig was rather flat during the opening fortnight, touching 51/10. It commenced to rise smartly on the 18th and finishes at 52/3.

Cleveland has been much in sympathy with Scotch pig-iron and dropped to 45/11½ by the 10th. It has since recovered to 46/2.

Rubber has been low and weak, dropping from 5/- on the 10th to 4/4½ on the 17th. It has since become steadier and closes at 4/2.

Alum, lump, loose, per ton	£5.12.6
Antimony, black sulphide powder, per ton	22. 0.0
Borax, British refined crystal, per ton	16. 0.0
Copper ore, 10 to 25 per cent., per unit	9/1½ to 9.7½
Copper sulphate, per ton	22. 0.0
Carbolic acid, liquid 97.99 per cent, per gal	1.4
Creosote, ordinary good liquid, per gal	0. 0.2
Camphor, 1 oz. tablets	1.9
Caustic soda, ash 48 per cent, ordinary, per ton	5.10.0
Litharge, flake, per ton	15.10.0
Mica, small slab, original cases, per pound	6d. to 2.0
Naphtha solvent, 90 per cent. at 160° C., per gal	0. 0.9
Petroleum, Russian spot	0. 0.5⅛
Sal ammoniac, lump, firsts, delivered U. K., per ton	42. 0.0
Sulphate of ammonia, f.o.b. Liverpool, per ton	13. 5.0
Sulphur, recovered, per ton	5. 0.0
Shellac, standard T. N., orange spots, per cwt.	4. 4.0
Tin ore, 70 per cent., per ton	£125 to 127. 0.0
Hydrochloric acid, per cwt.	5.0
Zinc, sheets, Vieille Montagne, f.o.b. Antwerp	29.10.0
Quicksilver, per bottle	8. 5.0
Platinum, per oz.	8. 6.6

On the month the following differences are noted:

Higher.	Amount.
Copper	£1.0.0
Tin	9. 5.0
Lead	3.9
Copper ore, per unit	0.1½
Copper sulphate	2.5.0
Tin ore	2.0.0
Carbolic acid	0.0.1
Lower.	
Haematite	0.1.6
India rubber, Para	0.1.1
Scotch pig	0.0.6
Cleveland warrants	0.0.4

London, England.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Electrically Refining Molten Pig Iron.—In our March issue, page 127, we published an article by Mr. J. B. Nau on the preliminary refining of pig iron, more especially of phosphoretic pig iron too high in silicon to be treated directly and economically in the open-hearth furnace. The essential principle is to submit pig iron, running from the blast furnace, to the refining action of solid pieces of iron ore. Silicon, phosphorus and carbon will thereby be eliminated, but in order to maintain the required temperature it will in general be necessary to supply heat to the charge during the process, as was shown by the heat-balance sheet in the article referred to. For this reason Mr. Nau proposes to carry out the process in an electric furnace, as it is the easiest way of controlling the temperature absolutely. Three recent patents of Mr. Nau refer to this process. From the last two we reproduce herewith the

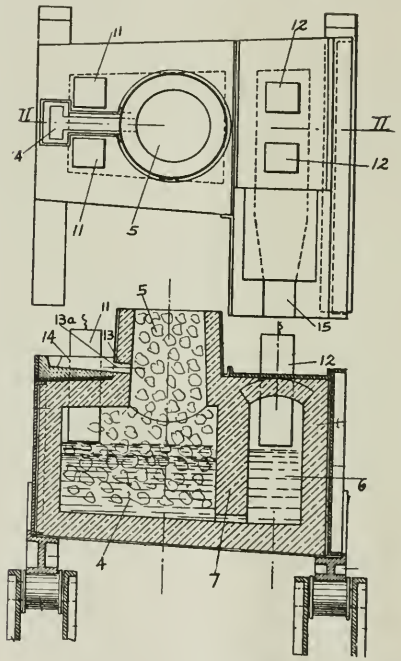


FIG. 1.—ELECTRIC FURNACE FOR REFINING OF PIG IRON.

tilting furnace in which the refining is carried out. As shown in plan and vertical cross-section in Fig. 1, it consists of two parts, a crucible 4 surmounted by an ore shaft 5, and a forehearth 6 separated from the crucible 6 by partition 7 and communicating with it through holes 8 near the bottom. The forehearth 6 is provided with an outlet spout (not shown in the illustrations) for pouring the refined metal when the furnace is tilted. 11 and 12 are the electrodes. After having heated the empty furnace by gas, preheated rich iron ore in solid pieces or in the shape of concentrate ore briquets is introduced into the crucible 4 through the ore shaft 5. The liquid pig iron from the blast furnace, which is to be refined, is poured into spout 14, enters the ore shaft through opening 13, percolates through the ore and passes over to the forehearth 6. Otherwise the illustration is self-explanatory. (984,590, Feb. 21; 990,765, April 25; 991,633, May 9.)

Electric Iron Ore Reduction.—An electric furnace specially adapted to the electric smelting of iron ores by a con-

tinuous process is described in a patent of Mr. EDWARD R. TAYLOR under Electric Furnaces.

Nickel Steel with the Aid of Electrolysis.—See the abstract of a patent of Betts for electrolytically refining alloys under Electrolytic Processes.

Electric Furnaces.

Electrode Holder.—A new construction of electrode holder of electric furnaces, due to Dr. PAUL L. T. HÉROULT, of La Praz, France, is shown in Fig. 2. Diagram *I* shows the carbon electrode *A* attached to the carbon holder *B*, which is constructed as a clamp encircling the carbon. This ring may be

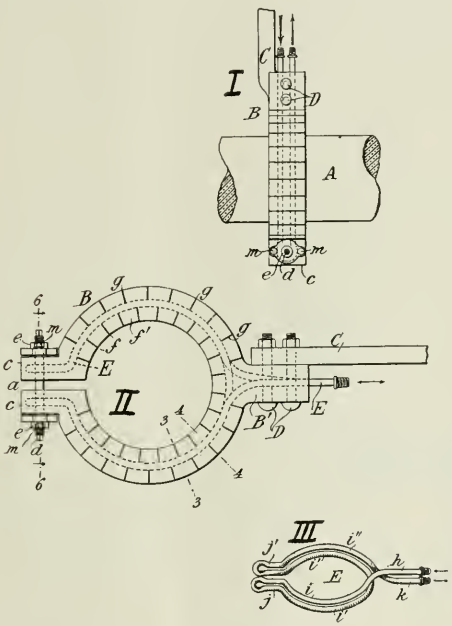

FIG. 2.—ELECTRODE HOLDER.

divided on one side *a*, as in diagram II, or at oposite sides. At the division *a* the clamp is formed with flanges *cc* through which passes a tightening screw *d*. To render the holder sufficiently flexible to readily adapt itself to slight irregularities in the surface of the carbon, it is slitted radially on its inner side at *ff* and on its outer side at *gg*, the outer and inner slits being staggered or alternated. The electric current connection is through the bar *C*, which is clamped to the arm *B'* by bolts *D*. For water-cooling a duct *E* is provided, consisting of an iron tube of the shape shown in diagram III. The main portion of the holder *B* is of copper or brass and is cast around the iron tube *E*, so that the latter is entirely embedded. (989,148, April 11, 1911.)

Electric Resistor Furnace.—The resistor furnace of Thomson and FitzGerald, the characteristic feature of which is heating of the charge by radiation from resistors on top of the furnace, and its application to zinc smelting have been repeatedly mentioned in this journal. To reduce the heat loss due to radiation Mr. JOHN THOMSON has now modified the construction by embedding the carbon resistor (which is otherwise of the same construction as before) in the charge itself. In order to prevent the electric current from leaking into the charge and in order to protect the resistor at the same time it is surrounded by a casing or shield. This casing is not in direct contact with the resistor, but there is an air space between them, which may be filled with an inert gas instead of air. For the construction of the casing fireclay, "crucible mixtures" (combinations of graphite and clay) and recrystallized silicon carbide may be used. (994,217, June 6, 1911.)

Titanium as Reducing Agent.—Mr. JOHN B. HUFFARD, of the Electro Metallurgical Company, of Glen Ferris, W. Va., produces alloys of titanium with vanadium or molybdenum, etc., by reacting on an oxide of the alloying metal (vanadium, molybdenum, etc.) with a titanium reducing agent, for instance, metallic titanium or titanium nitride, carbide or monoxide, etc. The titanium reducing agent is produced by the reduction of rutile; it may contain metallic titanium and relatively small amounts of nitrogen, carbon and oxygen. (992,423, May 16, 1911.)

This same titanium reducing agent is employed by the same inventor for the production of the metals tungsten, vanadium, molybdenum, etc., free from carbon. With tungstic acid the reactions are as follows:

$$2\,WO_3 + 3\,Ti = 2\,W + 3\,TiO_2.$$
$$2\,WO_3 + 3\,TiN = 2\,W + 3\,TiO_2 + 3\,N.$$
$$WO_3 + 3\,TiO = W + 3\,TiO_2.$$
$$WO_3 + TiC = W + TiO_2 + CO.$$

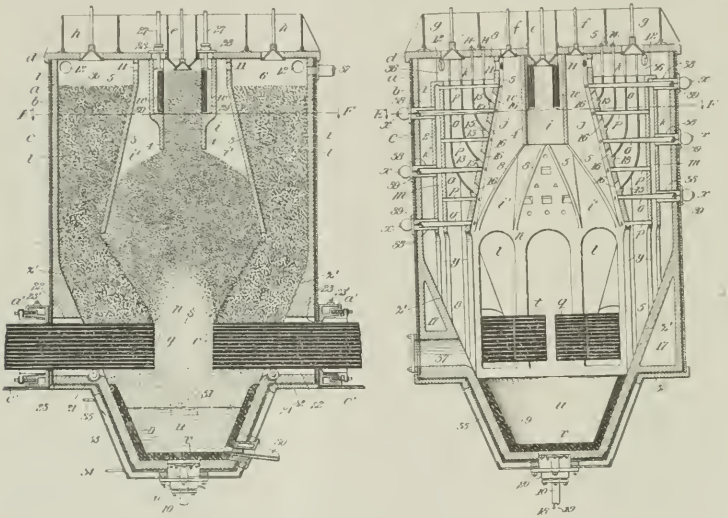
For the production of low-carbon metals the reducing agent should contain a minimum of titanium carbide since the oxidation of the combined carbon is not complete. In order to fully oxidize and utilize all of the titanium it is necessary to react on an excess of the reducible oxide. The resulting slags then contain both the oxidized titanium and the unreduced oxide of the charge. Titanium oxide not being acted upon by acids, the unreduced oxide may be dissolved out of the slags and recovered by evaporation. Tungstic oxide is readily dissolved out by hydrochloric acid. (992,422, May 16, 1911.)

Silicon Carbide, Silundum.—Mr. FRANK J. TONE, of the Carborundum Company, of Niagara Falls, N. Y., has formerly described a method in which shaped pieces of carbon are heated in proximity to a silicon-containing substance to such a temperature that the silicon combines with the carbon *in situ*, so that the shaped pieces of carbon are transformed into dense silicon carbide. (In Europe this is called silundum.) Mr. Tone has now found that if he makes his original shaped pieces not of carbon, but of a mixture of silicon carbide and carbon, he can vary the porosity and resistance of the product within wide limits. A mixture of ground silicon carbide and carbon, with tar, glue or silicate of soda as binding material, is shaped into the desired form and baked to remove moisture and other volatile materials. The article is then placed in an electric furnace and is embedded in a mixture of carbon and silica, or of silicon carbide and silica. The furnace is brought up to the temperature of the formation of carborundum, at which temperature vapors of silica and silicon are formed, which penetrate into the molded article to a considerable distance. These vapors reacting with the carbon change it into silicon carbide. The binding material is volatilized and the resultant product consists of silicon carbide bonded with silicon carbide in a dense, compact form. (992,698, May 16, 1911.)

Titanium Alloys.—For the production of ferrotitanium, Mr. A. J. ROSSI, of Niagara Falls, N. Y., proceeds as follows: A bath of molten iron is first provided in the electric furnace and this bath is covered with a layer of lime, CaO. Upon this is placed a layer of a mixture of titanic acid and carbon. The titanic acid is reduced to titanium, $TiO^2 + 2\,C = Ti + 2\,CO$; the titanium sinks downward and alloys with the iron. At the same time calcium carbide is formed, $CaO + 3\,C = CaC_2 + CO$. The calcium carbide, having reducing properties, promotes the reduction of the titanic acid and at the same time protects the molten alloy both from alterations by oxidation and volatilization. Toward the close of the process an additional blanket of carbon is added on the layer of calcium carbide in order to insure a reducing atmospheric atmosphere. Instead of titanic acid, as described above, titanate of lime, CaO,TiO_2, may be used. (986,505, March 14, 1911.)

Continuous Electric Shaft Furnace.—After many years of

successful experience with his electric furnace for carbon bisulphide manufacture Mr. Edward R. Taylor, of Penn Yan, N. Y., has undertaken in recent years to design an electric-shaft furnace which, while retaining the very satisfactory salient features of his carbon bisulphide furnace, would be especially applicable to reduction of iron ores in a continuous process. His latest design is shown in Figs. 3 and 4 in vertical section in two different planes, the second diagram showing the furnace empty. It is of stack form, the internal structure *a* being of brick or cement incased by a metallic shell *b* with an intermediate layer *c* of asbestos. *e*, *f*, *g*, *h* are feeding hoppers in the top, communicating with flue-shaped passages *i*, *j*, *k*-*k'* and *l* extending downward. The coke is introduced through the central hopper *e* into the passage *i*. The coarse ore is introduced through four hoppers *f* and passage *j*, symmetrically arranged around the center. The fine ore is introduced through the four external



FIGS. 3 AND 4.—ELECTRIC FURNACE FOR IRON ORE REDUCTION.

hoppers *g*, each of which communicates with two passages, a main passage *k* and a peripheral passage *k'*, separted from each other by hollow walls forming a gas space *m* within each wall, open at the bottom and also in direct communication with the working chamber *n* by way of outwardly flaring gas tubes *o*. The peripheral fine-ore passages *k'* communicate with the working chamber at their lower ends only. The main fine-ore passages *k* are provided with baffle plates *p* to retard the flow of the fine ore and permit gas spaces through the body of fine ore. Four other hoppers *h*, situated midway between the four external hoppers *g* and the peripheral passages *l*, are appropriated to the feed of resistance regulating material adapted to flow downward by gravity and to protect the main electrodes and regulate the conductivity of the charge at the heat zone. For this purpose broken electrode carbons may be used, crushed to suitable size.

There are four horizontal main electrodes *q*, *r*, *s*, *t*, arranged in two pairs at right angles to each other. They are located immediately above the hearth *u*. Secondary electrodes *v* and *w* are located at the bottom and top of the furnace respectively. An annular gas chamber 36 at the top of the furnace communicates freely with the coarse ore and coke passages and with the intermediate passages for fine ore and regulating material, and discharges through an outlet pipe 37. The tube *o* for circulating the CO and CO_2 gases within the furnace extend from the coarse-ore passages *j* outward into curbs 38, which project inward to the gas spaces *m* from outside the furnace, and electrically driven rotary blowers 39 are located within the outer ends of these tubes. To insure the inward feed of the ore stoking screws are provided, which are not shown in the illustrations here reproduced. Passages are also provided through which air may be blown into the center of the working chamber.

The height to which the central coke column is kept incandescent is determined by passing more or less current through it by way of the secondary electrodes *v* and *w*. This in turn determines the proportion of carbon in the molten metal as it reaches the hearth and facilitates producing either pig iron or steel at will. The gas-circulating blowers 39 insure the conversion of the carbon monoxide gas formed in the vicinity of the heat zone into carbon dioxide, the conversion of the latter into carbon monoxide, and so on. Considerable details are given in the specifications on the construction of the electrodes. (985,226, Feb. 28, 1911.)

Electrolytic Processes.

Electrolytically Refining Alloys.—Mr. Anson G. Betts, of Troy, N. Y., subjects an alloy which does not contain the two principal metals in a desired proportion to a separation into at least two other alloys, in one of which at least the ingredients are together in a more useful proportion. For this purpose the alloy is used as anode in an electrolytic cell, the two principal metals being dissolved, while many of the impurities are left as an anode slime. By varying the conditions of deposition he then alternately deposits at least two different alloys. Two examples are described, the refining of arsenic-antimony and of nickel-iron alloys.

The arsenic-antimony alloy is dissolved as anode in a solution containing antimony and arsenic trifluorides, an alkaline fluoride and hydrofluoric acid. When the solution is rapidly agitated arsenic deposits out faster than antimony and the cathode metal may thus contain more arsenic in proportion than is dissolved from the anode, until the solution becomes impoverished in arsenic. If now the solution is kept at rest and electrolysis continued an alloy is produced for a time, containing a less proportion of arsenic than is dissolved from the anode. When arsenic has sufficiently accumulated in the electrolyte, the first operation with rapid agitation is repeated. In practice there should be at least two refining tanks in use, through which the solution flows continuously from one to the other, and in one of which the solution is well agitated, while in the other it is nearly at rest. The alloys deposited in the two tanks are different from each other and from the anode and are generally also free of many impurities of the anode, as silver, lead, copper, etc. About one-half of the arsenic in the anode remains in the anode slime.

Iron-nickel alloys are treated as anodes in a solution of the sulphates, fluosilicates or other usable salts of iron and nickel. By varying the temperature the composition of the cathodic deposit is varied. Most of the impurities are eliminated as anode slime or remaining in solution. With an anode containing 6 per cent nickel, 6 per cent copper, 1 per cent manganese, 3 per cent carbon, 1 per cent silicon, by electrolyzing at a tem-

perature of 40° C. to 50° C. he deposits for a while cathode metal with 3 per cent nickel, while the percentage of nickel in solution increases. Then by electrolyzing at a temperature of 90° C. there deposits on the cathode an entirely different product, which may contain 13 per cent nickel and nearly 87 per cent iron, while the percentage of nickel in the solution diminishes. The solution is then cooled and the first operation repeated. In practice the two steps would be carried out in two different tanks.

"Nickel steels containing 3 per cent to 3.5 per cent of nickel are at present the most popular. One of the above-mentioned products of about this composition is directly convertible to an especially fine nickel steel nearly free from harmful impurities containing this amount of nickel, by melting with the proper additions, while the other product may be melted with other relatively impure iron to produce a lower grade of nickel steel. If the entire product made from anode metal of the composition given was of one kind containing about 7 per cent of

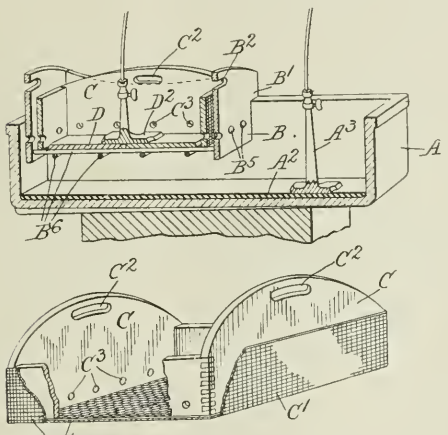


FIG. 5.—ELECTROLYTIC CELL FOR PARTING GOLD AND SILVER.

nickel it would require to be melted with outside non-electrolytic iron of lower grade to produce the very useful 3 per cent to 3.5 per cent nickel steel, and obviously would not be as good for making high-nickel steels as the 13 per cent alloy, for example." (987,947, March 28, 1911.)

Electrolysis of Brine Solutions.—In the electrolysis of sodium chloride solutions in diaphragm cells, like the Hargreaves cell, the solution coming from the cathode compartment contains undecomposed sodium chloride. To recover this and use it again is the object of a patent of Mr. GEORGE A. GABRIEL, of Brooklyn, N. Y. (assigned to the Bleach & Caustic Process Company). A second object is to renew and purify the anolyte and to remove any gases from it. These objects are obtained in a cyclic process in which evaporators, centrifugal driers, filters, etc., are employed. There are thirty-four claims. Claim 8 reads as follows: "In an electrolytic process, in combination with the step of electrolysis, the process of treating the discharged electrolyte remaining in the catholyte, which comprises removing the undecomposed electrolyte by concentrating the main body of the products of decomposition, converting the remaining products of decomposition contained therein into substances which purify the raw electrolyte, and then submitting the purified electrolyte to said step of electrolysis." Claim 24 reads as follows: "In an electrolytic process, in combination with a continuous main circulation of the electrolyte discharged from a cathode chamber, for purifying and supplying the electrolyte, a local or auxiliary circulation of the anolyte, including the steps of electrolysis and filtering." (959,730, May 31, 1910.)

Electrolytic Parting Cell.—What may be considered as an interesting further development of the well-known Balbach cell for parting gold and silver is patented by Mr. WILLIAM THUM, of Hammond, Ind., and shown in section in Fig. 5. *A* is a tank with an inclined bottom on which rests the cathode plate A^2 (for instance, of carbon), connection to the outside circuit being made through the cathode terminal A^3. The anode cell *B* is suported in the tank *A* by means of the projecting ledges B^4. Perforations B^5 are provided in all the walls. The bottom of the cell consists of a grid made up of the bars B^6. The anode basket *C*, which is located within the anode cell and rests upon the grid B^6, is provided with the canvas bottom C^1, as shown in the lower diagram, the handle holes C^2 and the perforations C^3 in its sides and ends. The anode plate *D* is situated within the basket *C* and rests upon the spacing bars, which rest in turn upon the canvas bottom of the basket. D^2 is the anode terminal. A modification of this construction is also described, in which the anode cell and basket are made in one.

If silver bullion containing gold is to be treated an electrolyte of silver nitrate with free nitric acid is used. The electrolyte is contained in the tank *A* at such a level as to be slightly above the perforations B^5 and C^3 in the anode cell and anode basket respectively. The silver dissolves from *D* as nitrate and the heavy silver nitrate solution sinks through the canvas and runs down over the full length of the surface of the inclined cathode plate A^2 on which the silver is deposited in shape of loose crystals. The electrolyte, the specific gravity of which has thus been reduced, rises now upward again and flows back across the upper part of the tank toward and into the anode cell through the perforations B^5 and C^3. The gold in the anode plate *D* is not dissolved and accumulates in the shape of mud or slime resting loosely on the perforated bottom of the basket.

The cell may be similarly used for refining bismuth. In this case an electrolyte of bismuth chloride and free hydrochloric acid is used. The bismuth is obtained in form of more or less coherent easily removable crystals, having the shape of trees, mushrooms and the like. (969,921, Sept. 13, 1910.)

SYNOPSIS.

GOLD AND SILVER.

Cyaniding Tailings.—Details of the treatment of a 500,000-ton tailing dump at the Oroya Brownhill, in Western Australia, are given in the March *Journal* of the Chamber of Mines of Western Australia, by Messrs. STEVENS and DEGENHARDT.. A vacuum filter plant was erected at the end of 1908 for the retreatment of a great mass of filter press tailing. The process consists of belt conveying to the plant, mixing with spent solution, agitation with cyanide, vacuum filtration and precipitation on zinc shavings.

The tailing treated consists of a mixture of 92 per cent. of an all-slimed product from bromo-cyanide treatment, and 8 per cent. of roasted concentrate. It is fine, only 2.5 per cent remaining on a 100-mesh screen. The average value is about $2 per ton, and by agitation with weak cyanide solution an extraction of $1 is obtained. Of the extracted value, one-half is present as dissolved gold in the 6 per cent. moisture contained in the dump; the $1 remaining in the residue when discharged is not soluble in stronger cyanide solution, and can only be extracted by regrinding and concentration, which would not be profitable. The tonnage treated is 730 tons in 24 hours.

A movable belt conveyer is placed along the side of the old dump, and the material is run on to it by men working with picks and shovels. As the dump is removed the belt conveyer is placed closer to it, each move giving about 10,000 tons. Taken over a period of two years the cost of the belt has been about 0.8 cent per ton.

The dump is easily moved, and three men working with picks on the dump, together with two men shoveling from the bot-

tom, can run about 250 tons per shift on to the belt. The material runs easily at 41.5 degrees, but in wet weather the rills must be a little steeper.

At the mill the material is mixed in a vortex mixer with spent solution from the extractor boxes. These mixers have cast iron impellers on 3-in. shafts and are driven at 350 r.p.m. by quarter-turn belts. From the mixer the pulp flows to the agitation vats, which are 17 ft. 6 in. diameter and 9 ft. deep. These vats have bottoms of 18-gauge plain galvanized iron and sides of 20-gauge corrugated galvanized iron, and last about three years. The bottom is usually the first part to wear out. Each vat has four angle-iron arms driven at 12½ r.p.m.

The spent solution tests 0.04 per cent. KCN, and lime to the extent of 1.5 lb. per ton of tailing is added in the mixers, to bring the protective alkalinity up to about 0.002 per cent CaO. The pulp is agitated for eight hours, and the solution tests 0.02 per cent. KCN when it is drawn off to the vacuum filters. Average cyanide consumption is 0.47 lb. of sodium cyanide per ton. Specific gravity of the pulp is maintained at 1.61.

The filter equipment consists of two vats each 10 ft. wide, 21 ft. long and 7 ft. deep, the bottoms being divided into two 60-degree discharge hoppers. The filter vats are filled by an 8-in. centrifugal pump, the wearing shaft of which lasts about 4½ months and the runner 9 months. It is operated 38 per cent. of full time by a 45-hp. motor. Each filter vat contains 34 frames 5 ft. 3 in. deep by 9 ft. wide and set 6½ in. between centers of frames. The frames will carry an average of 22 tons of dry slime at a charge, making cakes 1⅞ in. thick. Of the pulp charged into the vat 43 per cent. is removed as solution and cake, and 57 per cent. is pumped back. The cycle of operations is as follows: Filling vat, 5 minutes; forming cake, 30; emptying excess pulp and putting in wash, 8; washing, 30; emptying excess wash, 4; discharging cake, 7; total, 84 minutes. A vacuum of 27 in. is maintained during filtration, and the cake is discharged with 24 per cent. moisture and soluble gold equal to 6 cents per ton of dry slime.

The pregnant solution is clarified in presses and precipitated on zinc shavings. The consumption of zinc is 0.13 lb. per ton. Cyanide is added in the gold solution vat as strong solution to assist precipitation, and the solution entering the boxes contains not over 0.05 per cent. KCN. About one ton solution is precipitated for one ton of tailing treated. The total cost of breaking and treatment is about $0.52 per ton (2s. 1.28d.).

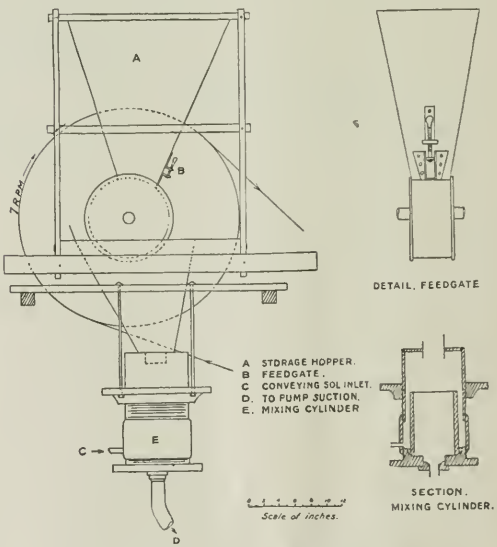
All-Sliming Treatment.—A fine example of the development of a cyanide process is given by Mr. Alex. Fyfe in a paper read before the Australasian Institute of Mining Engineers and published in the *Transactions* of that body. Beginning with stamp-amalgamation and separate treatment of slime and sand, with elimination of sulphides, which were treated separately, the process has been developed to a point where but one product is made and treated by cyanide. The change was gradual and resulted from numerous experiments, from each of which an excellent lesson was learned and applied.

The first step was an attempt to treat the sulphide concentrates at the mill instead of shipping them to smelters. The process included regrinding in tube mills, agitation with compressed air and filtering in presses. The cost of regrinding was high, as one tube 19 ft. 3 in. long by 4 ft. 8 in. in diameter could reduce only 10 tons in 24 hours, and the pebble consumption was 30 cwt. per week. Later coarse sand was added to the concentrate in an endeavor to improve grinding conditions, and this was so successful that the concentrate was fed into the mills grinding raw ore. Later amalgamation was dropped, and toward the end of 1908 cyanide solution was added to the mortars instead of clear water. This shortened the time of treatment and did away with the necessity of dewatering the slime before treatment with KCN, so that the vacuum filtration plant formerly used for this purpose was available for filtering pregnant solutions. Finally additional tubes were added and the sand ground to such a fine state that it was mixed with the slime and treated as one product. Thus from a complex system, with several products to treat, there has been evolved a simple process with but one product.

The solution added to the stamp mortars contains 0.10 KCN, and is added at the rate of 10 tons of solution per ton of ore. Lead acetate to the extent of 0.5 lb. per ton of ore also is added. The stamps weigh 1100 lb., drop 7 in. 105 times per minute, and have a duty of 7.6 tons per stamp per day. From the stamps the pulp flows to spitzkasten, the underflow from which goes to tube mills. The combined slime is settled and drawn off at a consistency of 1.5 solution to 1 of slime, and agitated in high tanks with air at a pressure of 38 lb. per sq. in. Time of agitation, 18 hours; cyanide consumption, 1.258 lb. per ton. Experiments showed that 87 per cent. of the total value is in solution before agitation begins, and that only a small additional extraction is effected in the tanks. The agitated pulp is then filtered in Moore filters and the solution precipitated in zinc boxes at the rate of 1.4 tons of solution per cubic foot of zinc in 24 hours. Expenses per ton of ore treated are distributed as follows.

Rock breaking	$0.104
Stamping	.166
Tube milling	.292
Classification (Wilfley tables)	.072
Treatment	.636
Precipitation and melting	.054
Assaying and sampling	.058
General expenses	.120
Total	$1.502

Zinc Dust Precipitation.—The formation of calcium carbonate during precipitation by zinc dust and the detrimental



ZINC DUST PRECIPITATION.

effects of this salt on precipitation are set forth by Mr. Allan J. Clark in the April, 1911, issue of the *Mining Magazine* (London). The formation of calcium carbonate may result from agitating, with compressed air, the solution before the precipitation of the precious metals, or by agitating with compressed air to form the zinc emulsion used for precipitation.

At the time the author's attention was first directed to the matter in hand, the method of preparing the zinc emulsion was that of agitating by compressed air in an inverted cone with a

continuous overflow to the suction of the pump, where it was mixed with the solution flowing to the presses. The first instance of the effect of calcium carbonate was noticed while precipitating a very weak and low grade solution of high alkalinity. This solution had been collected in shallow vats and agitated with compressed air, and was in prime condition for the formation of the objectionable salt. The precipitation offering some difficulty, the rate of flow was reduced without improvement in precipitation. The press was then opened, and a heavy deposit of calcium carbonate was found, caked on the press cloths or mixed with the precipitate. By eliminating the preliminary agitation of the solution the difficulty was remedied.

The author suggests that the formation of calcium carbonate diminishes the efficiency of the zinc by coating the zinc particles and preventing further action.

By eliminating the mixing cones and substituting the method of allowing the zinc dust to fall from an endless belt into a trough where it was washed by a stream of solution direct to the precipitation line, there was an increase in concentration of 63 per cent.; a decrease of consumption per ton of solution of 35 per cent.; and a decrease of zinc consumption per ounce of gold precipitated of 38 per cent.

Later, on account of the irregular action of the belt feeder, a new design of zinc dust feeder was installed. It is designed by W. H. Todd, foreman at the Homestake mill. It consists of a hopper with feed gate, and a mixing cylinder where a small stream of solution emulsifies the dust. No air agitation is used. Results of the first month's operation of the new feeder compared with the former method of emulsifying in a cone with air agitation show: Increase in concentration, 80 per cent.; decrease in consumption of zinc per ton of solution, 33 per cent.; decrease in consumption of zinc per ounce of gold precipitated, 31 per cent. The results warrant the statement that a reasonably regular supply of zinc is sufficient for all practical purposes when, as is usually the case, the zinc and solution travel some distance before entering the press.

Continuous Filter Press Process.

In the usual practice of handling oil seeds, fish scrap, slaughter house scrap, bagasse, etc., for the general purpose of removing the liquid from the solid, it is exceedingly desirable to employ a continuous process of operation, but in many types of apparatus now in use it is rather difficult to produce the necessary high pressure. With hydraulic or screw presses the pressure can be easily attained, but the process is essentially discontinuous. Any attempt to make the pressing process a continuous one is therefore of considerable interest.

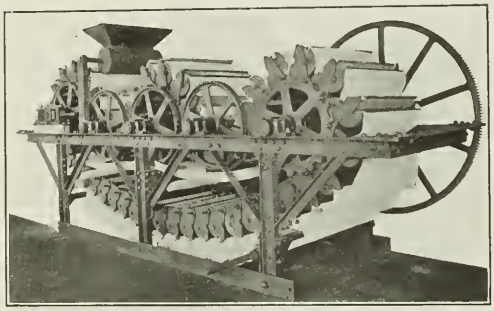
We had recently an opportunity to see in operation a new continuous pressing apparatus which is the invention of Mr. John J. Berrigan, of 136 North Centre Street, Orange, N. J. The apparatus which we saw in operation is reproduced in the adjoining illustration.

It will be seen there is an endless belt, running alternately around the top and the bottom of five successive rolls. But unlike other belt and roll arrangements, the closeness of the pinch between the faces of the belt and roll has nothing to do directly with the pressure to be exerted on the liquid and solid which are to be separated.

The belt is seen to carry a large number of pressure chambers. In the case of the apparatus illustrated their number is 54. The material to be separated is fed into them from the hopper shown on the top on the left of the illustration. Now each of the chambers is changed in shape while traveling with the endless belt around the rolls, that is the walls of the chamber are made to open or close like jaws while they are on top of a roll or on the bottom of a roll respectively.

When a certain chamber reaches the position on top of the first roll, it is wide open and is filled with material from the hopper. Then the filled chamber is carried by the belt downward and the walls are gradually closed, somewhat on the principle of a door jamb. When the chamber reaches the position below the second roll, the pressure becomes a maximum and the liquid is squeezed out and runs off through the filter cloth.

The chamber then begins to rise again and is again wide open when it reaches the top of the third roll. The pressure on the cakes is now relaxed, and at this point, according to requirements, sprays of water, steam or oil may be directed on the cake. When the chamber now begins to pass again downward, the cake in it is shifted from one side to the other side and thereby breaks up. The pressure begins to rise again, and when



CONTINUOUS FILTER PRESS.

the chamber reaches a position at the bottom of the fourth roll there is a second squeeze of liquid from the cake.

Then the chamber rises again and is wide open when it comes to the top of the fifth and last roll. But now after it has passed the top of the last roll and passes downward, it does not close, but on the contrary, when the belt with the chambers gets into the position below all the rolls, the filter cloth turns automatically inside out, as shown in the illustration, and the solid cake drops out.

The capacity of the machine depends on the number of chambers, the size of the chambers, and the speed. The speed is to be adjusted, according to the material under treatment. While the principle of the machine is thus clear, the reader may be referred for details of mechanical construction to three patents recently granted to Mr. Berrigan (994,631, 994,632 and 994,495, all of June 6).

The machine is certainly well designed mechanically. If pieces of wood or melting screws, etc., get incidentally into the charge no harm is done.

Perhaps most remarkable, however, is the small amount of power required since the machine shown in operation, weighing several tons, could easily be driven by hand. This is due to the well-balanced arrangement of the endless belt and accessories.

It will be decidedly worth while watching the introduction of this machine into commercial practice.

NOTES.

Messrs. **Toch Brothers,** the well-known manufacturers of paints, varnishes and enamels, of New York City, with works in Long Island City, have recently opened new works at Toronto, Canada, to supply the Canadian trade.

The **FitzGerald & Bennie Laboratories,** of Niagara Falls, N. Y., have been removed from Falls Street to the corner of Highland and Whirlpool Avenues, Niagara Falls. The new location affords greatly enlarged and improved facilities for the work of these laboratories.

The Elmore Concentration Plant at Sulitelma, Norway, using the oil-vacuum-flotation process, is being enlarged from

a daily capacity of 500 tons to about 900-1000 tons. This will be the largest flotation plant used for the treatment of copper ore. Common fuel oil is used, and the consumption is reported to be 2.7 lb. per ton of ore treated. No acid is used.

The Camp Bird, Ltd., reports that the January operations at its properties resulted in a net balance applicable to profit amounting to $96,515.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in December, 1910, was 68. The total tonnage milled during that period was 1,869,124 tons of ore; 9736 stamps were in operation with an average duty of 7.33 tons per 24 hours. Tube mills in commission numbered 190. The yield for the month was 640,995 fine ounces gold.

The Flow of Heat Through Furnace Walls is the title of Bulletin No. 8, recently issued by the Bureau of Mines. The results of the investigation described in this bulletin justify the following conclusions: In furnace construction a solid wall is better than a wall of the same total thickness containing an air space, as the former is a better heat insulator. This statement is particularly true if the space is close to the furnace side of the wall and if the furnace is operated at high temperatures. If it is desirable in furnace construction to build the wall in two parts, so as to prevent cracks being formed due to the expansion of the brickwork on the furnace side of the walls, it is better to fill the space between the walls with some "solid" (not firm, but loose) insulating material. Ash, crushed brick or sand offer high resistance to heat flow through walls with an air space. Furthermore, any such loose material by its plasticity reduces air leakage, which is an important feature deserving consideration.

The Magma Copper Company is one of the new copper propositions that has recently come into prominence. Unlike many of the Western copper mines, it is a high-grade proposition and will probably be a heavy producer when fully developed. It is in Pinal County, Arizona, 20 miles west of the Inspiration, 12 miles northeast of the Ray Consolidated, and is being developed at depth. The output of the mine will be largely smelting ore.

The Arizona Copper Company produced during the month of April, 1911, 1420 tons of copper.

ORE TREATMENT (*Continued*).

362,022, April 26, 1887, H. Liepmann, assignor to the Cassel Gold Extracting Company (Ltd.), of Glasgow, Scotland.

Similar to the preceding, except that the asbestos-cloth diaphragms are supplemented by movable diaphragms of earthenware or compressed layers of asbestos cloth to prevent diffusion of the alkaline liquors from the cathode back into the anode compartment. The supplemental diaphragms are movably carried by screws. In operation the powdered ores are placed in the revolving drum, or anode compartment, the dense partitions being forced up against the permeable ones. The drum being revolved and current supplied, the metals dissolve, but their solution is retained within the anode compartment. The supplemental diaphragms are then withdrawn, and lime added to the anode solution. The solution then passes through the permeable fixed diaphragms into the tanks, where the gold is electro deposited.

370,764, March 20, 1888, Charles F. Croselmire, of Newark, N. J.

Zinc. Pulverizes galena carrying zinc, silver and iron, roasts with an air of steam jet, and treats with dilute sulfuric acid. The zinc, iron and manganese dissolve. The latter are precipitated as oxids by injecting air into the solution. The zinc is then electrodeposited, or it may be precipitated as a carbonate or oxid. The undissolved residue is washed, briquetted and smelted.

387,036, July 31, 1888, Charles Peters Bellows, of Gloversville, N. Y.

Gold and silver. Treats sulfids, titanids, iridids, osmids, chromids, antimonids, to render them free-milling and capable of amalgamation. The ore, crushed to the size of fine gravel, is placed in a perforated crate or basket surrounded by cotton cloth. A copper anode bar is embedded in the ore. The basket is placed in an insulated tub of wood or porcelain containing a solution of sodium chlorid, to each gallon of which is added one ounce of caustic soda. Steam is led into the solution by an insulated pipe, and another steam pipe may extend into the gravel. Current is passed from the anode in the ore to a copper-sheet cathode surrounding the crate, thereby dissolving the refractory substances, or causing them "to chemically combine with the substances in the bath and remain in solution or be deposited in the ore as an innocuous salt."

391,360, Oct. 16, 1888, Henry H. Eames, of Baltimore, Md., assignor to John J. Kelly, of same place.

Gold and silver. Converts sulfied ores into chlorids by electrolytic chlorin, liberated from a solution of sodium or calcium chlorid, acidified by sulfuric acid or copper or iron sulfate. The cell is a circular iron vessel lined with Portland cement and constructed to resist internal pressure. Vertical electrode-plates of copper and zinc are supported on insulators at opposite sides of the cell. Centrally located in the cell is a circular casing for effecting circulation of the solution, having an inlet at the bottom at one side and an outlet at the top at the other side. In one form, this casing contains a revolving agitator, and steam is supplied to the bottom of the vessel through an insulated pipe. In a modification, the casing contains a steam-coil connected to pipes extending through the top and bottom of the cell and having rubber insulating connections. The ore is pulverized to an impalpable powder and is placed in the cell outside of the casing, being kept in suspension by the circulation. In using the first cell, steam is supplied at a pressure of 25 pounds per square inch, maintaining a temperature of 250°.

BOOK REVIEWS.

Practice of Copper Smelting. By **E. D. Peters,** Professor of Metallurgy, Harvard University. Large 8vo., 703 pages, 121 illus. Price, $5. New York: McGraw-Hill Book Company

This is practically a revision to date of "Modern Copper Smelting"—a book so well known and appreciated that its merits need no eulogy. We can, therefore, confine our remarks to the main features of the revision.

Wet processes are outside the scope of the book; electrolytic refining is left out because of it being too large a subject, although it is an almost integral part of the smelting process of producing copper; foreign practice is almost altogether absent. We feel sure that if Dr. Peters were as familiar with foreign practice as he is with American he would have included more of it in his book—that we would have found Mansfield, for instance, represented by more than one little slag analysis. This is the principal shortcoming of the book; it informs Americans wonderfully well on what they are doing themselves, but gives very little information about foreign practice.

There is not a chapter in the book which is not full of valuable information; the work is a high-class treatise on modern American copper smelting practice, which no one interested in copper smelting can afford to be without.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. IX | New York, August, 1911. | No. 8

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

239 West 39th Street, New York.

Western Office, 1510 Court Place, Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.
Telephone Calls 4700 Bryant.

E. F. Roeber, Ph.D., Editor.
H. C. Parmelee, Western Editor.

J. M. Muir, Manager.

Yearly subscription price for United States, Mexico and United States dependencies, $2.00; for all other countries, $2.50 (European exchange, 10 shillings, 10 marks, 12.50 francs.)

Copyright, 1911, by the Electrochemical Publishing Company.

Entered as Second-Class Matter at the Post Office at New York, N. Y., under the Act of Congress, March 3, 1879.

New York, August, 1911.

Trends in Iron and Steel Production.

As most of the important statistics of iron and steel production in the United States in 1910 have now been reported a glance at the results of the year may be of interest. The pig iron output was 27,298,545 tons, and while it broke the previous record, made in 1909, by 3 per cent it was much below the capacity. Indeed, in the twelvemonth from July 1, 1909, to July 1, 1910, production was practically 30,000,000 tons, and conditions were such as to leave room for the belief that in the calendar year between 32,000,000 and 33,000,000 tons of pig iron could have been made. At the lower estimate the actual production was 15 per cent short of the capacity, even though a new record in output was made.

The lead of Bessemer steel over open-hearth, first established in the "off" year of 1908, was more firmly established, as in 1910 production of open-hearth steel ingots exceeded that of Bessemer by precisely 75 per cent, while the lead of basic open-hearth over Bessemer, disregarding acid open-hearth entirely, was 62 per cent.

While the production of electric steel was only the modest quantity of 52,141 tons, this exceeded the production of any other country. As the introduction of this method is very recent, rapid gains in tonnage are to be expected for this year and next.

Without any apparently heavy demand for steel rails the production was 3,634,029 tons, thus exceeding the production of all previous years with the exception of 1906. The production of rails is not destined to see the violent fluctuations which have occurred in the past, when the bulk of the rails purchased were either for the building of new track or the replacement of old and light rails which the rapid adoption of heavy cars and locomotives suddenly made unfit. A large part of the annual rail demand is now due to the wearing out of rails in ordinary service, and as railroad traffic does not vary greatly from year to year the production is correspondingly uniform.

The production of open-hearth rails closely approached that of Bessemer in 1910, the total of 3,634,029 tons being made up of 1,917,900 tons of Bessemer, 1,715,899 tons of open-hearth and 230 tons of iron rails, so that Bessemer production was 53 per cent of the total. The production was much less than the capacity, which may be stated at 7,000,000 tons if all possible equipment be included. It should be observed, however, that many of the rail mills are interchangeable, rolling billets or sheet bars in place of rails upon occasion, and when they are engaged on these products merely the rail finishing department is idle. This flexibility was long ago found to be very desirable on account of the wide fluctuations in rail demand from year to year. It would not be difficult to make nearly as large a tonnage of open-hearth rails in a year as was made of all rails last year, but it is not at all certain that this will be

done. There is still a definite demand for Bessemer rails, and, of course, the difference of $2 a ton in the market price is not an unimportant factor with many roads, particularly for track over which the traffic is relatively infrequent.

The Power Problem for Electrochemical Plants.

In any new electrochemical enterprise, as in any new industrial undertaking, the concrete question always comes up at an early date, "where shall we locate?" It is almost tautology to say, "at the place where we can make the most money." With respect to electrochemical processes an impression prevails that the largest single factor in determining the cost of operation is the cost of power. This is undoubtedly true as a general rule, but at the same time it is true that there are a great many other factors which play an important rôle, and all must be balanced and properly proportioned. When this is considered, the availability of large amounts of cheap hydroelectric power for the electrochemical plant will not be found so absolutely necessary as a cursory examination of the subject might indicate. This is especially true in the case of conditions in the United States. In brief, the location of the electrochemical plant is a question of commercial geography. Besides the problem of power, there must be considered the conditions of the labor market, of shipping facilities by rail or water, of freight rates, of supply of raw materials and fuel and of the market for the finished product.

Each of these elements has its bearing on the final result and each has its own factor of commercial efficiency. In any multiplication of efficiencies each factor, large or small, counts toward the final result; 60 per cent multiplied by 70 per cent by 80 per cent gives a higher efficiency than 95 per cent by 90 per cent by 30 per cent. The balancing of the different commercial efficiency factors so as to produce the maximum net return is the problem which confronts the modern engineer. To consider all the various commercial factors and to evaluate the resulting equation is something that never is perfectly done, but usually only moderately well done. It is not so hard to reason, given certain premises, but to make accurate observations and to draw particular conclusions, especially unpleasant conclusions, is difficult.

It is instructive to consider the conditions which have resulted in the formation of the three great electrochemical centers of the world. Considered in their basic relations, these are Niagara Falls, the coast of Norway and New York Harbor. Decidedly there must be unusual features that have existed to condense electrochemical plants around these places as nuclei. Norway has the cheapest power and is the most remote from the centers of civilization, though transportation by water is convenient and cheap, but the labor supply is rather poor. New York can produce power at a fair, but not low, cost, but is itself a great financial and industrial center and the supply of labor is abundant. Niagara Falls has fairly cheap power, midway between the cost in Norway and in New York, and lies between three great American manufacturing districts, with a good labor market. We can see the pretty balance of the commercial factors in the different characteristics of the products made in Norway, New York Harbor and Niagara Falls by Electra's fiat.

Norway makes principally nitrogen products—both nitrates and cyanamide—from atmospheri air. She needs cheap power and air. Power is cheaper in Norway than anywhere else in the world. Air is cheap anywhere, hot in the tropics and from the promoter's lips, but no location has any monopolistic rights on air. Electrochemical plants locate in Norway when the cost of power is the greatest determining factor.

The electrochemical industry of New York Harbor—located in New Jersey as well as on Long Island—is entirely the electrolytic refining of copper bullion. The closeness of the brass and copper mills, the ease with which coal for reverberatory smelting is supplied, the dominance of American copper mines, the extent of the labor market, the Metropolitan banking facilities whereby loans on the valuable staple can be negotiated—all these factors have contributed many advantages for this special purpose, so that almost all Western copper smelters now ship their bullion East for refining and 75 per cent of the copper of the world is refined near New York.

At Niagara Falls power during the inception of the electrochemical industry from 1890 to 1900 was abundant and cheap (and while power is no longer abundant there for electrochemical work, it is still cheap). To this had to be added the good conditions for labor and supply of raw materials and the closeness to the potential markets for the then new products, such as aluminium, carborundum, graphite and calcium carbide. The optimist can see here why things as they are now have succeeded. Copper refining is impossible in Norway and nitrate or cyanamide manufacture from air is impossible in New York Harbor. Each is possible within certain limits at Niagara Falls, where the manufacture of nitrates from air has been a failure and the manufacture of cyanamide is a success.

Having in mind the bearing of commercial conditions on the location of these three electrochemical centers, we can see that in the United States we have widely varying possibilities for electrochemical industry. After the first period of industrial electrochemistry is over, characterized by the creation of new industries for the manufacture of hitherto unknown products, electrochemical activity has entered during the last year into a new era by taking hold of a wider and broader field. Electrochemical methods are being introduced into the older metallurgical and chemical industries. Steel refining in the electric furnace is the most momentous single feature of this evolution. But there loom up now at the horizon the latent potentialities of electrochemical methods—both wet and furnace methods—in non-ferrous metallurgy in the big and beautiful West, with its unlimited metallurgical possibilities; and it is no exaggeration to say that no one appreciates more clearly these potentialties of electrochemistry than the progressive Western metallurgists themselves. So this development is bound to come, and, in the nature of things, it must be profoundly affected by the availability of one or the other source of power.

Three sources of power are essentially available—water, gas and steam. The beginnings of electrochemistry were intimately connected with water-power developments. Besides Niagara Falls and Norway, this is true for Schaffhausen, for France (especially Savoy) and Italy, as well as for numeous smaller centers of electrochemical activity, of which only Sault Ste. Marie, Lockport, Penn Yan in this country may be mentioned; and it is noteworthy that the erection now going on of the first American works for the manufacture of nitrates from atmospheric air is intimately connected with the water-power de-

velopment of the Southern Power Company. Yet water-power has its limitations for electrochemical work in two directions. Firstly, if the specific nature of an electrochemical plant requires a location not too remote from an industrial center, such location means the nearness of existing industrial plants that can pay a higher price for power than an electrochemical plant can usually afford; if the electrochemist and the power salesman come together and the electrochemist offers half a cent per kw-hour (which may be the limit he can afford to pay) he is liable to turn the promoter of the hydroelectric concern irate. Secondly, the number of water-powers which can be developed very cheaply is limited. In many cases the engineering difficulties to be overcome in construction of dam and pipe line are so enormous and the capital investment becomes so high that, in spite of the relatively low operating cost, the rate charged for power must be high, as it is in at least one instance which we have in mind in the West. Nevertheless, it would be wrong to assume that such a water-power plant could not expect to sell power for electrochemical work. A water-power plant of this kind would not be built in a district in which a gas plant or a steam plant could supply power at less cost. And, on the other hand, if an electrochemical plant is erected in such a district, this is done in spite of high power cost, for the sake of the other advantages which the district may offer.

The erection of its own hydroelectric power plant does not seem good business for a new electrochemical enterprise in most cases, in view of the large capital investment that would be required. It is generally hard enough to get together the usually considerable capital which is required for the electrochemical installation itself proper. It is, therefore, better business, at least in the beginning, to buy the power from a water-power company. Water-power companies are usually reasonable in such circumstances.

From water-power we turn to gas. The gas engine is an attractive proposition, especially in a natural gas field or where blast furnaces or by-product coke ovens furnish cheap gas. The capital cost is much lower than that of a water-power plant and for a natural gas plant one-fourth cent per kw-hour may be considered a fairly representative figure. Indeed, were it not for the uncertainty about the life of the natural gas field, power generated from natural gas in a gas engine would be ideal for the electrochemical plant. The minimum figures for both capital cost and operating cost exist in this case. With blast-furnace gas or with by-product coke-oven gas both the capital cost and the operating cost are somewhat higher, but, on the other hand, the uncertainty is removed. Further, the gas will not be given away and some charge must be made for it. Probably the two most magnificent blast-furnace gas-power plants in existence are the two U. S. Steel Corporation plants, working in parallel, at Gary and South Chicago. At South Chicago the charge made to the electric furnace plant for steel refining by the Héroult process is half a cent per kw-hour. Of course, for electric steel refining the blast-furnace gas plant is logically the ideal solution of the power problem.

In many cases producer gas offers decided advantages for electrochemical work, as well as for chemical and metallurgical work in general. We have especially in mind a chemical manufacturing plant in Denver, which is conspicuous by the ingenuity and originality of its conception and methods. It shares with Standard Oil the distinction of turning absolutely everything into some useful product. Cheap bituminous slack is used in the gas producer and the cost of power is something like half a cent per kw-hour. But as the company refuses to be discussed in print, its plant is simply mentioned here to show that the advantages of producer gas for chemical work do not only exist on paper, but are a proved reality.

In turning finally to steam the advances made by the steam turbine in recent years are certainly striking. At the present time steam turbo-generators and accessories are sold very cheaply. The use of high speed and high pressure means that a maximum of $\frac{1}{2} m v^2$ is raced through a minimum of cast iron, steel and copper. Whereas the capital cost of a steam power plant was formerly $70 to $80 per kilowatt, the enforced competition among the companies building machinery for generating stations and especially the competition against the needs of the industries has reduced this figure about 25 per cent. Hard times make low prices. With coal of fair quality at $2 per ton f.o.b. plant and with plenty of condensing water, electrochemical power can be furnished by the turbo-generator very cheaply—so cheaply indeed as to make the average electrical engineer look skeptical.

But it must be remembered that the average electrical central station engineer does not appreciate the conditions of the electrochemical plant and its requirements. The usual electrochemical plant has a load-factor of over 95 per cent and also a high power-factor. Moreover, its land is cheap as compared with city land and its taxes low. Remembering all this, it is probably no exaggeration to estimate that with all proper charges power can be supplied under the conditions stated above at one-third of a cent per kw-hour, if the plant has a capacity of 5000 kw. Under the usual load conditions of central stations the cost will probably be more than twice this figure. There is necessarily a vast difference between a plant designed for and operating under a fluctuating load, as is the case with a central station, and a plant designed for a maximum of economy under a load that is fixed and constant, as is the case with the power plant for an electrochemical works.

While we have not discussed the possibilities of the steam engine for electrochemical work at all, it is but fair to say that this old reliable prime mover has been doing and is doing faithful service in numerous electrolytic copper refineries and will hardly be discarded here in the near future.

To sum up, the object of this discussion was to emphasize two points. Firstly, that the power cost is not all-important in an electrochemical process, as the different efficiencies must be balanced against each other. Secondly, that every kind of prime mover as its field in the electrochemical power plant. On the streets of New York City the push cart, the horse-drawn vehicle, the gasoline truck and the electric truck compete with each other in carrying goods. Each is used according to the needs and ability of the owner. So, in supplying electric power for electrolysis, electric smelting and refining, the steam engine, the hydraulic turbine, the gas engines and the steam turbine will continue to compete against each other. This freedom of choice in the power plant augurs well for the inevitable expansion of the electrochemical industry.

Chicago Meeting of the American Institute of Chemical Engineers.

The third semi-annual meeting of the American Institute of Chemical Engineers was held in Chicago from June 21 to June 24. All business sessions and meetings for reading papers were held at the Congress Hotel.

At the opening meeting on June 21 the members of the Institute were welcomed to Chicago by Mr. Wade, representing the Mayor of Chicago, and by Dr. T. B. Wagner, representing the Local Committee. Members were invited to visit the important chemical industries of Chicago, many of which were inspected during the meeting.

The reports of the various officers and committees were then presented. The membership committee reported a healthy growth, the present membership being 150. A very large number of requests for information with reference to conditions of membership are received, but on account of the high requirements for membership the number admitted is small.

The secretary reported that the third volume of Transactions would soon be issued. The growth in papers published is shown by the fact that the first volume contained 11 papers and 204 pages, the second 19 papers and 308 pages, while the third will contain 25 papers and about 410 pages. All papers are read by every member of the publication committee, which results in the rejection of papers of little value and the improvement of those published. A rapidly increasing demand is noticed for the Transactions.

The report of the treasurer showed a balance on hand of about $1,100.

The committee on medal reported $300 on hand and presented for approval or criticism a number of designs for the medal. The committee was opposed to the bust of a prominent chemical engineer on the medal or the use of the name of any chemical engineer for the medal, a symbolical devise being preferred. Non-members as well as members may compete for the medal which shall be known as the American Institute of Chemical Engineers' Medal, but the paper for which the award is made must be presented to the institute and published in the Transactions.

The report of the committee on chemical engineering education was read by the chairman, Dr. Samuel P. Sadtler. The most important part of this report consisted in the digest of the replies received to the questionaire on chemical engineering education sent out with the December Bulletin of the Institute. Thirty-seven replies were received to the 19 questions submitted. In reply to the question as to whether the prevailing system of chemical engineering education is adequate an emphatic "no" was given in a large majority of the answers. As the question evidently referred to a four-year course, the vote may be taken as approving the present tendency to lengthen the chemical engineering course to five years.

With reference to the subjects to be included in the course on chemical engineering a number of responses stated emphatically what seemed to be the general opinion that students should not waste time in college playing with "chemical practice," but that fundamentals should be thoroughly taught and experience with practical work acquired in the factory.

With reference to the defects of present courses the opinion seemed to be general that the college failed to devote sufficient time to those chemical manufacturing operations and appliances which constitute the element or operative units out of which nearly every chemical factory is built up.

A paper stating what could be accomplished in the four-year chemical engineering course was then read by Prof. J. H. James, of the Carnegie Technical School, of Pittsburg.

A paper giving a summary of the work of the committee on five-year engineering courses of the University of Ohio was read by Prof. James R. Withson, of the same university. The report of the committee and the two papers read on education will be printed in the form of a bulletin so as to afford discussion by mail.

During the afternoon the plant of Swift & Company was inspected. Dr. William D. Richardson gave a brief explanation of the processes used after luncheon had been served by the company. The entire operation of killing, cutting, curing, smoking and cold storage as well as the soap plant and glycerine refinery were shown.

During the evening President Frerichs delivered an able address on "Methods of Attacking Chemical Industrial Processes." Complete detailed drawings and models of an installation for the manufacture of soda by the Solvay process were shown. The great difference in conditions and prices between Germany and the United States was shown by estimates on a process which would be a failure here, although very successful in Germany. A process for the extraction of bismuth from its ore was also given in detail.

On Thursday morning by a special car members reached Argo, Ill., for a visit to the large new plant of the Corn Products Refining Company. The very extensive use of concrete in this plant was noted and members were interested to learn how this material would withstand the action of sulphurous acid. All parts of the plant were inspected, including the converters, sugar and starch houses. When the plant is completed it will have a capacity of 100,000 bushels of corn per day. Many of the members spent the entire day at the plant. Others visited the laboratories of the Dearborn Drug & Chemical Works, after which an automobile sight-seeing trip around Chicago's beautiful boulevards and parks was taken.

On Thursday evening a subscription dinner was given at the Congress Hotel. The most interesting feature of the dinner was the presentation of the institute medal to Mr. F. J. Wood, of Marx & Rawolle, for the presentation of his paper on "The Multiple Effect Distillation of Glycerine," which was published in volume 2 of the Transactions of the institute. The process is remarkably economical in coal consumption, ease of control and operation as well as purity of product. It is in operation at the Brooklyn plant of Marx & Rawolle as well as in Toronto, Canada, and in England.

Dr. Edward Gudeman, of Chicago, acted as toastmaster and kept the company in the best of humor. The first speaker was President Frerichs, who called attention to the fact that the institute was organized just three years ago with a charter membership of 40. Mr. A. Bement, Dr. Geo. A. Rosengarten, Secretary Olsen and Prof. A. H. White also gave toasts.

On Friday morning the following papers were read:

"Industrial Chemical Calculations," by Prof. Jos. W. Richards. This paper will be printed in form of a bulletin and will come up for discussion at the next general meeting.

"Rapid Determination of Tin in Food Products," by Dr. Edward Gudeman.

"Distillation on the Continuous System," by Chas. L. Campbell. This paper gave a complete discussion of both the theory and practice of purification by distillation of complex liquids. Very fine samples of lead and silver linings on copper and steel were also shown by Mr. Campbell.

Friday afternoon the plant of the By-Products Coke Corporation at South Deering was visited, while some members visited the works of the Carter White Lead Company at West Pullman.

On Friday evening a paper by Dr. William M. Grosvenor on "The Institute and the United States Patent System" was read. In this paper the defects of the present patent system were shown. A communication from the St. Louis section of the American Society of Electrical Engineers was read on the same subject. It was urged that a special patent court should be established and that judges should be permitted to employ experts for independent advice. A committee was appointed to draft resolutions to be presented to President Taft urging reform of the patent system.

A paper on "The Practical Value of Calorific Tests on Anthracite Coal" and another on "Two Methods of Testing Asphalt," by S. F. Peckham, were read.

On Saturday the plant of the Indiana Steel Company at Gary, Ind., was inspected. An inspection car was provided to carry the visitors around this very extensive plant. Aside from its huge size the most noticeable feature was the clean and orderly appearance of the entire plant. The coke used is produced in Lemet-Solvay by-product ovens from which 80 tons of ammonium sulphate are produced daily. The motive power used is largely electrical, produced by 17 3600-kw generators driven by 34 gas engines using furnace gases. The open-hearth furnaces, of which there are 14, are heated by producer gas. Much interest was shown in the huge electrically driven rolling mill.

A portion of the members also visited the Standard Oil Refinery at Whiting, Ind., as well as the Universal Portland Cement Company at Buffington, Ind.

The attendance at the meeting was about 50 and marked interest was shown in all the sessions and excursions.

The Iron and Steel Market.

The moderate burst of market activity in June has been followed by a very dull July. The June activity was clearly due to the release of orders which had been piling up during the period of uncertainty in the minds of buyers as to whether prices would decline and which released by the reductions of May 29 indicating that price questions were settled for the time being. After this artificial freshet the stream of business dropped to the low level which is normal for midsummer. Rather strenuous efforts were put forth in the fore part of July by interested parties to conceal the relapse and make it appear that the market was still active. Incontrovertible evidence was furnished, however, that new buying was very light and that the mill activity, although reduced slightly from the June average, was still due in considerable part to business which had been booked in June. By the closing week in July mill activity had been further reduced, the average output of finished steel products by all interests being probably well below 60 per cent of total capacity, whereas in June a level of about 70 per cent had been maintained for a time.

The market has been quite colorless as to distinct developments. Buying has been light simply because to the reserve felt by buyers in a general period of conservative business action there is added the restraining influence of its being the summer season when many men are away on vacations and business is normally light.

The control of finished steel prices is substantially as firm as it has been at any time, though possibly not as secure as before the action of the Republic Iron & Steel Company in May, withdrawing from the counsels of the steel producers and pursuing an independent course as to the price of steel bars. This company is maintaining the same prices as other interests, but it has not formally returned to the fold, and with that example before the trade the possibility of one interest or another electing to pursue independent action, should such a course appeal to it, is somewhat increased. In no quarter can be seen any influence which would tend to advance prices, while the possibility of accident effecting reductions at one point or another, if remote, is not invisible. Should it at any time become apparent that a general reduction in prices would be likely to stimulate such a general buying movement as to fill up the mills and make possible an advancing market through individual action of producers, there is every reason to believe the course of declaring an "open market" would be pursued. This was probably the main influence prompting the break of February, 1909, for while that movement had the appearance of being an accident, time has given evidence that the course of the market, with a great dip and subsequent recovery, was fairly well thought out in advance.

Only a small number of the mills closed July 1 for repairs and inventory. In some cases the only closing was for Tuesday, Independence Day, while in other cases Monday was taken as well and in fewer instances the whole week.

The wage scales of the Amalgamated Association have all been signed. These scales affect only certain iron, sheet and tin mills. Most of the iron mills of the Central West are governed by this iron scale, which was signed before the expiration of the old scale on June 30 by the Republic Iron & Steel Company and by the mills in the Western Bar Iron Association after a two days' conference at Cambridge Springs, July 6-7. The leading sheet and tin plate interest is entirely non-union, while about 40 per cent of the independent mills are organized. These agreed upon a continuance of the existing scale.

Little buying of wire products has followed the reduction of $2 a ton effective June 20. Existing contracts were adjusted to the new basis, and for a fortnight specifications on such contracts were slightly increased. It is between seasons for the wire trade, but the usual fall buying is expected to commence during the second half of August.

Pig Iron.

The drop of Southern iron to a basis of $10, Birmingham, which occurred in June did not bring out the buying for second half which was expected in many quarters. Early in July the directors of the leading cast-iron pipe interest, which frequently leads in the buying of Southern iron, met and concluded not to buy for the present. Other large consumers have shown little interest, and buying of Southern iron has continued from hand to mouth. In most cases of market swings Southern iron leads Northern by from two to four weeks, and Northern iron has also lagged, there being scarcely any forward buying, while here and there prices have softened slightly. A very interesting development has been the continued blowing-out of merchant furnaces in the Mahoning and Shenango Valleys until only six of the eighteen are in blast. Most of the furnaces which went out merely kept in blast until their supplies of ore were exhausted, while purchases were not made for the current season. If these furnaces do not take action soon they will pass into the winter without ore and an unprecedented situation will be revealed. Pig iron prices are regarded as below cost of production to these furnaces, unless they have ore supplies of their own, and can use the profit on ore to cover the loss on pig iron. A number of lake front merchant furnaces are idle, but not nearly as large a proportion as in the valleys. There has been further blowing-out of furnaces in Virginia and eastern Pennsylvania, and at last it is believed that production of merchant iron is below the consumption. The market at the close of July may be quoted as follows: F.o.b. Birmingham, $10 for No. 2 foundry; delivered Philadelphia, $15 for No. 2X foundry and $14.25 to $14.50 for basic; f.o.b. valleys, 90 cents higher delivered Pittsburg, Bessemer, $15; basic, $13; No. 2 foundry, $13.50; gray forge, $13; malleable, $13.25 to $13.50.

Steel.

Specifications for July deliveries of sheet bars against contracts have been very good, fully equaling those of June and exceeding those of May; billet specifications have been lighter than for June. There has been scarcely any buying in the open market. Billets continue quotable at $21 and sheet bars at $22, f.o.b. maker's mill, Pittsburgh or Youngstown, while with the June reduction of $2 a ton rods are quotable at $27, Pittsburgh.

Finished Products.

Prices of finished products, f.o.b. Pittsburgh, except where otherwise stated, are as follows:

Plates, 1.35 cents for tank quality, ¼ in. and heavier.

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Shapes, 1.35 cents for beams and channels, 3 in. to 15 in. inclusive, zees and angles 2 x 3 in. and larger.

Steel bars, 1.25 cents, base; iron bars, 1.25 cents to 1.30 cents, Pittsburgh; 1.27 cents to 1.30 cents, Philadelphia, and 1.20 cents to 1.25 cents, Chicago.

Wire nails, $1.70 per keg, base; plain wire, 1.50 cents; galvanized barb wire, 2 cents.

Black sheets, 28-gage, 2 cents; galvanized, 3 cents; blue annealed, 10 gage, 1.50 cents; painted corrugated roofing, $1.40 per square; galvanized, $2.55.

Tin plates, $3.70 per base box for 100-lb. cokes.

The Western Metallurgical Field.

Chemical Engineering at the University of Washington.

The growth of chemical engineering education in the West is typified by the work done in the University of Washington at Seattle. Special courses leading to the degree of Bachelor of Science in Chemical Engineering are open to students, under the direction of competent industrial chemists who are directing attention to the solution of some problems of the Northwest.

Referring to the course of study, the work in mathematics, physics and shopwork, is the same as that required for students in civil, mechanical and electrical engineering. The general engineering work taken by the student in chemical engineering includes mechanical drawing, surveying, mechanics and hydraulics from civil engineering; machine design, steam engineering and experimental engineering from mechanical engineering, and industrial electricity from electrical engineering. This work comprises 54 per cent of the chemical engineering course. Special emphasis is laid on the fundamental processes underlying industrial chemistry and the student is taught general inorganic chemistry, analytical, organic and physical chemistry, with supplementary courses in special lines of work. The study of raw materials used in manufacturing processes in the Northwest also receives attention and a special laboratory is provided in which industrial processes may be tried out on a suitably large scale.

This special laboratory is equipped with a steam still, steam superheater, continuous extraction apparatus, hydraulic press, filter press, alcohol still, wood pulp digester, steam jacketed vacuum still, vacuum dryer, clay testing furnaces, pulverizers, melting furnaces, rotary cement kiln, wood grinder paint mills, mixing machines, electrically heated wood distillation retort and cement testing apparatus.

The university invites the co-operation of local industrial concerns in solving industrial chemical problems. To this end the concern desiring any investigation to be made furnishes the means for prosecuting the work, and the university places its industrial laboratory at the disposal of a competent investigator. In this way it is hoped that some problems may be solved to the mutual advantage of the university and the community.

Dr. H. K. Benson, who is in charge of the work, has organized his students into a Society of Undergraduate Engineers for the purpose of better informing the student of the possibilities of chemical engineering, and giving him a broader outlook of the field before he enters commercial work.

First National Copper Smelter to Close.

An echo of the old controversy between the farmers and smelters of northern California is heard in the report that the First National Copper Company is to close its plant at Coram. This smelter, better known perhaps as the Balaklala, is one of several that were originally ordered by the court to make arrangements to abate the nuisance alleged by the farmers to arise from the free discharge of smoke and fume into the atmosphere. Pursuant to that decree the company installed, at considerable expense, what is considered to be the most efficient means known of condensing fume and reducing the sulphur content of the discharged gases. Perhaps it was too sanguine, and agreed to more rigid stipulations than were necessary. In any event, it appears that the company is unable to live up to its agreement, and the consequence is that the farmers have pressed their case to the extent of causing the company to cease operations.

The decision probably will have a more widespread effect than merely to close this one plant. Other smelters operating in the vicinity are working under an agreement to remove noxious solid and gaseous substances from their furnace gases, and the farmers will make tests to see that the provisions are being carried out. The First National Company undoubtedly will continue to make refinements in its methods in the hope that the plant can be operated some time in the future.

Bureau of Mines.

Dr. Joseph A. Holmes, director of the Bureau of Mines, was in Denver last month en route to Alaska to investigate conditions there for the Department of the Interior. While in Denver he was entertained by Colorado mining men who took advantage of the opportunity to present to him the mining situation in the state, and point out the possibilities for federal assistance through the Bureau of Mines. Perhaps Colorado is not so much in need of new mines as improved metallurgy, and it was on this theme that the speakers at two meetings dwelt at length. An effort was made to impress the Director of the Bureau with the fact that there were many problems to be solved in connection with the treatment of low grade ores, and that it would be to the advantage of the mining and metallurgical industry in general if these problems could be attacked by the Bureau. Federal assistance is sought because a long line of experimentation must be planned and pursued, and private enterprise is not always equal to the task.

Dr. Holmes explained that the Bureau was in full sympathy with the needs of metalliferous mining and the problems of ore treatment, but that there were no funds available with which to carry on such work. The metal mining interests will have to impress Congress with the need of this work if they expect to secure the help of the Bureau of Mines in solving their metallurgical troubles.

Improvement at Cananea.

In the annual report of L. D. Ricketts, president of the Cananea Consolidated Copper Company, some interesting details are given of the metallurgical work during 1910. The impounding of tailings and the recovery of the water is now accomplished in an inexpensive manner. The tailings are stacked in such a way as to allow the water to settle back of the dam. This water contains about 0.5 lb. copper per 1000 gal., and this metal is recovered by precipitation on iron before the water is re-used in the mill. The copper recovered repays the cost of impounding the tailings and in the future no more of these will go down the creek. The concentrator is making a saving of 75 per cent, which is exceedingly satisfactory.

In the reduction division the cost of treating a dry ton of new copper-bearing material was $2.69 as compared with $3.09 in 1909. Reverberatory costs increased slightly, but this will be changed when the extensive improvements inaugurated last year are in operation.

Tests of dust losses in the various departments showed that serious loss was suffered in the converter fume, amounting to about $30,000 a year. Dust chambers and a stack were accordingly constructed to handle these fumes, and were so proportioned that when all converters are running the velocity of the gas in the flues will not exceed 3 ft. per second. As a result of all the improvements made at the plant Dr. Ricketts predicts that the cost of treating a ton of new copper-bearing material in the reduction division will be not more than $2.25.

Drying in Vacuum.

By B. Viola, M.E.,
Member American Society Mechanical Engineers.

(The conclusion of the serial on evaporators and vacuum pans, published in the April, May, June and July issues.)

If materials form crystals, as in the manufacture of sugar or other crystallizable materials, we are able to concentrate the liquors till the crystals begin to form, let the whole cool off and separate the superfluous liquors from the crystals by some mechanical device.

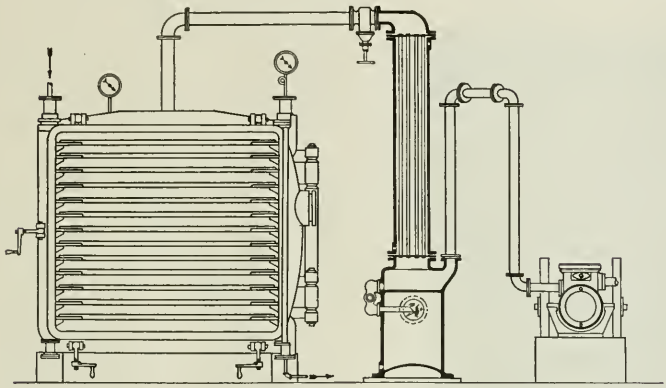

FIG. 50.—ASSEMBLY OF THE PASSBURG VACUUM CHAMBER, DRYER AND AUXILIARIES.

It is, however, different when we want to get the dry substance of a solution which does not crystallize. Then all the dissolving liquor (solvent), whether it is water or some other liquid, has to be evaporated. To a certain density these solutions can be evaporated either by open fire or in a vacuum evaporator, yet in a great many cases the concentration does not suffice; in fact, when it is desirable to remove all dissolvents, it has been found impossible to do so by such an evaporation without a detrimental effect to the dry product, for the reason that such a high concentration causes an overheating of the material, and in this respect vacuum pans fail.

As the water contained in the solutions is reduced, the ebullition of the liquid becomes more sluggish and the temperature of the boiling point of the remaining water rises; consequently an overheating of the material when the final stage of concentration is reached, can very easily take place. The degree of concentration where such overheating would be injurious varies with different materials.

The concentration of liquids by the open or vacuum-pan method, effective as it is, fails more or less according to the material when the last traces of moisture have to be removed.

To supply the need thus created, and realizing the varied uses to which such an apparatus might be put, Messrs. Emil Passburg and W. Strohn, about thirty years ago, commenced investigations and conducted a series of practical experiments from which ultimately the invention of the vacuum-chamber dryers, Fig. 50, were brought about. This is the foundation of the present system of vacuum drying.

The apparatus consists of an evacuated iron chamber fitted with steam-heated shelves or horizontal coils, on which the drying material rests in comparatively thin layers on trays. The result obtained from these vacuum drying chambers was for many materials highly satisfactory, but at the same time a certain amount of labor was involved in charging the trays with the wet material and again emptying them from the dry material. An apparatus which gave, if possible, still better results than the chambers, and at the same time insured a great saving of labor, was the outcome of the constructions, Figs. 51 and 52.

This apparatus, Fig. 51, which is being used in many industries with the greatest satisfaction, is known as the Passburg vacuum single-drum dryer. The apparatus consists of an iron casing of sufficient strength to withstand the outer atmospheric pressure when evacuated, which is very considerable, approaching about 15 lb. to the square inch, a steam-heated rotary drum which dips into the liquid and coats itself with a thin film.

On account of this very thin film of absolute evenness, which can only be obtained by dipping, the wet material is dried in one revolution, the number of revolutions, of course, being regulated according to the nature of the material, the percentage of water it contains, etc.

The thickness of the film of the rotary drum is regulated by the level of the solution contained in the trough or lower part of the outer casing of the apparatus and into which the drum dips. For this purpose observation glasses are provided, by which means the level of the liquid can easily be observed and regulated by a valve.

In the trough provision is also made for coils, through which the cold water passes in order to keep the liquid at the required temperature below the boiling point in the particular vacuum maintained in the apparatus. This feature is quite necessary, where milk, glue, and similar materials are being dried. Where, however, emulsions have to be treated, such as white lead, etc., and where a rapid precipitation of the solids

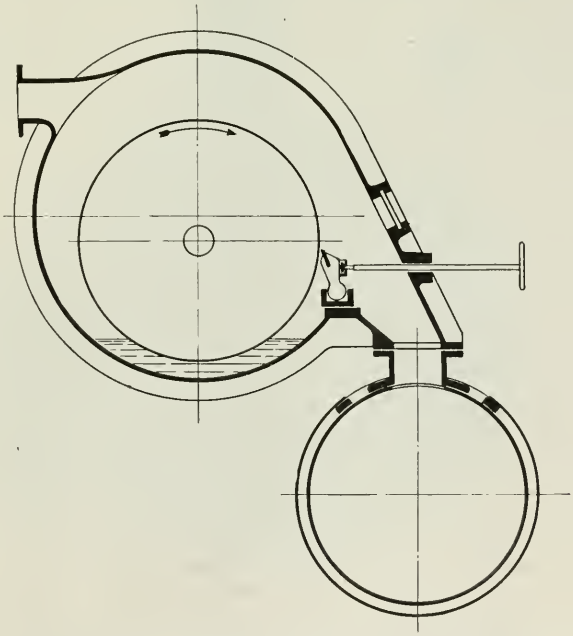

FIG. 51.—CROSS SECTION OF A PASSBURG SINGLE DRUM DRYER

may occur, the place of the cooling coils is taken by suitably-designed agitators.

The ends of the rotary drums are protected by shields so that no liquid whatever may coat the former; in fact, it is only the cylindrical drying surface of the drum, which is at each revolution coated with and freed from the dried film and which comes into contact with the liquid to be dried.

The temperature to which the drying film is exposed rarely exceeds 95 to 122° F. (35-50° C.), and as heating steam of from 20 to 25 lb. pressure may be used for heating the rotary drum, it will be apparent that the enormous difference between the temperature of the heating medium and of the boiling point of the water contained in the wet material, which in such a case as given above approaches 176° F. (80° C.), will insure a most rapid evaporation of the water, notwithstanding the low temperature at which such evaporation takes place.

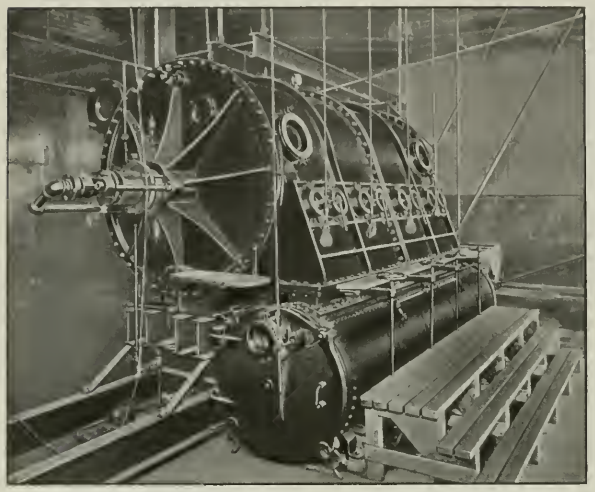

FIG. 52.—ASSEMBLED PASSBURG VACUUM SINGLE DRUM DRYER.

These drum driers work absolutely continuously and automatically, the liquid being drawn in by the vacuum maintained in the dryers and the dry material, which is removed by means of a scraper from the drum, drops into suitable receivers which can be arranged in such a manner that they can be emptied alternately and periodically without breaking the vacuum in the apparatus, and consequently without even temporarily interfering with the drying process.

Such a thin film of wet material in direct contact with the heating surface requires only a fraction of a minute to have all the water it contains evaporated therefrom by boiling; that is, by rapid and not by slow evaporation, and as this process takes place under a high vacuum, the temperature to which the drying material is subjected is consequently a very low one.

The number of revolutions of such an apparatus varies from 4 to 10 per minute, or in other words, the time during which the drying material is subjected to a low temperature can be counted by seconds.

Provision is also made by specially-designed apparatus, so that no loss of dust occurs.

The saving of steam, as no loss by radiation takes place, is naturally very great.

These apparatus offer the further advantage that where material of a poisonous nature, as, for instance, cyanide of potassium, white lead, etc., are dried therein, the laborers are fully protected, since by means of the automatic feed and discharge of such rotary-drum dryer neither the wet nor the dry material enters the drying room, and consequently all detrimental effect on the health of the laborers is absolutely prevented.

The author had the opportunity to work with such apparatus and to find the great advantage of the system, comparing it with the old-time hot-air drying system; that is, by slow evaporation. The most important fact is that the received dry material is always of the same quality, supposing a little attention is paid to the apparatus.

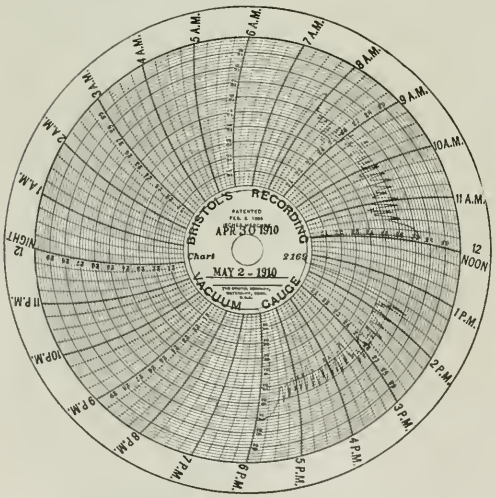

FIG. 53.—VACUUM RECORDING CHART OF A SINGLE DRUM VACUUM DRYER.

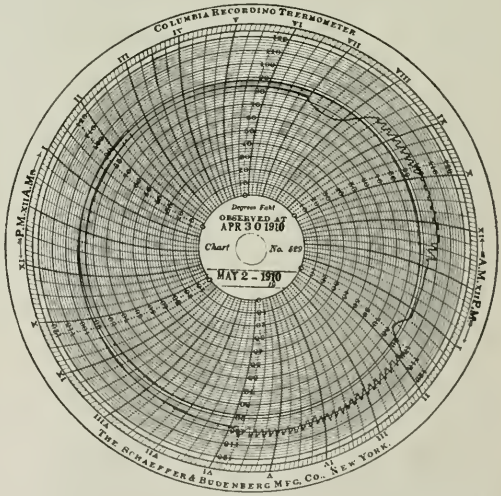

FIG. 54.—TEMPERATURE RECORDING CHART OF THE SURFACE CONDENSER CONNECTED WITH A SINGLE DRUM DRYER.

The feed into the drum should always be carefully watched so that the liquid has approximately the same height in the receiver, and the heating surface of the heating drum be kept steady. Should the liquid in the receiver be used up to a certain extent, then it has to be fed again. This can be done either

by some automatic device so that the feed of the solution corresponds with the evaporating capacity of the drum, and if the former is once set for that purpose the liquor level within the dryer, into which the drum dips, will automatically remain the desired one, suitable for the material. Or it can be done by the attendant himself.

In this way little variations can be noticed on the vacuum, as

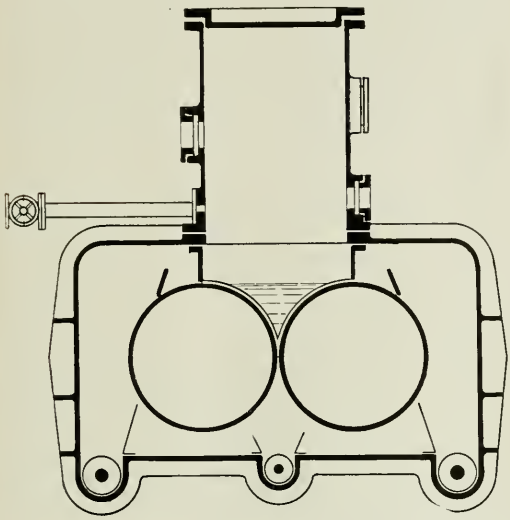

FIG. 55.—CROSS SECTION OF A PASSBURG VACUUM DOUBLE DRUM DRYER.

naturally, by feeding the drum with fresh liquid, a certain quantity of air is drawn in. These changes can be seen plainly on Fig. 53, the recording vacuum chart, and hardly amount to more than 1 in.

At what vacuum the drying process has to be performed depends upon the material, and it is an important fact that no two materials can be handled exactly alike. Every material must be treated on its own merits, and oftentimes small auxiliaries are very essential to the success of an entire apparatus.

Another important factor in vacuum drying, which affects eventually also the vacuum, is the temperature in the condenser. This should be kept approximately constant, and if this involves some difficulty it is the best to equip the plant with a temperature controller, to regulate the flow of the condensing water.

The chart of such a controller can be seen in Fig. 54, where the variations of this temperature are not more than 3° F., giving an excellent result.

The most remarkable difference can be seen on the chart at 7 a. m., when the recording thermometer shows about 81½° F., this being the temperature of the working room; but at that time the cold water was turned on, the drying began, and by and by was raised to the working temperature. At 11:45 a. m. the drying process was stopped again till 1:15 p. m., and this variation of the temperature can be seen.

Though the above-mentioned apparatus have proven most useful for drying liquids, still they could not be employed where materials of high concentration or pasty or similar form had to be dried, and this led to the invention and successful introduction of Passburg's vacuum double-drum dryer as illustrated in Figs. 55 and 56.

With this apparatus the wet material is either pumped or forced by some other means into the evacuated chamber, within which two steam-heated drums rotate as shown. The material is fed on top of the two rotary drums, the latter by their rotary movement coating themselves by pressure with a thin film of the wet material, which is also dried in one revolution, similar to vacuum dryers containing a single drum only.

The thickness of the film on both drums is regulated by the space between them, which can easily be adjusted. Provision is made that any wet or insufficiently dry material which may drop from the drum is collected and again conveyed back to the feed pump, so that no loss in that respect occurs. The dry film is also removed from the drums by means of scrapers similar to the one employed in the single drum, and the dry material drops into suitable receivers, which again are emptied in a similar manner as described with single-drum dryers.

For materials which do not coat the rotary drum with an even film by means of the drum dripping into the material, a single-drum dryer with roller feed can be used, Fig. 57. This kind of dryer is used for heavy color pastes as produced in the manufacture of aniline dyes and similar materials. In fact, these pastes are so heavy that they cannot be drawn into the dryer by means of the vacuum maintained and have to be forced into the apparatus by means of the feed-pump.

From the construction or design of the above-mentioned vacuum shelf, single or double-drum dryers, it will have been noticed that no heat transmitted to such dryers has any means of escaping unused except by radiation from the outer shells

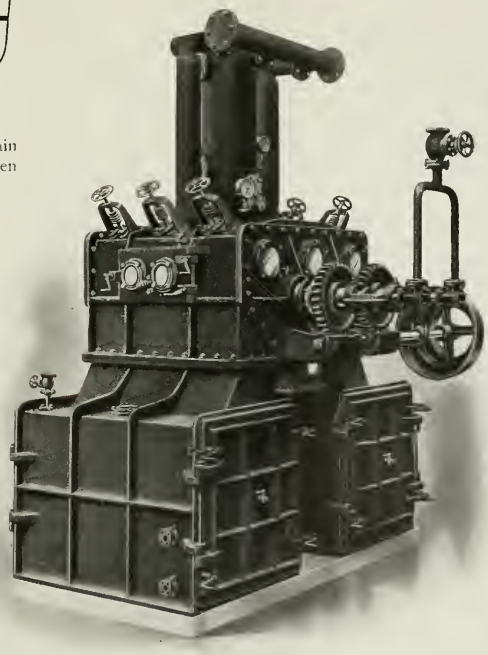

FIG. 56.—ASSEMBLED PASSBURG VACUUM DOUBLE DRUM DRYER.

of the drying apparatus, and this can be minimized by an efficient coating of a good non-conductor of heat.

All other heat imparted by means of the heating medium, be it either steam or hot water, is absorbed by the water contained in the drying material for its own evaporation. There is no other outlet for any unused heat, as in the case of drying

under atmospheric conditions, where, as stated before, it is absolutely necessary to frequently exchange the air in the drying room, and in many cases heated air, in order to allow at least a fairly rapid evaporation.

As soon as the air in the drying room, be it hot or cold, has charged itself with a certain amount of moisture; that is, all that it can carry, it must be removed, as otherwise it will

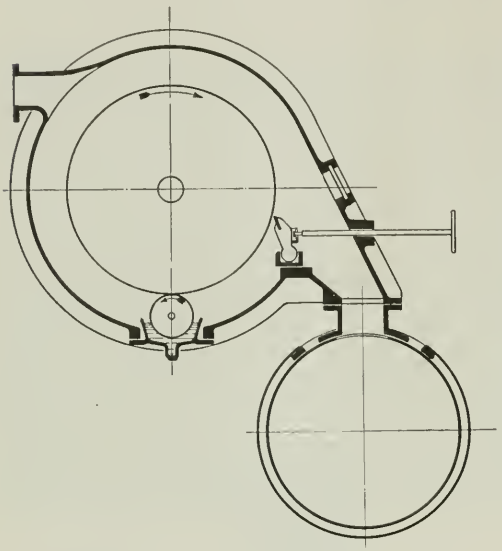

FIG. 57.—PASSBURG SINGLE VACUUM DRUM DRYER WITH ROLLER FEED EQUIPMENT.

directly stop a further evaporation of moisture from the material. This steam-saturated air, if remaining stagnant, forms a kind of fog or moisture-laden atmosphere in the drying room. A quick exchange of air is obtained by means of fans or similar apparatus, and the drying process is thereby aided.

With heated air an enormous quantity of heat is carried away by such air, runs to waste, and leaves the drying room unused.

The B. F. Sturtevant Company of Boston, Mass., states in one of its catalogs that even under favorable circumstances, where some of the heat was saved for reuse, the loss of heat by means of hot-air drying was as follows:

	Percent of total heat.
Required to vaporize moisture in stock	32
Lost by leakage, radiation from tower, and unaccounted for	37
Lost by radiation from return duct and by introduction of fresh air at fan room	31
Total heat imparted to air	100

The above data shows that only about one-third of the heat imparted to the drying air was really utilized for removing the moisture contained in the material. As this statement was made by a firm who are certainly experts and specialists in building hot-air drying systems, it may be considered as a fair statement, and certainly does not underrate the value of such drying systems. It gives an impartial proof of the unavoidable loss which is connected with any drying system where an air current is used.

Where materials of a hydroscopic nature have to be dried, absolute dryness can, of course, never be obtained by means of hot air, as naturally the drying material can never be dried below the moisture contained in the hot air used as a heating medium, and with materials which are of an inflammable nature at a certain temperature, hot-air dryers show great disadvantages, as they can easily produce an explosion, while with materials which easily oxidize the continuous heated air current has also naturally a detrimental effect.

Another important advantage of drying under vacuum is that the evaporation takes place in the absence of atmospheric air with all its impurities. Under such a rapid exchange as would be necessary when evaporating under atmospheric conditions, the air would partly deposit such impurities and thereby add to the quick deterioration of perishable materials, which deterioration may even continue in the dry material and thereby nullify the results of the drying or concentrating process.

Where discoloration is feared from the deposit of dust, the drying of such materials has no difficulty at all. When white lead, for instance, is dried by hot air under climatic conditions where the atmosphere is heavily laden with moisture, it is impossible to obtain either a dry product or a product with an even moisture content.

However, in a vacuum dryer the dry white lead has an even moisture content of .25 per cent, is free from a coating of dust or dirt, and has a white color.

Milk or egg powder, produced on the single or double-drum dryers, have proven to be practically free from obnoxious bacteria, lactic acid and overheated butter-fat, which latter tends to give the dry product a rancid taste.

On account of the low temperature employed during the rapid evaporation of the water in these liquids, which are partly emulsions and partly solutions, the albumen remained soluble also, and this is the most important and practically indispensable factor.

The result of the drying process is not only an increased keeping capacity of the dry products, as no germs are prevalent to start decomposition in the absence of water, but also the flavor of the re-dissolved powders could scarcely be distinguished from the fresh material.

This drying apparatus and process will consequently obviate the cold-storage system with all its recently much-discussed drawbacks and give the consumer a cheaply preserved and wholesome article of food at a reduced cost in all seasons of the year.

The old slow-drying method, which was only possible during the summer months when the atmosphere was not too heavily charged with moisture, has caused great loss to the manufacturers of glue; and even now, where a more rapid drying system by means of hot air and fans is frequently used, the gelatinized glue cakes either become mildewy and spoiled through the long drying process or the gelatinized glue becomes liquid again and flows through the net on which they were put for drying.

The losses have been obviated by the adoption of the vacuum drum dryers, which produce, quite independent of climatic conditions, a glue powder of even moisture contents, solubility and color.

I have briefly touched upon some of the various devices and types of apparatus used in evaporation and for the final removal of the last traces of moisture from materials which are desired to be thoroughly and perfectly dry in their final state.

The principles involved in their operation are many and complex. The removal of moisture from given materials is a scientific problem.

That its elimination cannot be successfully accomplished by "rule of thumb" methods is becoming recognized by those engaged in the manufacture of products in which drying is an important factor.

Brooklyn, N. Y.

The Application of the Turbo Blower in the Iron and Steel Industries.*

By J. E. Johnson, Jr.

I have been very much interested in the subject of this turbo blower since it was in its initial stages in the shops of the General Electric Company, the subject of blowing engines being one of profound importance to the blast-furnace manager. Men of this calling are commonly not members of the American Society of Mechanical Engineers and I trust that some discussion by one of the few who are will not be amiss.

The efficacy of the control of the volume of air blown is the question which will arise in the mind of every practical furnaceman as soon as he gives this subject consideration. Changes in quantity of air as small as 1 per cent or 2 per cent are frequently made in the quantity of blast delivered to the furnace as one of the means of controlling its operation, and this makes it obvious that exact control is a very necessary feature of any blast-furnace blowing apparatus.

I had the pleasure of seeing the installation of the turbo blower at the Port Henry plant of the Northern Iron Company about a year ago, and the simplicity of the governor is certainly admirable, but is a feature not exactly easy of comprehension to a man without thorough mechanical training, and a prejudice against these machines is likely to exist in the minds of many furnacemen on this account, which will make their introduction slower than it perhaps otherwise might be.

It is a well accepted fact that the efficiency of the turbine is far higher at low pressures than it is at high, while, on the other hand, it is equally well known that for high pressures only the reciprocating engine has a considerable advantage over the turbine. The result is that the most economical form of steam-driven apparatus is a combined unit in which the steam expands down to about atmospheric pressure in a good reciprocating engine and is then delivered to a turbine on its way to the condensers.

The very remarkable results obtained with this combination by Mr. Scott at the Interborough plant in New York have, in the opinion of many, given a decided check to the development of the gas engine.

In a similar way it has been known for years that for very low pressures the centrifugal blower, of which the turbo is simply a development, was more economical than a piston blower.

On the other hand, for higher pressures the piston compressor is undoubtedly to be preferred, particularly in blast-furnace work, on account of its operating as a meter as well as having much the highest efficiency as a compressor.

A condition of piston-blowing engine design is that the air cylinder must be large enough for the greatest volume to be handled and strong enough for the highest pressures attained, with the result of enormous size and very massive and expensive construction in modern blowing machinery.

In spite of their high cost it is notorious among operating men that really reliable blowing engines are exceedingly scarce. The problem of the valves is in itself one of great difficulty. It is almost impossible to get an air-inlet valve with sufficient area to allow the cylinder to fill absolutely without heavy loss by suction, and at the same time quick enough to give correct results at the speeds required of modern engines.

The turbo blower, on the other hand, suffers from the disability that it must have stages enough to blow the highest pressure ever required, although this high pressure will not, in ordinary operation, be required 1 per cent of the time, the normal pressure being perhaps only half as great.

If, therefore, we make a turbo blower to deliver air of a certain nearly constant, moderate pressure, and a blowing cylinder of comparatively small size, strong enough to deliver air to the desired maximum pressure we shall have bettered the conditions of operation of both apparatus, increasing their efficiency and reducing their cost. In other words, the turbo blower and reciprocating compressor combined are more efficient than either apparatus alone, exactly as the engine-turbine combination is more economical in the consumption of steam.

For the best and cheapest blowing engine, therefore, we should have a combination of these two units, a turbine-driven turbo blower, delivering air partly compressed to the compressing end of a steam-driven blowing engine, the steam from the cylinder of this engine driving the turbine before passing to the condenser.

It may be objected that this is a complicated unit, but this is not the case. Most large modern furnaces require three of the best types of large reciprocating blowing engines to operate them. These are, in good modern usage, disconnected compounds—a high-pressure steam cylinder on one engine, a low-pressure on the next, etc.

A turbo-blower supplying air compressed to 8 lb. to two of these would enable them to deliver as much air as three drawing air from the atmosphere, and the efficiencies which are guaranteed in the use of exhaust steam by the builders, combined with the guaranteed efficiency of the turbo, indicate that this can be done at a decided saving in first cost and with an efficiency certainly no lower, probably higher, than that of either unit alone. This does not make any allowance for the possibilities of spray inter-cooling between the turbo and the reciprocating compressors, which, in ordinary practice, would be good for about 4 per cent additional saving at a very low cost.

The advantage of maintenance is undoubtedly with the turbo, as compared with reciprocating engines. At the same time the magnitude of the alternations of stress in the reciprocating engines is greatly reduced by delivering to them partly compressed air, and the problem presented by their inlet-valve gear, which has given so many bad hours to both furnacemen and engine designers, is practically eliminated by delivering to them denser air under pressure.

It, of course, cannot be denied for a moment that the efficiency of the reciprocating machine as a compressor is far higher than that of the turbo, except for the lowest pressures, while the advantages of positive metering of the air by the reciprocating engine will cause furnacemen to accept the combined apparatus without that hesitation which they feel toward the non-positive turbo.

The governing of such a combined unit is extremely simple. The ordinary governor on the engine unit does all that is necessary and no governor other than one to prevent racing is necessary on the turbine. The steam supply of the engine passes directly to the turbine. As long as all conditions remain constant the speed of the turbine will be unchanged, but if the pressure required by the furnace increases a little, more steam is admitted to the steam engine by its governor, and this increased quantity of steam speeds up the turbine to a slight extent and so causes it to deliver air compressed to a slightly higher pressure. This slight increase automatically compensates for any slight lag due to the greater load on the engine and for the lower volumetric efficiency of the piston-blowing engine at higher pressures as compared with low.

If, on the other hand, the speed of the piston engine is deliberately increased to deliver more wind, the increased supply of steam to the turbine will enable it to deliver a proportionately increased quantity of air at virtually the same pressure. Of course, some hand control will be applied to the turbine to enable the receiver pressures to be adjusted to the best conditions, but, once this is done, other changes will seldom be required.

For these reasons I believe that the steam-driven blowing plant of the future should consist of a turbine-turbo, piston-engine, piston-compressor combination.

*A discussion of the paper of Mr. Richard H. Rice, presented at the recent convention of the American Society of Mechanical Engineers.

This combination will have its greatest field in applications to existing plants where, as is so often the case, the existing blowing engine, while old, is by no means worthy of the scrap heap, but is unable to deliver quite the pressure or quite the volume demanded by modern conditions. In such a case the introduction of a turbine-turbo, taking steam from the engine and supplying precompressed air to it, will use what is now waste energy in the steam and apply it in such a way as to increase both the capacity and the permissible pressure of the existing blowing cylinder.

A further advantage which the turbo has as the primary machine is that of an inlet free from pulsations. These are much more serious in inlet than in outlet, for the reason that the volume and velocity of the air are so much greater.

One of the serious problems which had to be overcome in the application of the dry blast was the construction of cooling chambers whose walls would not be thrown down by the pulsations produced by the piston compressor on the incoming air. The smooth inlet of the turbo will eliminate entirely difficulties arising from this source.

The necessity of massiveness both in stationary and in reciprocating parts, and the conditions of operating the air valves, have operated to limit the best size of blowing engines, so that these are not only not increasing in size, but those now built are commonly as large as some that were built ten or twelve years ago.

The turbo-blower, on the other hand, lends itself admirably to enormous capacities in the same way that the turbine is commonly built for certain classes of service in sizes that have never been approached in reciprocating engines. For this reason it will not only be possible, but advisable, at large plants to install one turbo to supply several reciprocating engines, all of which, of course, will exhaust to it. This will contribute still more to low first cost, small space requirements and small maintenance charges.

I wish to express in conclusion my conviction that the introduction of the turbo compressor marks the beginning of a better era for the mechanical equipment of blast furnaces, but that its best and easiest application will be in conjunction with rather than in supplanting piston-blowing engines.

Ashland, Wis.

The Vacuum Filter Process in Western Australia.*

By T. B. Stevens and W. R. Degenhardt.

The stationary-frame vacuum-filter process was introduced into Western Australia four years ago, and has since been developed and improved until it now forms one of the chief methods of slime treatment on these fields.

The object of the present article is to point out, more particularly, the novel features of the plants in operation in this State.

Nature of Material Treated.—The material treated in vacuum-filter plants varies from the finest oxidized slime to an all-slimed product from sulphide ore. No slime of any grade has yet been tried that could not be economically handled.

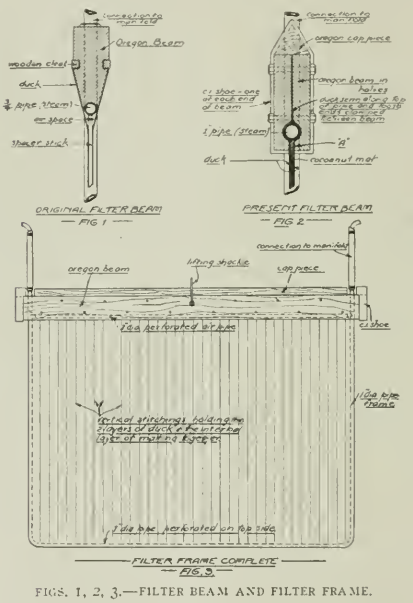
The worst filtering slime yet tested was an oxidized clay containing no fine sand, obtained from the Never Never mine (near Southern Cross). This slime gave a cake only ⅜ in. thick, containing 3.46 lb. of dry slime per square foot after 40 minutes of vacuum. It could be successfully washed and discharged. Average oxidized slime will form in 25 minutes a cake 1¼ in. thick, carrying 8 lb. of dry slime per square foot. An all-slimed sulphide product will, in the same time, form a cake 2½ in. thick, carrying 18 lb. of dry slime per square foot.

It is always advisable to make experiments with a single filter frame before a plant is erected. The appearance of slime as regards its cake-forming power is often deceptive; thus, Rand slime is considered a perfect slime free from sand and is practically a pure clay, but with this slime a 3-in. cake can be readily formed. The slime that contains most sand is not always the most easily formed into a cake. It appears that a well-sized slime, i.e., one containing particles of approximately equal sizes, best forms a cake, the reason being that the interstitial space through which the solution can pass is greater than in a mass of closely packed particles of variable sizes. This subject has been carefully studied in connection with sand leaching.[1]

The cakes from oxidized slime will, as a rule, contain 30 per cent to 33 per cent of moisture, while an all-slimed sulphide product will contain from 23 per cent to 25 per cent.

The Filter Frames.—The present filter frame is the result of considerable experimental work. The trouble with all the earlier frames was that the cakes cracked on exposure and consequently fell off. Practically all frames are now built of 1-in. steam pipe and are covered with 16-oz. duck, with cocoa-mat between.

The filter cloths are sewed with vertical seams 3 in. apart, this spacing having been found to be the best. Undoubtedly a



FIGS. 1, 2, 3.—FILTER BEAM AND FILTER FRAME.

great part of the filtered solution passes through the stitch holes instead of the cloth, and it has been found that bags with seams 6 in. apart do not take cake so quickly as those with 3-in. spacing. Bags with seams only 1 in. apart have been tried, but these did not form the cake so quickly as the 3-in., the reason being that the close stitching drew the cloth so tightly to and compressed the cocoa-mat that very little space was left in the mat for the solution to pass through.

The weight of the pipe, frame and cake is hung from two supporting beams of special section. The detail of these beams is important. The beam at first used (Fig. 1) had many disadvantages. The wooden cleats were not strong enough to hold the cloth and the weight of cake. The cloth also had no support where it joined the beam, thus causing cracks to form there on exposure. It is also obvious that if the cloth were allowed to stretch the cake would crack at the top.

Another difficulty was that the cake formed on the cloth where it was stretched over the beam and could not after-

*Slightly abstracted from the *Journal* Chamber of Mines of Western Australia.

[1] See "Cyaniding of Gold and Silver Ores." Julian and Smart; 1st edition; p. 49.

wards be dislodged by the air discharge, thus necessitating constant hand-cleanings. The air pressure also caused rapid wear of the cloths, for when the air was turned on a great strain was put on the vertical seams at the top of the bag, and it was only a matter of a few charges before holes appeared, allowing the slime to leak into the filtered solutions.

All these disadvantages have been overcome in the improved frame. (Fig. 2.) In this frame the support of the cloth is

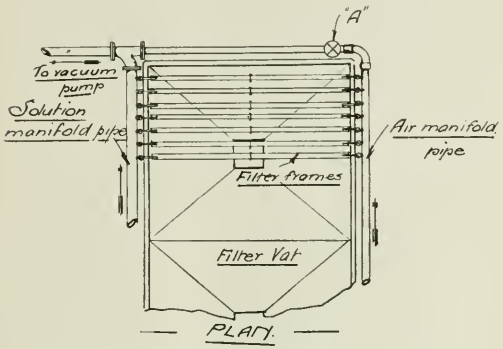


FIG. 4.—MODIFIED METHOD.

satisfactory, as it is clamped securely in the split beam. No cloth is exposed on the outside of the beam, consequently no cake can form on it. The shape of the edge *A* is designed so that it just presses on the cloth, but not so tightly as to prevent the passage of compressed air. The vertical seams come just up to this ledge, and it is, therefore, impossible for them to rip.

Frames are usually made of a uniform size (Fig. 3) of 9 ft. wide by 4 ft. 9 in. deep; this permits the use of a covering of duck 72 in. wide. The capacity of a plant is adjusted not by the size, but by the number of frames employed. Taking into account the handling of the frames for renewals, and the time occupied in filling and discharging the filter vats, this size of frame has been proved, from practical experience, to be the most efficient; deeper frames take considerably longer to discharge owing to the choking of the cakes.

If a plant is working on slime that will form a cake less than 1½ in. thick piping of smaller size than 1 in. may be used for building the frames, but with cakes above this weight nothing less than 1-in. steam pipe will stand the shock of the falling cakes. Pipes are liable to break where they join the beam, owing to the leverage exerted on them when the falling cakes spread the frames at the bottom. It is advisable not to fix the frames in the filter vat too securely, as a slight motion of the beams decreases the shock to the frames.

Various devices have been tried for obtaining the necessary spaces for the flow of the solution between the cloths of the frame. Wooden laths were first used, one being placed between each 3-in. seam; these were fairly satisfactory, but they did not give the support to the cloth that the cocoa-mat does and the cakes are, therefore, more liable to crack during exposure. Ripple iron, i.e., galvanized iron with small corrugations, as used at the Waihi mine, New Zealand, was also tried, but as this had to be used without vertical seams trouble was experienced in discharging the cakes. When the air was turned on the cake was stretched but not discharged.

With very free-filtering slime, i.e., slime that will form a cake of 2 in. or more in 20 minutes, it has been found that the cakes form thicker at the bottom than the top. The reason for this has been traced to the fact that the filter mat is not sufficiently porous to allow the solution to be drawn off as quickly as it passes through the cloth. This difficulty has been obviated by using the top pipe of the frame, as well as the bottom one, for drawing off the solution. Fig. 4 illustrates this method, which may be described briefly as follows: In taking cake or washing, both the solution and air cocks on the frames, as well as the valve *A*, are left open, thus enabling each cock to draw from approximately half a frame. When the cakes are ready to discharge valve *A* and the air valves on the frames are closed; compressed air is then admitted to the other end of the air manifold and the air cocks are opened one at a time to discharge the cakes.

The same result could be obtained by using larger pipes for the frames and a larger solution manifold, but this would add needless weight to the frames. This arrangement is also useful as an addition to an old plant, where, by reason of the internal deposition of lime, the pipes become too small for the flow of solution.

Filter Vats.—The chief point to be considered in the design of filter vats is the method of discharge. It was obvious from the beginning that in Australia sufficient water could not be obtained to discharge them by sluicing with water pressure as practised in America. It was required to discharge the residue into the residue dam in the form of a pulp as thick as could be handled. This has been effected by mixing devices of different designs placed in the bottom of the filter vats.

Fig. 5 shows the most successful type, in which the cakes are dumped through discharge doors into a separate mixing agitator below. This allows of very quick discharge—less than 10 minutes—as the mixing can be completed after the discharge doors are shut and the filter vat is at work on the next charge. This type is always adopted where water from the Goldfields Water Supply is used for sluicing purposes, since water used exclusively for sluicing and not entering the treatment plant is supplied at a cheaper rate than that used for general purposes.[2]

Filling Filter Vats.—It is essential that the filter vats should be filled and emptied quickly. Two methods have been employed:

1. Filling by a small pump and gravitation. In this arrangement the pulp and wash are elevated to storage vats by small continuously running pumps, and the filter vats are rapidly filled from these through large pipes, as required. The excess pulp and wash from the filter vats is run out into two storage vats situated below and then elevated to the upper vats.

2. Filling by a large pump running intermittently. In this arrangement only one set of storage vats is required. These are placed on the same level as the filter vat, from and to which the pulp and wash are pumped as required.

Both methods have their advantages. The capital cost in each case is much the same, for, while with the gravitation plant extra storage vats are necessary, the pumping plant requires

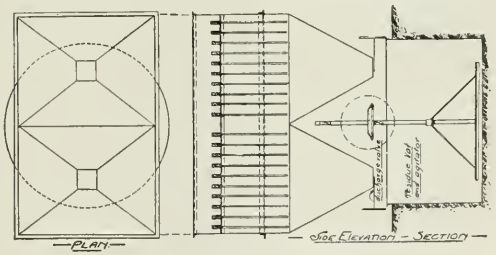

FIG. 5.—FILTER VAT.

a more powerful pump and larger piping and valves. As regards power cost, there appears to be little difference, since the gravitation plant requires power for running two small pumps continuously on a high lift, and for stirring two extra storage agitators, whereas the pumping plant requires only sufficient power to drive a large pump on a low lift.

[2]For general water services the price is 7s per 1000 gal. and for sluicing water is 6d per 1000 gal.

For a mine with a large power plant or one buying power from a central generating station, the sudden addition of a big load, such as a large pump, is of little account, but for a mine with a small power plant of its own the smaller but continuous load is the more convenient. As a rule, it has been found that where only one filter vat is required the gravitation filling is good, but where two or more filter vats are necessary the pumping plant is undoubtedly better.

Pumps.—For a high lift triplex plunger pumps are most efficient, and these call for no remarks. For a large capacity on a low lift the centrifugal pump is the best; the pumps most in use are of the Kershaw type. The casings of these pumps are made in halves with internal hard liners, which, with other working parts, are easily renewable. The cast-steel ported runner is fitted with cast-steel renewable shoes and is carried on a heavy mild-steel shaft. The shaft is run in a specially sealed four-part bearing with wedge-adjustable brasses, inside wearing ring and nipple. A stuffing box and gland for greasy packing are also provided. The runner shaft is connected by a muff coupling to a short shaft carrying the fast and loose pulleys between two outer standards having heavily flanged gunmetal bearings and loose thrust collars. All bearings are provided with water-circulating pipes and cocks to supply clean water under pressure to keep the bearings free from sand and grit. Stauffer lubricators are also fitted. The loose pulley is brass-bushed and fitted with a Stauffer lubricator; it is run on a cast-iron sleeve, which is secured to the spindle and which is the full width of the pulley face.

Wet-vacuum pumps without intermediate receiver have been found quite satisfactory and capable of maintaining a vacuum up to 27 in. These pumps are usually of 8½ in. diameter, single cylinder, 10-in. stroke, double-acting up to 40 r.p.m., according to the number of frames to which they are connected. They are fitted with vacuum and air vessels to promote uniform action. The pistons are of the trunk type, ordinary square packing being used.

Valves.—For filling and emptying the filter vats 6-in., 8-in. and 10-in. pipes are used. Where it is possible to do so quick-opening valves are arranged so that they may be operated from the working platform by means of extension spindles and hand-wheels.

In a plant lately designed 12-in. valves are proposed to be pneumatically operated. This improvement is suggested for the reason that most of the work in operating vacuum slime-plants consists of opening and shutting valves. Considerable power is required to open and shut a large valve, and even with a treble thread the manual operation is slow. The pneumatically operated valves act at once and will thus effect an appreciable economy of time and labor.

Clarifying Solutions.—In most cases it has been possible to make use of old filter presses for clarifying solutions; the solutions are, as a rule, very clear and a by-pass is arranged so that in the case of a leaky bag the delivery of the vacuum pump can be turned back into the filter vat. Where filter presses have not been available, filter-bag frames, placed in an elevated gold solution vat, form an inexpensive and effective clarifier. The frames are similar to those used in the filter vats, but are long and narrow. The suction is obtained by the fall to the zinc-boxes. The frames are usually cleaned once in each shift by closing the delivery to the extractor boxes and inflating the bags with air; this causes any deposited slime (which is very tough) to peel off into the bottom of the vat. After the frames have been cleaned the delivery is kept shut off as long as possible to allow the slime to settle. The settled slime in the bottom of the vat is sluiced out once a week into one of the treatment agitators.

Washing of the Cakes.—The time of economical washing varies greatly with the nature of the slime, and can only be definitely determined by taking progress assays from the discharge of the vacuum pump. This subject has been already discussed in an earlier number of the *Journal*. The time occupied in washing is always greater than that required for taking cake. It has been found that a low-grade slime (under 8s. per ton) obtains a good wash when the amount of solution sent to the extractor boxes is equal to about one-tenth more than that contained in the original pulp. As in all other filter processes, it is essential that the wash should be kept low in gold; to do this the filter vat must be quite free from pulp when the wash is put in and this can be easily effected by spraying down the sides of the vat with spent solution as the pulp is emptied out. If this be done, the wash will not gain more in gold by contact with the vat and cakes than can be counteracted by dilution with the make-up of barren solution and fresh water.

Notes on the Metallurgy of Wrought Copper.

By F. Johnson, M.Sc.

Metallic copper is unique among all the known metals by reason of its malleability, ductility, electrical and themal conductivity, strength, toughness, comparative resistance to corrosion and immunity from oxidation, strength in torsion, capability of taking a high polish, high melting point, beautiful luster when chemically treated, ability to be worked into any conceivable shape, etc.

Its property of forging well at a red heat is one which enormously enhances its usefulness.

By reason of its great malleability, in which property it stands third in the table of metals, it can be hammered or rolled into sheets which have an immense range of application in the arts and in the engineering industries .

Its ductility enables it to be rolled and drawn into the finest wire, its possession of this property ranking it high in the order of ductile metals.

In electrical conductivity it is second only to silver, and this property alone has accounted for the production of millions of tons of the metal.

Its resistance to corrosion has enabled it to successfully withstand the advance of all competitors, as a material for such purposes as sheathing ships' bottoms or lining pump cylinders, while it also enables it to be used for culinary articles, chemical and distilling apparatus, boilers, etc.

Its immunity from oxidation is of great service wherever it is used, and this property, where nails, bolts or screws of the metal are used in contact with wood, gives it a peculiar advantage over iron. Unlike rust, what superficial oxide is formed has no corroding influence on the wood into which the metal enters.

Its thermal conductivity places it supreme among all competitors for use as firebox plates, stays and tubes of locomotive boilers, where its economical advantages over iron and steel are in the direction of greater durability and evaporative power.

Wherever heating surfaces are employed copper is pre-eminently desirable, its thermal conductivity being two and one-half times greater than that of iron. Steam, feed-water and many other pipes are also best made of copper.

Its toughness, tensile strength and torsional strength enable it to withstand all the stresses which it is ordinarily called upon or expected to encounter, e.g., telegraph and telephone wires and overhead electric trolley wires, etc. Any means of improving these properties, however, will always be acceptable.

Its luster, color and applicability to various shapes render it a favorite metal with art metal-workers; chasing, embossing and polishing being operations of ease to the skilled workman.

It is not proposed to say anything of the use of copper for alloying purposes, except that in all alloys which have to be rolled or drawn freedom from arsenic, lead and antimony is desirable. Copper is used for alloying with tin, zinc, aluminium and nickel chiefly, the number of variations of its alloys with these and other metals being almost infinite and their name legion.

The casting of copper, whether in the form of ingots for alloying, cakes for rolling into sheets, bars for drawing into wire, or billets for forging and drawing into tubes, etc., is an extremely important and delicate operation owing to the property which molten copper possesses of dissolving its own oxide. The elimination, in part, of oxygen is the keynote of copper refining, just as the regulation of the quantity of carbon in iron is the keynote of steel making. Copper containing too much oxygen is cold-short, and, if oxygen is in great excess of the percentage contained in an alloy consisting entirely of the copper-cuprous oxide eutectic, the metal is also hot-short. If oxygen is removed to too great an extent, the metal then has greater solvent power for reducing gases, which it is incapable of retaining entirely during solidification, the expulsion of these gases causing the surface of an ingot of the metal to rise in the mold, thus showing a central ridge, or perhaps a worm-like excrescence, such a phenomenon being popularly known as "spewing" or "the worm coming out." (See Fig. 4.)

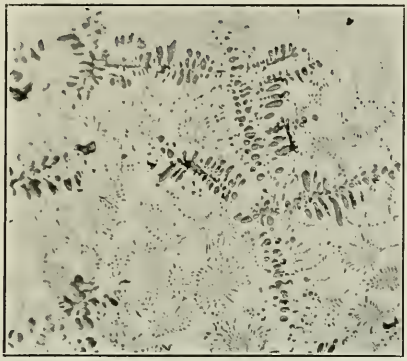

FIG. 1.—STRUCTURE OF OXIDIZED COPPER BEFORE POLING, SHOWING DENDRITES OF CUPROUS OXIDE IN A MATRIX OF COPPER CUPROUS OXIDE EUTECTIC. MAGNIFICATION 100 DIAMETERS.

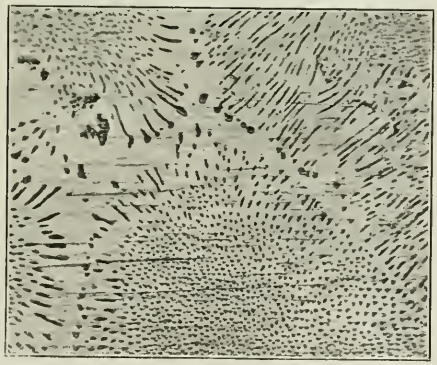

FIG. 2.—STRUCTURE OF COPPER AFTER ELIMINATION OF SOME OXYGEN BY POLING. SHOWS COPPER CUPROUS OXIDE EUTECTIC (0.47% OXYGEN). MAGNIFICATION 300 DIAMETERS.

All the phenomena occur with all kinds of copper when refined on a large scale, even with the purest electrolytic copper. When the oxygen is in excess the surface of an ingot shows a depression and it is said to be "under-pitch." When it shows an elevation, or "spews," it is "over-pitch"; when it exhibits a level surface it is said to be "tough-pitch," and in this condition the combination of its physical (including electrical) and mechanical properties has reached its highest possible degree (for "refined" copper).

The foregoing are the broad general principles of refining, but every refiner of impure copper knows that it is possible to pole up charges of certain brands until an ingot will show a level surface, whereas the copper will be "red-short," and only by stopping poling at a stage where an ingot shows a depression can such copper be rendered fit for rolling or forging hot.

Micrographs 1, 2 and 3 show the structure of copper during the process of poling, illustrating clearly the reduction of cuprous oxide as poling proceeds. The cuprous oxide is completely soluble in the molten copper, but, as shown in the micrographs, is insoluble in the solid metal, separating out as a definite constituent, Cu_2O, which is light blue in color and is easily distinguished from cuprous sulphide by the property which it possesses of etching black when treated with hydrofluoric acid. Cuprous sulphide remains unchanged when similarly treated.

Where the Cu_2O exceeds 3.5 per cent to 4 per cent dendrites of Cu_2O make their appearance, as shown by the firtree-like constituent in No. 1. This is the first constituent to separate out during cooling of the liquid solution and its presence increases the viscosity of the copper before and during solidification, causing the copper to pour thickly. The other constituent which forms the matrix is the eutectic alloy comprising an intimate mixture of minute copper and cuprous oxide crystals, or, as they may be conveniently called, "oxidules."

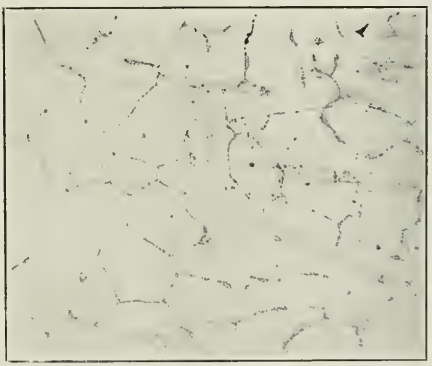

FIG. 3.—STRUCTURE OF TOUGH-PITCH COPPER, SHOWING CRYSTALS OF COPPER SURROUNDED BY EUTECTIC. MAGNIFICATION 300 DIAMETERS (0.08% OXYGEN).

This eutectic structure is clearly seen in No. 2; its melting point and composition, according to Heyn,[1] are respectively 1084° C. and 3.5 per cent Cu_2O (see Fig. 5).

Fig. 3 shows the structure of "tough-pitch" copper, where, instead of the one constituent as in No. 2, there are two, viz., first, copper crystals which have separated out from the liquid solution, leaving the mother liquor (solution of cuprous oxide in copper) to feed them with copper until it reaches the eutectic composition, and, second, the solid eutectic itself.

Some interesting observations in connection with the properties of copper at various stages of the "pitch" have been made by Messrs. Hofman, Hayden and Hallowell in a paper read before the American Institute of Mining Engineers (Vol. XXXVIII). They prove that the gradual elimination of oxygen is synchronous with an improvement in electrical conductivity, but, strangely enough, the conductivity reaches a maximum while the copper is still decidedly "under-pitch" (0.2 per cent oxygen). They also prove that those traces of iron and sulphur which remain in "set" copper, after the oxidizing stage

[1] Mittheilungen aus den Königlichen Versuchsanstalten zu Berlin, 1910, XVIII, p. 315.

of refining, are not affected by the subsequent poling operation.

In a recent paper[2] the writer advanced a theory to account for the behavior of copper as influenced by the process of poling.

It must be remembered that when poling starts the bath of molten copper is very nearly saturated with cuprous oxide and

FIG. 4.—INGOT OF OVERPOLED COPPER, SHOWING "WORM."

that the effect of thrusting a pole of wood into such a bath is the rapid reduction of the oxide accompanied by the evolution of gaseous oxides of carbon, hydrogen, water-vapor, etc.

As the poling continues and the proportion of metallic copper increases, the latter has the property of dissolving some of the evolved gases, which it was formerly incapable of dissolving when saturated with oxide.

As more and more copper is thrown out of combination with oxygen, so more and more gases are dissolved. The gas for which copper has the greatest affinity under these conditions is hydrogen, which is probably derived from the decomposition by molten copper of the hydrocarbons in the pole, free carbon being precipitated and rising to the surface.

Trial ingots taken from time to time will show a depression at the surface and are said to be "under-pitch." This depression, however, becomes smaller and smaller until, when the charge is up to "pitch," it disappears and the surface of a trial ingot is quite level. If the poling be pushed beyond this point the surface will rise and form a convexity.

If sample ingots of (1) "under-poled," (2) "tough-poled" and (3) "over-poled" copper be broken and their fractures examined it will be seen in case (1) that the fracture is "dry,"

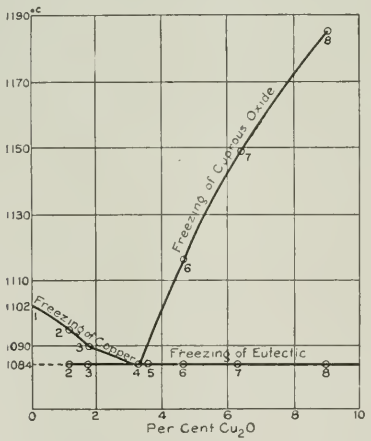

FIG. 5.—FREEZING-POINT CURVE OF ALLOYS OF COPPER AND CUPROUS OXIDE (HEYN).

with no silkiness of grain and no vesicular cavities; in case (2) the fracture is silky, with tiny vesicular cavities, uniform in size and distribution; in case (3) the fracture is still silky but there are more cavities, some of them larger than others, the larger ones occurring nearer the surface.

These cavities were evidently filled with gas, released at the moment of solidification; the bubbles of gas, by reason of their natural buoyancy, exerted an upthrust which tended to oppose the effect of liquid shrinkage and so prevented the surface from being depressed.

In the case of "under-poled" copper they were not sufficiently numerous to oppose this effect, while in the case of "over-poled" copper they occurred in such quantities as to not only oppose the formation of a depression, but to elevate the surface and in some cases to cause some of the semi-molten copper to be projected from the ingot.

In the case of "tough-poled" copper the bubbles of gas were present in just sufficient quantity to oppose the formation of a depression and no more.

Thus all ingots of comparatively pure copper, when poured at the proper "pitch," show a level surface.

The Effect of Mechanical Work on Copper.

Copper, after hot-forging, is stronger, more ductile and of closer grain than the cast metal. Hot-rolling can be carried to such an extent as to confer on the copper a tenacity which the same copper, after severe cold-working and annealing, cannot exceed. But hot-working should be stopped at such a temperature as will allow a certain amount of molecular rearrangement or recrystallization to take place following on

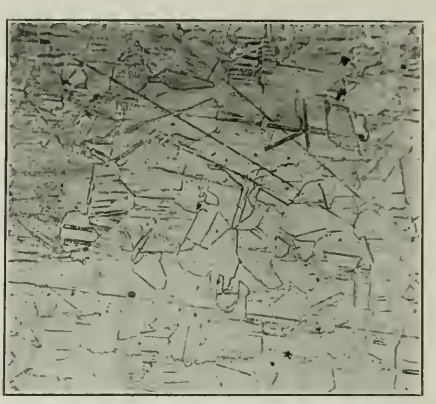

FIG. 6.—CAST COPPER DEOXIDIZED WITH MANGANESE, SHOWING "TWINNING." MAGNIFICATION 100 DIAMETERS.

distortion. That is to say, hot-wrought copper should have the closest and finest crystalline structure attainable short of the confused structure by working the metal at too low a temperature.

Subsequent cold-working may then be possible to a greater extent before annealing will be necessary. Cold-working, stage by stage, continuously strengthens, i.e., increases the tensile strength and limit of elasticity, but diminishes the extensibility. Le Chatelier states that pure copper can attain to a tenacity of 27 tons per square inch when drawn into wire, but this cannot be exceeded even by repeated drawing. Annealing has the effect of lowering the tensile strength and raising the elongation.

These figures (for cold-wrought and annealed copper) have a limit, and the standard to take is that where maximum strength and ductility are just obtained in cold-wrought specimens which have been annealed for a known length of time at a known temperature in a non-reducing atmosphere.

Cold work produces a state of instability which may render the metal susceptible to "age-cracking" or secular brittleness.

There are two clever theories with regard to the cause of this state of instability. Firstly, however, let it be understood that the cold-working must be of sufficient severity to stress the metal beyond its elastic limit in order to produce deformation of a serious nature.

[2]Inst. of Metals, No. 2 (1910), Vol. IV.

Beilby is responsible for the theory that those layers of the soft crystals which are contiguous to their boundaries assume a different condition—a hard, amorphous condition which confers on the metal, by virtue of its enveloping inter-cellular hardness, greater elasticity and tensile strength, greater brittleness and reduced toughness.

In short, cold work distorts the crystals, causing gliding of

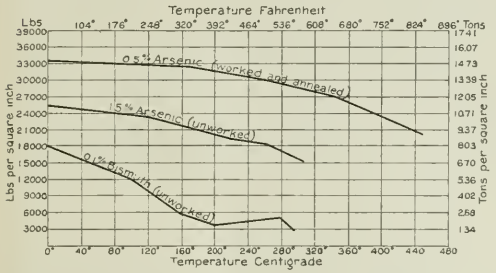

FIG. 7.—TENSILE STRENGTH AS FUNCTION OF TEMPERATURE.

crystalline elements over one another, along those planes where there is least cohesion; then appears the hard, non-crystalline variety which, thanks to its instability at a definite temperature, reverts back to the soft crystalline state once more when the annealing temperature is reached.

To Ewing and Rosenhain we are indebted for the theory of "slip-bands," and it will best serve the purpose of the writer to quote from an article written by Mr. Rosenhain for the *Times Engineering Supplement* of Nov. 6, 1907:

"It has been found that, when the application of force causes a crystal to change its shape, it accommodates itself to the new shape imposed upon it, by a process of sliding or slipping which takes place between the layers of minute crystalline elements of which each crystal is built up. After deformation the crystal remains a crystal as before, but the layers of its elements have been displaced relatively to each other. Further deformation results in further slipping, until, ultimately, the surfaces upon which slip can occur—originally plane in the undeformed crystal—have become converted into complicated systems of minute steps. If the attempt be made to push the deformation still further, then at some point or other of the cross-section of the metal two adjacent layers will slip far enough over each other to become entirely separated, and the fracture thus started will run through the metal and will follow all the minute steps of the surfaces upon which slip was at that moment taking place.

"The surface of the resulting fracture will thus be minutely stepped, and, in the case of a tensile fracture, the surfaces of these steps will all be sharply inclined to the direction of the extension. According to the degree of ductility of the metal and the scale of its original crystalline structure, the resulting fracture will show a more or less minutely stepped surface, giving the appearance of a fibrous fracture. That fractures so produced actually possess this stepped character can be clearly seen in properly prepared sections examined under high magnifications."

Mr. Rosenhain explained this theory somewhat fully at the second meeting of the Institute of Metals in January, 1909, during the discussion on "The Mechanism of Annealing of Certain Copper Alloys," by Messrs. Hudson and Bengough.

If metals are submitted to stress and at the same time their polished surfaces are viewed under the miscroscope the development of "slip-bands" may be clearly seen; they increase in number as the stress intensifies. Where the fracture ultimately occurs, parting takes place not along an irregular line following the boundaries of the crystals, but along the line coinciding with the least adhesive slip-bands or gliding-planes which have been developed through each crystal while submitted to stress.

Consequently where the structure is fine, the line of fracture will be straight and sharply defined; where coarse, it will be less regular and serrations will appear. So we may expect metal of perfectly homogeneous fine structure to be stronger than (a) metal of heterogeneous structure, i.e., where fine and coarse crystalline areas occur side by side, or (b) metal of homogeneous, but uniformly coarse structure.

In case (a) fracture will develop and rupture occur where the structure is coarse and the strength of the coarse areas will represent the strength of the whole metal.

In case (b) gliding-planes will be fewer in number but more pronounced, and their development less hindered by the hemming-in and arresting action of those less mobile inter-crystalline planes of greater mutual adhesion, which are more frequent where the structure is finer.

The effect of "twinning" is characteristic of wrought copper. Its explanation is perhaps rather obscure and is more easily understood by a study of crystallography. Suffice it to say that a crystal boundary of wrought copper may circumscribe one or more pairs of crystals (parallel laminæ), each pair having two sides coinciding, the other two sides running parallel thereto.

Distortion and recrystallization have completely disturbed the original polyhedral structure, the deformed and compressed crystalline elements having been compelled to take new and, as it were, unnatural situations. Even hot-wrought copper exhibits "twinning." Very homogeneous castings of copper or its alloys have a structure which is very susceptible to "twinning," the mildest deformation producing "twins." Micrograph (Fig. 6) shows a copper casting, deoxidation having been effected by means of manganese. The specimen was merely sawn from the casting, annealed for twenty minutes at 800° C. and slowly cooled, then polished and etched.

Behavior of Copper at High Temperatures

The influence of increased temperature on copper and its alloys, as on all metals, is to weaken the structure. Active crystalline growth, increased amplitude of molecular oscillation,

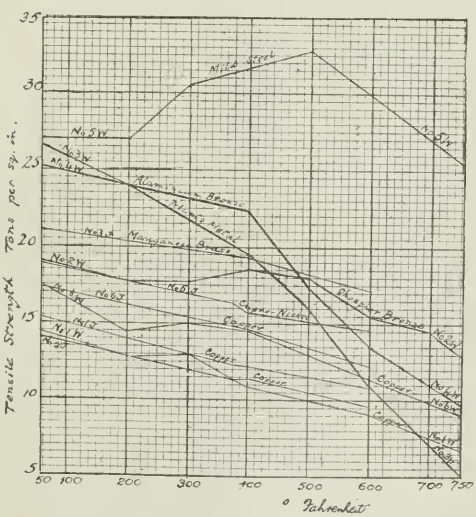

FIG. 8.—ALTERATION OF STRENGTH OF ALLOYS AT HIGH TEMPERATURES.

developing at still higher temperatures into incipient disintegration or, in the case of "burnt" metals into inter-crystalline oxidation, all render the metal less tenacious. Le Chaterlier found that pure copper fell off in tenacity with increase of temperature from a tensile strength of 14.7 tons per square inch

at 15° C. to 12.9 tons at 200° C., and then fell off rapidly until at 530° C. the tensile strength was 4.6 tons per square inch.

Roberts-Austen [see plate 31 (reproduced in part herewith, Fig. 7) of the Second Report Alloys Research Committee[3]] showed that pure copper and arsenical copper showed little decrease in tensile strength compared with copper containing 0.10 per cent bismuth, which, at 160° C. or 320° Fahr., possesses only one-third of the tenacity which it possesses at 15° C. The copper containing bismuth was considerably weaker than the pure and arsenical forms, even at normal temperature. Although throwing considerable light upon the malignant influence of bismuth the results tend to give one an exaggerated idea of the potency of the evil for the following reasons:

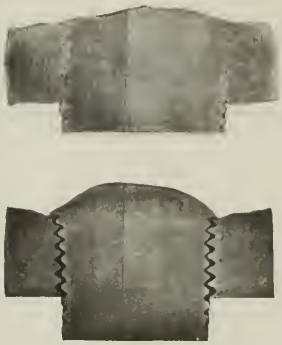

FIG. 9.—SHOWS ADVANTAGE OF COPPER OVER STEEL FOR FIREBOX STAYS, WHERE FIREBOX IS MADE OF COPPER.

Firstly, copper containing 0.10 per cent bismuth is rarely met with nowadays, and it may be said safely that the effect of bessemerizing is to remove bismuth from the pale of practical hurtfulness. Bismuth is very volatile, and Keller has shown that over 90 per cent of the bismuth contained in the original matte was volatized during the converting operation.

Gibbs states that "not only does the degree of elimination of any impurity depend upon the proportion originally present, but also upon the proportion of other impurities present." Be that as it may, bismuth is rarely met with in bessermerized copper in sufficient proportion to render the copper unfit for commercial purposes, although the writer has had personal experience of bessemerized copper containing sufficient bismuth to render it unfit for rolling hot.

As to the smaller quantities of copper produced by methods of roasting in reverberatory furnaces, including the processes of "bottoming" and "direct" refining, bismuth is not eliminated to nearly such a high degree as it is in the converter, while copper produced direct from blast-furnace smelting may possibly contain very nearly all the bismuth, arsenic, antimony, etc., originally present in the charge, so searching is the reducing action of the fuel and sulphur in contact with the metalliferous materials of the charge. Needless to say, very little of the world's supply of copper is produced direct from the blast furnace.

Secondly, commercial copper invariably contains an equilibrium-proportion of an element which profoundly modifies the harmful effect of bismuth, viz., oxygen.

Thirdly, in all copper required by engineers for purposes where electrical conductivity is of no account, and where toughness, strength and ductility are the desiderata, the presence of arsenic up to or even exceeding 0.5 per cent is eminently desirable, and this again suppresses the deleterious influence of bismuth, both at low and at high temperatures.

So it is important to know, having shown that Prof. Roberts-Austen's results are exaggerated by the artificiality of his otherwise splendid experiments, in what proportion bismuth is admissible in copper required by engineers to possess strength, toughness and ductility at all temperatures.

It is here that the writer would make rather full reference to a splendid paper read before the Institution of Civil Engineers in 1902 on "Locomotive Firebox Stays." The author, Mr. F. W. Webb, conducted a series of experiments on the suitability of various kinds of copper and copper alloys for staying locomotive fireboxes. The most frequent sources of trouble are those arising from *wastage of heads,* from *leakage* and from *breakages.*

(1) Wastage occurs principally in the vicinity of the brick arch where the heat is most fierce.

(2) Leakage occurs wherever the joint between the stay and the firebox plate has become loosened.

(3) Breakages occur principally at the top corners and may be attributed to the expansion and contraction of the inner copper casing. When they occur at the lower part of the box they are invariably due to overheating, consequent on becoming thickly coated with a non-conducting layer of boiler scale.

Exhaustive practical trials were made with engines fitted with stays of various kinds and extending over a number of years with the following results:

The above table has been compiled from the data furnished by Mr. Webb in the paper to which reference has been made.

In Fig. 8 are plotted the results of Webb's experiments on the various alloys used when tested at high temperatures. Their numbers and compositions are given in Table II, together with those of similar alloys tested by Mr. S. W. Johnson under similar conditions. Webb's alloys are marked W, those of Johnson being marked J.

TABLE I.

Material of Stay.	Total Mileage.	Mileage per Replaced Stay.	Description of Engine.	Boiler Pressure.	Cause of Replacement.
Copper	5,622,064	844	Compound Express Passenger	200 lb.	Wasted heads and leakage
Copper	277,800	277,800	Compound Express Passenger	200 "	Nil.
Muntz Metal	169,058	262	Passenger	150 "	Wasted heads and leakage.
Brass { Cu 91 Zn 9	284,978	5,588	Coal-Engine	150 "	Wasted heads, leakage and breakages.
Bronze { Cu 97 Sn 3	113,657	791	Express Goods	150 "	Wasted heads and leakage.
Aluminium Bronze	2,400	Not stated	Express Goods	150 "	Breakages.

So it would appear that high tensile results at normal temperatures serve rather to indicate unreliability in practice. Nor do good tensile results at high temperatures necessarily indicate reliability in practice, e.g., mild steel. This only shows a mileage per stay of 610 as against 844 for copper, and this under much less severe conditions than the copper stays had to endure. The hardness of a metal when used for firebox stays where the fireboxes are of soft copper seems to be the main cause of failure. Screwing a hard metal into a soft one has the effect of abrading the thread in the latter, but, what is much more serious, subsequent riveting has the effect of expanding the hole in the copper firebox plate, causing imperfect contact between the stay and the firebox, and so leading to leakage. (See Fig. 9.)

Uniformity of tensile tests over a wide range of temperature is more probably a truer guide where the metal is of sufficient softness; the comparatively soft phosphor-bronze No. 2 W shows higher results and greater uniformity than copper Nos.

[3]Inst. Mechanical Engineers, 1893

6 W, 1 W, I J and 2 J, but even its slightly higher degree of hardness leads to greater leakage. In this connection Mr. Webb's experience was that nothing provided so excellent a joint as a copper stay, the best joint being where the stay was of copper containing slightly less arsenic and therefore possibly softer than the copper plate into which it was screwed.

What is required is a metal as soft as or softer than commercial copper, of greater strength in tension, of greater elasticity, greater resistance to alternating stresses and capable of maintaining its superiority under the variable thermal conditions of a modern locomotive boiler working under high pressure. In addition it must have a melting point not appreciably lower than that of copper and a similar coefficient of expansion.

Cupro-nickel and cupro-manganese seem to be the most suitable alloys yet tried, although cupro-manganese does not wear so well as copper in the vicinity of the fire.

The greater tendency to red-shortness in all copper alloys

(b) The elongation for equal loads within the stretching limit increases generally with increasing temperature.

(c) The elongation is raised by cooling to $-20°$ C.; between $+20°$ and 300° C. it is nearly constant, while higher temperatures generally lower the elongation of the *annealed* material and increase that of the *mechanically hardened* material.

(d) The increased tenacity and elasticity conferred by mechanical working remain up to 200-300° C. practically unaltered, then, as the temperature increases, these properties fall off until at 500° C. they are the same as those possessed by the annealed material at that temperature.

The elongation of mechanically worked material remains lower than that of annealed material up to 300° C.; beyond this temperature it may have a higher or lower value up to 600° C., depending on its composition.

(e) As regards chemical composition it would appear (although this point is not clearly brought out in the research)

N.B.—It is to be regretted that the oxygen contents were not included in the above figures.

of whatever composition is a serious defect, the breaking down of cold metal being more expensive than breaking down hot in course of manufacture.

Alluding once more to the testing of metals at high temperatures it should be noted that mechanical tests at the temperature of an air or oil bath are not comparable with the actual conditions in practice, e.g., where a stay is strongly heated at one end and kept cool at the other.

Mention must now be made of the work of the Royal Technical Research Commission of Berlin (1898) concerning the influence of heat, and of the conclusions at which that commission arrived after an exhaustive series of experiments on copper rods and strips of different composition and of different mechanical treatment.

Table III gives the composition of the different kinds of material used in the research and the following is a summary of the results of the investigation into the influence of heat thereon.

(a) The tenacity of the material is diminished with increase of temperature, the effect being much greater above 200°-300° C. than below.

that the more impure copper retains the proportionality derived by mechanical working better at higher temperatures and gains greater tenacity where the treatment has been the same.

It is very interesting to note that these experiments have been amply confirmed by Webb as regards the beneficial influence of tin. Copper containing 2 per cent or 3 per cent of tin, if carefully deoxidized, seems to behave better than pure or even ordinarily impure "refined" copper at high temperatures.

Technical College, Swansea, Wales.

A New Primary Cell.

In a paper presented before the British Institution of Electrical Engineers, Mr. W. R. Cooper describes a new primary cell invented by a Hungarian engineer, Stephan Benkö. As described, it is chemically an ordinary zinc-sodium bichromate cell and its original feature rests in the mechanical construction, which permits to overcome polarization at the carbon electrode. The fundamental idea is that polarization is due to the electrolytic change of the electrolyte at the carbon

electrode, and that, therefore, if the layer of electrolyte next to the carbon electrode is removed as soon as it is changed electrochemically the e.m.f. should be maintained constant and no polarization should set in.

The construction is indicated diagramatically in Fig. 1. Here the carbon is shown at C, and this is best described as a flattened cylinder, open at both ends. The hard surface of

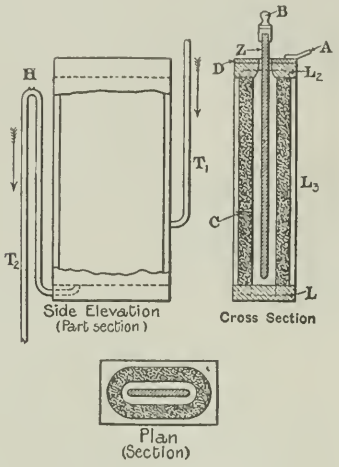

FIG. 1.—DIAGRAM OF BENKÖ CELL.

this carbon, as received from the carbon makers, is removed by scratch-brushing so as to leave it easily porous. The carbon is then provided with a lead cap, L_1, at the bottom, and a lead ring, L_2, at the top, thus providing a vessel open only at the top. A lead shell, L_3, of sheet lead 1 mm to 1½ mm in thickness, is then fitted round the carbon, leaving a small space between the carbon and the shell, and is jointed autogenously to the lead cap at the bottom and the lead ring at the top so as to form a chamber all around the carbon.

Thus there are two chambers, one inside the carbon and one outside. The outer chamber is provided with a Tube, T_1, and a second tube, T_2, is fitted to the lead base and is carried through to the inner chamber. The latter tube is carried up and bent over, and there is a small hole, H, at the top of the bend. Finally, a copper plate, D, corresponding with the lead ring, is soldered on to the lead, and forms one terminal, A, of the cell.*

The zinc, Z, is inserted into the inner chamber and carries the second terminal, B. When in action the electrolyte is delivered by the lead tube, T_1, into the outer chamber, when it percolates through the carbon to the zinc: it then flows off through the lead tube, T_2, the form of which maintains the level constant within the carbon. As there is a hole at H, syphoning does not occur, though this may be made to take place in cells so constructed by closing the hole with a finger for a few minutes. This is often convenient when it is desired to empty the cell.

It will be noticed that the current is carried away from the carbon at both top and bottom, and owing to this form of construction, and to the excellent contact between the carbon and the lead, very much heavier currents can be taken than is possible with the usual form of joint. A working drawing of what is termed the "Type A" cell is reproduced in Fig. 2, in which the lettering of Fig. 1 is retained as far as possible. The zinc plate is carried in an ebonite frame, F. The tubes T_1, T_2, are provided with unions and rubber washers, W_1, W_2, for coupling to other tubes as may be found necessary.

The carbons at present are not made larger than is shown in Fig. 2, but if larger cells are required this is effected by fitting two or more carbons into one shell. These are thus permanently connected in parallel, and the zincs are correspondingly coupled together.

The particulars of the "single" cell are:

Width	1¾ in.
Length	6¼ in.
Height (including terminals)	9¼ in.
Weight (including zinc)	8.8 lb.
Maximum current continuously with L solution	17.5 amp
Power	26.25 watts

The current stated is for a voltage of 1.5 volts per cell, the e.m.f. being 2 volts.

In the case of a battery the electrolyte is contained in a lead-lined tank, from which it flows (due to its own head) down to a common supply pipe from which each of the cells is supplied by a tube, the junctions being by ebonite unions and rubber washers, as already described. Similarly the waste from each cell is carried into a common waste pipe, from which an inverted U-pipe is taken to maintain the level in the cells, and this discharges into a lower tank. By means of a cock the common waste pipe can be opened to this tank so that the cells can be drained when the supply of electrolyte has been cut off.

The arrangement is compact, the width across the front of the stand being only 25½ in. and the depth from front to back being 24½ in. In order to give the necessary head the overall height is 7 ft. 9 in. for a 7-cell battery (and has recently been reduced). Air pressure might, of course, be used instead of a gravity feed; this would give greater compactness and might be preferable under certain conditions. But even with the arrangement shown, for a battery giving a minimum work-

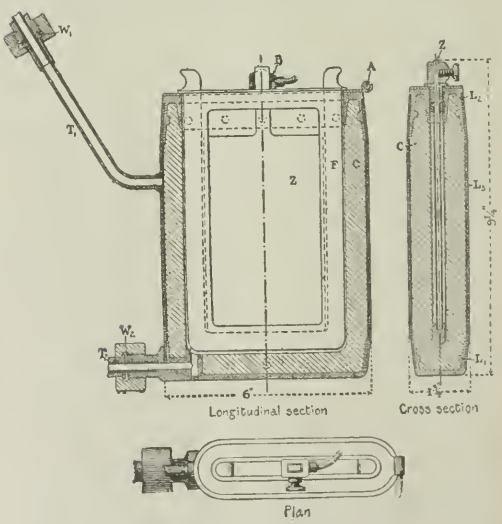

FIG. 2.—STANDARD TYPE OF SINGLE BENKÖ CELL.

ing pressure of 10.5 volts and a power up to about 260 watts continuously, the space required must be regarded as relatively small.

With a given flow of electrolyte an extremely constant current can be maintained up to a certain limit. This limit depends largely, of course, upon the composition of the electrolyte. Various electrolytes may be used, and in the case

*In later designs this copper plate has been abandoned, the terminal being jointed together to the lead ring

of bichromate solutions Mr. Benkö recommends the following formulæ: For electric light, 60 grams of sodium bichromate and 120 c.c. of sulphuric acid per liter of water (solution "L"); and for heavy currents, 100 grams of sodium bichromate and 150 c.c. of sulphuric acid per liter of water (solution "P").

The limiting currents obtainable continuously with the two first solutions in terms of the area of the zinc (taking both sides into the measurement) may be taken as follows:

	Per square decimeter	Per square foot
Solution "L"	6 amp	56 amp
Solution "P"	10 amp	93 amp

There is some local action due to the reaction of the acid electrolyte with the zinc, and this local action varies with the flow of electrolyte and with the current taken from the cell

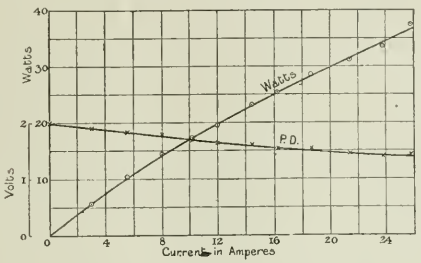

FIG. 3.—RELATION OF TERMINAL VOLTS AND TERMINAL WATTS WITH AMPERES.

(owing to the fact that this alters the composition of the electrolyte) and with the state of the zinc.

There is also some polarization, but it is difficult to separate it from the internal resistance. Fig. 3 shows how the terminal pressure and terminal watts vary as the current is increased. The currents were not taken momentarily from the

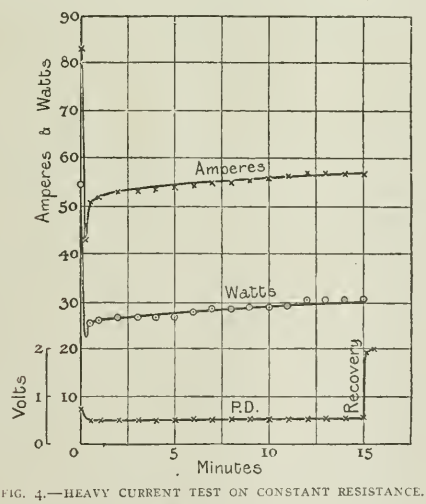

FIG. 4.—HEAVY CURRENT TEST ON CONSTANT RESISTANCE.

cell, but the external resistance was decreased step by step as quickly as the readings could be taken, and therefore polarization no doubt reduced the higher current readings to some extent. The highest outputs shown would not be maintained for any long periods, as the cell is overloaded. This test was made with solution L.

The test shown in Fig. 4 was made with a similar single cell, using the stronger solution P at a head (between the bottom of the tank and the top of the overflow tube) of 45¾ in., which gave a flow of about 1.9 liters per hour. In this test the external resistance was maintained constant, and the fall of current was observed for 15 minutes. The current might have been maintained longer, but the cell became very hot with such a heavy discharge.

Short-circuit tests with the L solution showed momentary currents of 100 amp at a terminal voltage of 0.5 to 0.6 volt, the current falling to 80 amp at the end of 5 seconds. With the stronger P solution momentary currents of 200 amp were taken at a terminal pressure of 0.5 to 0.55 volt. It follows, therefore, that the internal resistance is well below 0.01 ohm, an extremely low figure. This result is no doubt due largely to the excellent contact between the lead shell and the carbon, both at the top and at the bottom.

The Benkö cell has the advantage that it is small, easy to handle, and requires no careful attention. When it is not required it can be left on one side without fear of deterioration, the only desirable precaution being the running of some water through it to free it from the used electrolyte after heavy work. The laboratory, the charging of ignition cells, electroplating on a small scale, and possibly submarines (owing to the peculiar conditions involved) are fields in which such a battery would prove useful. There is also the electric lighting of yachts having no generating plant. It is also thought that the cell would be useful for telegraphy and in special cases for country-house lighting.

The simplest method of working such a battery is to turn on the flow of electrolyte when the light is required, and the flow would be turned off on retiring at night. With regard to labor, it may be mentioned that the zincs weigh 1 lb., and if we take 3 lb. (allowing for waste and unused zinc) per kw-hour, then a single cell will give ⅓ kw-hour and a battery of 17 cells will give 5 2/3 kw-hours before the zincs need be changed. If a house is using 1 to 2 kw-hours per day this means that the zincs are changed once or twice a week. As the operation is very simple, it takes very little time.

From the point of view of labor the electrolyte is more important than the zinc. With a constant output the amount of electrolyte per kw-hour will be, say, 7¾ gal. If, however, a battery such as we have assumed is allowed to flow steadily at a rate of ½ liter per cell, then a 5-hour run would require 9½ gal. This emphasizes the desirability of automatic regulation of the flow.

If hand regulation is adopted and not properly applied the amount of solution required might thus be as much as 15 gal. per day in the winter, or say, 10 gals. per day if the electrolyte is used twice and "refreshed" by adding new electrolyte to it. On the other hand, with automatic regulation this quantity once or twice a week for 1 to 2 units per week would be enough. With proper arrangements the handling of these quantities would take very little time. These figures emphasize the fact that the cost of running depends largely on the method of running.

As far as can be judged the cost of repairs should be small or negligible, and equally the interest on capital is scarcely worth considering. Mr. Cooper concludes that electrical energy can be generated in this cell at about 50 cents per kw-hour under favorable conditions, and this cost will vary according to the carefulness of the regulation.

The Analysis of Manganese Bronze.*

By James R. Huber.

In nearly all of the specifications for manganese bronze castings it is quite noticeable that attention is called to the physical requirements and very little is said regarding the chemical analysis. This is no doubt partly due to a lack of knowl-

* A paper presented at the Pittsburgh meeting of the American Brass Founders' Association.

edge on the part of the engineers who draw up the specifications of the exact composition of this rather complex alloy.

A method for the analysis of this alloy was worked out in our laboratory last year and published in the Metallurgical and Chemical Engineering for August, 1910 (vol. VIII, p. 463). This analysis presents several difficulties, especially the determination of zinc and aluminium. As we have gained knowledge by experience, we have been able to make some improvements on the original method.

A 5-gram sample is dissolved in 40 c.c. of 50% nitric acid (HNO_3). The small precipitate of metastannic acid obtained is invariably in such a finely divided state that much time is consumed in endeavoring to obtain a clear filtrate. A slight cloudiness in the filtrate will mean a result from 0.05% to 0.15% too low on the tin.

We find it advisable to cool the solution after boiling off the brown fumes, stir, and pour on a double S. & S. No. 589 blue ribbon filter paper. Fill the funnel once or twice and then apply suction, gradually at first, until the paper is well clogged with the precipitate. If the first of the filtrate is not clear, return it to the beaker and pour it on the paper again.

With these precautions, it is seldom necessary to repeat this operation and a practically clear filtrate is obtained. It is better to wash the precipitate with hot 10% nitric acid (HNO_3) instead of 2%, as the more dilute wash water has a tendency to start the precipitate running through the filter paper.

The filtrate is then evaporated to white fumes with concentrated sulphuric acid (H_2SO_4). Five c. centimeters is not enough, as the mass forms a hard cake and has a tendency to spatter when nearly dry. We now use 15 c.c. to 20 c.c. With this amount it will not be necessary to make a further addition when removing copper by electrolysis. The bronze will not contain any lead if made with high-grade spelter, but, should a trace be present, it is filtered off and weighed as lead sulphate ($PbSO_4$) on a platinum Gooch crucible. The filtrate is diluted to 500 c.c. in a 500-c.c. graduated flask.

Four 100-c.c. portions are measured out with a pipette or graduated flask into tall non-lipped 200-c.c. beakers. Two of them are neutralized with ammonium hydrate (NH_4OH), 7 c.c. of a mixture of 2 parts 50% nitric acid (HNO_3) and 1 part 50% sulphuric acid are then added and the solution diluted to about 150 c.c. The copper is plated out, using either a rotating anode or a solenoid. With the latter a brighter and more adherent deposit is obtained in less time than with the former.

The shape of the spiral anode causes the deposit to be more evenly distributed over the surface of the cathode and a much stronger current can be used. With a gauze cylinder cathode having 150 to 200 sq. cm of surface, 10 amp will deposit about 1¾ grams of copper in 15 minutes. Three amperes was the highest current we were able to use with the rotating anode and obtain a satisfactory deposit. We find it better to dry the cathodes in an air bath at about 100° C.

From these two portions we have duplicate determinations on the copper. In the filtrate from one the iron is precipitated with ammonium (NH_4OH), dissolved in dilute hydrochloric acid (HCl), reduced with stannous chloride ($SnCl_2$) and titrated with potassium permanganate ($KMnO_4$), according to Blair. In the other portion the manganese is determined by the well-known bismuthate method. Rinse off the anode with a little sulphurous acid (H_2SO_3) to remove the slight deposit of manganese dioxide which forms upon it and add these washings to the solution in the beaker. Bromine water and ammonium hydrate (NH_4OH) are then added, the solution boiled and the precipitate of manganese dioxide (MnO_2) filtered out and redissolved in sulphurous acid (H_2SO_3). Ten centimeters nitric acid (HNO_3) and 30 c.c. water (H_2O) are added, the solution boiled a minute and ¼ gram of sodium bismuthate added. Heat till the pink color entirely disappears. Add a few drops of sulphurous acid (H_2SO_3) to clear the solution, and boil again to expel all nitrous fumes. Cool the solution until quite cold and again add a slight excess of sodium bismuthate. Stir a minute or two and then add 50 c.c. of 3% nitric acid (HNO_3) and filter through asbestos on a platinum cone, using suction. Wash with 50 c.c. more of 3% nitric acid (HNO_3), reduce with standard ferrous ammonium sulphate solution and titrate the excess with potassium permanganate ($KMnO_4$), which has been standardized against the ferrous ammonium sulphate.

The copper is removed from the other two 100-c.c. portions by electrolysis without the addition of nitric acid (HNO_3). The zinc is separated from the aluminium, manganese, and iron by precipitation with hydrogen sulphide (H_2S). Instead of reducing the iron by boiling with metallic iron or aluminium, or sodium thiosulphate, as suggested in Waring's modified method, we find it saves time to reduce with sulphurous acid (H_2SO_3). The use of aluminium is prohibited as we determine aluminium in the filtrate from the zinc. Methyl orange is used as an indicator when neutralizing the solution, and as it is not sensitive in a hot solution, it would be necessary to cool after boiling with any of the above reducing agents. In using sulphurous acid (H_2SO_3) it is only necessary to add about 10 c.c. to the cool solution, stir and neutralize with sodium hydrate ($NaOH$) and sodium bicarbonate ($NaHCO_3$), using methyl orange as an indicator.

We obtain the zinc sulphide in a granular condition and entirely free from iron by precipitating in the presence of hydrochloric acid (HCl) and ammonium sulphocyanide, as suggested by Kemmerer in an article in the *Journal of Ind. and Eng. Chem.* for September, 1910.

After neutralizing, dilute the solution to 400 c.c., add 4 or 5 drops of hydrochloric acid (HCl) and about 2 grams of ammonium sulphocyanide (NH_4SCN). Heat to boiling and pass a rapid stream of H_2S for about a half hour, keeping the beaker on a hot plate. Under these conditions the precipitate is rarely, if ever, slimy, but, should it form in that condition, it might as well be thrown away as it is impossible to filter it clear.

After the gas has been passing about 15 minutes, and the zinc is nearly all precipitated, add a drop of a dilute solution of sodium bicarbonate ($NaHCO_3$). If the black precipitate of ferrous sulphide (FeS) formed dissolves instantly, add another drop. But do not add any more if the black precipitate dissolves slowly. This precaution is taken to insure complete precipitation of the zinc.

There is a possibility that enough acid will be liberated in addition to the 4 or 5 drops added to prevent the last traces of zinc sulphide (ZnS) being precipitated. As this addition is not made until after most of the zinc sulphide (ZnS) is formed there is no danger of iron being carried down. Continue passing the gas about 15 minutes longer. Allow the zinc sulphide (ZnS) to settle, filter and wash with hot water. Dissolve in dilute hydrochloric acid (HCl) and precipitate as phosphate with sodium ammonium hydrogen phosphate ($NaNH_4HPO_4$).

The aluminium is determined in the filtrate after boiling off the hydrogen sulphide (H_2S) and concentrating to about 200 c.c. Add a little nitric acid (HNO_3) to decompose the ammonium sulphocyanide (NH_4CNS). Boil off the cyanogen fumes, add 5 grams of ammonium chloride (NH_4Cl) and precipitate the iron and aluminium as hydroxides by making the solution exactly neutral with ammonium hydrate (NH_4OH). Boil, filter and dissolve in dilute hydrochloric acid (HCl). Dilute to 400 c.c. Add 10 c.c. of a 10% solution of sodium ammonium hydrogen phosphate ($NaNH_4HPO_4$) and then ammonium hydrate (NH_4OH) until a slight but permanent precipitate forms. Then add 1½ c.c. of con. hydrochloric acid and 50 c.c. of a 20% solution of sodium thiosulphate ($Na_2S_2O_3$). Heat to boiling and add a mixture of 15 c.c. of a 20% solution of ammonium acetate and 8 c.c. of strong acetic acid. Boil 10 minutes, allow to settle, filter and wash with hot water. The precipitate is ignited and weighed as aluminium phosphate.

Sinter Roasting at Trail.

The Dwight & Lloyd Metallurgical Company, of New York City, has put in two of its sintering machines at the smelting works of the Consolidated Mining & Smelting Co. of Canada, Ltd., at Trail, B. C.

There are a number of these plants in operation in various parts of the world, namely, nine in the United States, one in Mexico, five in Australia and several in Europe. The largest plant at present is one of those in the United States, with a capacity of 450 tons per diem. One still larger, of 500 tons capacity, is being erected at Broken Hill, N. S. W., Australia. Several others are under construction in the United States and Australia, respectively. Of those installed in the United States all but one have had, or are having, their capacity increased. The plant lately completed at Trail is the first to be installed in Canada, and has a daily capacity of about 200 tons dry weight fed to the machine.

The Dwight-Lloyd machine is particularly adapted to handling concentrates, flue dust and all classes of fine ores, converting them into a coarse cake which, owing to its strength and porosity, is highly suitable for reduction in the blast furnace. It will economically sinter and desulphurize mixtures having from 8 per cent to 18 per cent sulphur, and of sizes from ¼ in. down to 200-mesh or finer, making from them a coarse, porous product which will contain between 2.5 per cent and 5 per cent sulphur.

The machine proper consists of a structural steel framework carrying a suction box, a hopper, a line of cars or pallets, tracks for these to run on, and driving mechanism. The last mentioned consists of a pair of steel sprockets driven by a train of gears. The cars or pallets are planed on the bottoms and ends, so that they make an absolutely air-tight joint one with the other. In the bottom of these pallets are fastened cast-iron herring-bone grate bars, with slots ¼ in. wide. These pallets slide along the top of a large steel-plate suction box with planed cast-iron top. At each end of the suction box is a dead-plate which serves to make an air seal for the pallets as they pass on or off the suction box.

At Trail there are two large sprocket wheels about 8 ft. in diameter, on a heavy shaft, which constitute the means of operating the whole machine. On the underside of the machine there is a straight inclined track connecting at each end of the machine with a piece of curved track. The manner of operating the machine is as follows: The pallets are delivered by gravity into the sprocket wheel, the teeth of which engage the pallets by their small wheels or rollers, picking them up one pallet at a time. The curved track at the end of the machine serves as a guide to keep these wheels engaged with the teeth of the sprocket wheel. When they reach the top there are two guides on the end of a wind box on which the pallets come down, and the sprocket teeth then push them in a straight line over on to the wind box. At the same time they pass under a hopper full of ore which feeds a layer of ore mixture of uniform thickness onto the grate bars. Just at the point where a pallet passes onto the end of the wind box there is a gasoline burner by means of which the top part of the layer of ore is ignited. A high pressure exhauster is connected with the wind box by a pipe, and this draws air through the layer of ignited ore. By this means most of the sulphur contained in the ore is burned away, and at the same time the heat resulting from its combustion sinters the material, there being enough heat developed to slag the silica and iron contained in the mixture. While this is going on the pallet is slowly traveling across the wind box, and the speed of travel is so regulated that by the time it shall reach the end of the wind box the material is completely sintered. At the end of the wind box the wheels of the pallet are again engaged by the track which lifts the pallet and allows it to fall about 24 in. around the curved track at the end. It strikes the fallen pallet ahead of it with such force that the sintered cake is discharged from the grates and to a great extent cleans the slots of any adhering sinter. The cake then falls into a hopper or directly into steel cars with sufficient force to break it into pieces suitable for feeding into the blast furnace. The sintered product, therefore, does not require to be broken by hammers as is the case with some other processes. The length of the machines at Trail is 47 ft. over all. The effective hearth area is 42 in. by 264 in. There are 42 pallets on the machine, each 42 in. by 24 in.

The system of ignition depends largely on local conditions and the size of the plant. Gasoline is being used at Trail, but gas, crude oil, coal, coke, or even wood, may be used if more convenient. The gasoline burner is simply an arrangement which gasifies the gasoline in a coil made of brass tubing into the body of which the liquid fuel is sprayed by a needle valve. The gasoline comes out through a number of exceedingly small holes in the bottom of the body of the burner, and the flame is made to impinge against the surface of the moving layer of ore.

The supply of ore comes from large storage bins, one for each class of ore treated. From the bottoms of these bins the materials are fed automatically onto a conveyor belt, the proportion of each kind being regulated by varying the discharge opening in the bin. The conveyor belt discharges into a bucket elevator which, in turn, discharges to another belt conveyer placed near the roof of the building leading to a storage hopper above the sintering machines. By means of automatic feeders the ore is fed from this bin into a pug mill, and at this stage the required moisture is incorporated in the ore mixture, a special valve delivering the water in the shape of a fine spray. The mixed and moistened charge then falls into the hopper of the machine, whence it is fed onto the moving pallets.

The motive power for the whole system of mixing and feeding, and for the machines themselves, is simultaneously regulated, so that once the feeders are set to the proper openings for a given mixture the whole plant may be accelerated or slowed down at will by adjusting one speed regulator. This can be done without changing the proportions of the ore mixture, the composition of which will, therefore, remain uniform.

Any source of continuous power may be used. At Trail the power is supplied by three alternating current motors, two of which drive the fans and one the machines, feeders, elevators, etc. The total power consumption of this plant is about 75 hp, viz., 30 hp for each of the two exhaust fans and 15 hp for the remainder of the plant. The fans are specially constructed for heavy service, with water-jacketed bearings. They are run at a speed of 850 r.p.m. and produce a vacuum of 10 in. to 11 in. of water. The 24-in. pipes connecting the suction boxes with the fans are of riveted steel.

The Dwight-Lloyd machines are used for both lead and copper ores, both of which are smelted at Trail. The whole process, from the time the ore is dumped into the first receiving bins until the sinter is discharged into cars for removal to the blast furnaces, is absolutely automatic. At the Selby works, California, the sinter is also taken away from the machine by a steel bucket conveyer and automatically delivered to a 100-ton steel storage bin. The 200-ton plant at Trail is operated with only three men on a shift.

Mr. Henry J. Stehli, of New York City, superintendent of the Dwight & Lloyd Metallurgical Company, was at Trail in May, personally supervising the starting of the plant there. If successful, as it is confidently expected it will be, the operation of this plant will do away with the use of the Huntington-Heberlein roasting system now in use at Trail; also with the briquetting of flue dust, for this material will be mixed with the charge and sintered. The Huntington-Heberlein installation comprises seven roasters and 24 converters.

It is of interest to note, by the way, that the Dwight-Lloyd process is also being used for sintering fine iron ores and iron-furnace flue dust. A mixture of these is made and the heat developed by the combustion of the carbon in the flue dust is sufficient to sinter the entire mass into a solid but porous cake, which closely resembles that made from lead or copper ores.

It is claimed that three points of superiority are noted in comparing the Dwight-Lloyd process with other roasting systems, viz.:

1. The cost of installation per ton-day capacity of this plant is only one-half to one-quarter that of any other roasting appliance.

2. The cost of operation is from $1.50 to $2 per ton less than that of the old hand-rabbled reverberatory roasters.

3. In connection with several of the plants installed there has been a noticeable increase of the capacity of a blast furnace running on a charge containing sinter produced by this process; in one case as much as 20 per cent. This is due to the great porosity of the sinter and the fact that it is practically fused to a slag.

Trail Smelter Statistics.

The extent of smelting operations at Trail will be indicated by the following approximate figures, which are for the calendar year 1910: Tons smelted, 445,210; metal contents, gold, 138,901 oz.; silver, 2,017,007 oz.; lead, 33,871,837 lb.; copper, 5,282,139 lb. These figures for the company's fiscal year ended June 30, 1910, were generally higher, especially in lead production (42,368,816 lb.), while gross value of metals produced was nearly $400,000 greater ($5,911,767). Figures for nine months ended March 31, 1911, show a further decrease in tonnage and gross value of production, the tonnage smelted during this period being 304,587 tons, while the approximate gross value was $3,334,000, of which 55 per cent was gold.

The following figures give details of the company's operations for the nine months mentioned:

1910— Month.	Tons Received.	Tons Smelted.	Approximate. Gross Value.	Percentage of Gold.
July	35,641	35,138	$384,000	62.7
August	33,453	32,301	420,000	49.5
September	33,333	31,105	288,000	57.5
October	34,356	34,132	430,000	47.2
November	35,053	36,066	421,000	56.5
December	35,310	36,364	351,000	53.4
1911—				
January	34,505	32,958	349,000	57.7
February	32,323	32,315	326,000	57.8
March	35,096	34,208	365,000	54.8
Totals	309,070	304,587	$3,334,000	55.2

Of the total quantity of ore received, as above, 46,755 tons was custom ore and the remaining 262,315 tons came from the company's own mines, as under:

	Tons.
Center Star Group, Rossland	139,972
Snowshoe, Boundary	83,201
Sullivan, East Kootenay	25,362
St. Eugene, East Kootenay (concentrate)	6,129
Richmond-Eureka, Slocan	2,476
Queen Victoria, Nelson	1,984
No. 7, Boundary	1,718
Phoenix Amalgamated, Boundary	1,143
Molly Gibson, Nelson	330
Total output for nine months	262,315

The greater part of the ore from the company's mines was gold-copper, namely, 228,018 tons; the remaining 34,297 tons was lead-silver ore and concentrate.

Slag Disposal at Grand Forks.

The Granby Consolidated Mining, Smelting & Power Company, Ltd., operating a copper smeltery at Grand Forks, Boundary district, B. C., is preparing to dispose of its slag by a different system than that which has been in vogue for some years.

Up to the present time the hot slag has been hauled from the furnaces to the dump in slag cars by steam locomotives, but hereafter the slag will be granulated and disposed of in a manner described below.

The extent of the smelting operations of this company, the smeltery of which is stated to be the largest copper reduction works in the British empire, and second only to the great Washoe works at Anaconda, Mont., is indicated in the following brief outline of the smelting plant and equipment at Grand Forks.

There are in use eight rectangular, water-jacketed blast furnaces; six 44 in. by 266 in., and two 48 in. by 260 in. at the tuyeres; depth, 15 ft. 8 in., having a total capacity of 4000 tons to 4500 tons of ore per diem; 12 Connersville blowers, with a total air capacity of 239,000 cu. ft.; specially designed mechanical furnace charging system; hot slag haulage by 14-ton steam locomotives with 44-cu.-ft. slag cars; three converter stands 84 in. by 126 in., operated by electricity, and one stand 72 in. by 100 in. operated by hydraulic power; converter capacity, 50,000,000 lb. of copper per annum; three blowing engines with a total capacity of 19,700 cu. ft. of air per minute, and much accessory plant and machinery.

During the earlier years of the company's operations the slag was granulated by water and run to the dump by gravity in the usual manner. Then, as the dump filled to an extent, making it difficult to maintain the grade requisite for this method of disposing of the slag, it became necessary to substitute the hot slag haulage system which is now about to be dispensed with in favor of a return to water granulation and a method of disposal described below.

Four large receiving bins will be erected below the present level of the slag dump and at a distance of about 150 ft. from the blast furnace settlers. The slag will be granulated by water immediately after its discharge from the settlers, in the customary manner, and be conveyed thence to the receiving bins in the launders. From the bins it will be distributed over the dump by a series of conveyer belts, at first up a gradual incline to a maximum height of about 100 ft. and then by a cross-conveyer to the dumping place. These belts will be the ordinary 30-in. conveyers. The incline will at first be over a series of trestles, but later the grade of the dumped slag will be so regulated as to give the requisite incline up to whatever height it will be found economically practicable to carry it. The belts will be operated by two electric motors.

Two main reasons have caused the management of the company to make this change in the method of slag disposal. One is the excessive cost of the present haulage system, owing to the slag having to be hauled about three-quarters of a mile to the dump, and the high cost of maintenance of locomotives and slag cars. Second, the increasing difficulty of disposal by the present system, as the dumping-room below the present level becomes more and more curtailed. The substitution of the new method for that long in use is expected to involve an outlay of between $30,000 and $40,000, but important compensating results will be lower cost of slag disposal and provision of dumping-room for fully 10,000,000 tons of slag. To long continue the present hot dumping system would mean the changing of the course of the north fork of the Kettle River, with resultant cost of land that would be destroyed thereby, so the change determined upon will avoid a large expenditure in that direction and at the same time bring about a substantial reduction in operating costs.

It will probably be about four months, or near the end of September or beginning of October before the proposed change will be effected.

The Utilization of the Wastes of a Blast Furnace.

By Edward M. Hagar.

Until the last decade, practically the only utilization of the wastes or by-products of a blast furnace was the use of a portion of the waste gases to raise the temperature of the incoming blast through heating the brick work in so-called hot stoves, and in some cases a small portion of the power value of the gases was obtained by burning them under boilers to generate steam for driving the blowing engines.

At the present time the calorific value of the waste gases is being utilized directly in gas engines for blowing purposes and for generation of electric power, a considerable portion of the slag is used in the manufacture of Portland cement, and the flue dust, consisting of the finest ore and coke particles, is being collected and converted so as to be rechargeable into the furnaces.

The aggregate saving or profits resulting from these three developments is a matter of millions of dollars per annum, and in a modern blast-furnace plant it would almost seem that pig iron was the by-product, and, indeed, the investment in the equipment to utilize these former wastes exceeds that of the blast furnace itself.

The writer, in his work, has come in contact with these evolutions, with plants in operation or under construction, of a capacity to produce 12,000,000 bbl. of Portland cement per annum from slag and limestone, using over 1,300,000 tons of slag in a year, these plants being driven entirely by electric current generated by gas engines directly from the waste blast-furnace gases, the power requirements being 40,000 hp for 24 hours every working day.

In one of the cement plants the first commercial method for reclaiming flue dust was discovered.

By using the blast-furnace gases directly in combustion engines, after suitable washing to remove the grit, the power obtained from a given amount of gas is equal to at least two and one-half times that obtainable by burning the gas under the boilers for generating for use in steam engines.

A modern blast furnace of the usual size, with gas-blowing engines and gas engines driving electric generators, will provide sufficient gas to furnish 7000 kw of electric power, in addition to driving its own blowing engines.

This permits the most modern steel works, such as those at Gary, Ind., to practically do away with the use of coal for power purposes, operating the rolling mills by electric power from the surplus gases.

The United States Steel Corporation, of which the Universal Portland Cement Company is a subsidiary, has already installed 250,000-hp gas-blowing and gas-electric units, which, it can easily be figured, displaces or saves the consumption of approximately 1,000,000 tons of coal per annum as compared to the old-fashioned method.

With the modern high-blast pressures and the use of fine Missabe ore, the finest of the particles, together with the coke dust, are blown out through the top of the furnaces and are caught in the flues, dust catchers and gas washers.

The iron ore in this dust amounts to fully 3 per cent of the total ore charged, which aggregates the large amount of approximately 1,250,000 tons per annum in this country. Until within a few years this dust has been thrown away or used as filling, although containing about 40 per cent metallic iron.

For many years efforts were made to use this material by compressing it into briquets, but the cost of the operation, together with the fact that the briquets disintegrated and the dust was again blown out, led to an abandonment of the briquetting plants.

The first commercially successful method of utilizing the dust was discovered by passing the material through the cement kilns at South Chicago. Experiments showed that with the proper heat treatment the coke dust could be burned off and the iron ore conglomerated into nodules or nuggets averaging over 60 per cent iron content. These nodules, when fed to the blast furnace, were easily and completely reduced. The fact that the sinter of the flue dust contains such a high percentage of iron and that all of the sinter is reduced, together with its physical shape assisting the steady movement of the charge downward in the blast furnace, thereby preventing so-called slips, makes the sinter more valuable per ton than any ore.

It was necessary to derive mechanical means for preventing the accumulation of the sinter on the walls of the kiln. Plants have been in operation for some years using this process, with endless chains carrying scrapers constantly passing forward through the kiln, and cooled in water on their return outside of the kiln.

Recently other methods of utilizing dust have been devised which may prove successful commercially, and the indications are that within a short time the greater portion of this former waste will be prevented.

The development of the Portland cement industry in this country and the extension of its uses have been marvellous, and the following table shows a remarkable increase in the production of Portland cement in the United States every year since 1895, when this country first reached the production of approximately 1,000,000 bbl.

Year.	Production of Portland Cement of United States. Barrels.	Production of Universal Portland Cement. Barrels.	Percentage of Universal to Total American Production of Portland Cement.
1895	990,324	.....	....
1896	1,543,023	.....	....
1897	2,677,775	.....	....
1898	3,692,284	.....	....
1899	5,652,266	.....	....
1900	8,482,020	32,443	0.39 per cent.
1901	12,711,225	164,316	1.29 per cent.
1902	17,230,644	318,710	1.85 per cent.
1903	22,342,973	462,930	2.08 per cent.
1904	26,505,881	473,294	1.78 per cent.
1905	35,264,812	1,735,343	4.92 per cent.
1906	46,463,424	2,076,000	4.55 per cent.
1907	48,785,390	2,129,000	4.36 per cent.
1908	51,072,612	4,535,000	8.89 per cent.
1909	62,508,461	5,786,000	9.27 per cent.
1910	73,500,000 gov. est.	7,001,500	9.52 per cent.

It may be of interest to note the increasing percentage of the total American production shown by Universal Portland cement, which is the only Portland cement manufactured in this country using slag as one of the raw materials. With the new plant now approaching completion the aggregate production of Universal Portland cement in the Chicago and Pittsburgh districts will amount to over one-eighth of the country's total. Expressed in weight, the output of the finished product will be over 2,000,000 gross tons per annum.

Our plants in the Chicago district will consume all the available slag that is suitable for the purpose from an aggregate of nineteen blast furnaces in the South Chicago works of the Illinois Steel Company and in the Gary works of the Indiana Steel Company.

Comparing the pig-iron production and Portland cement production of this country in figures of long tons, the percentage of Portland cement to pig iron in 1890 was six-tenths of 1 per cent, in 1900 10 3-10 per cent, and in 1910 47 per cent. The continuation of any such relative growth would mean that before 1920 the tonnage of Portland cement would considerably exceed

*Presented before the Congress of Technology at the Fiftieth Anniversary of the Granting of the Charter of the Massachusetts Institute of Technology, on April 10.

that of pig iron. I would hesitate, however, to predict that such would be the case.

Portland cement is defined by the United States Government as the product obtained from the heating or calcining up to incipient fusion of intimate mixtures, either natural or artificial, of argillaceous with calcareous substances, the calcined product to contain at least one and seven-tenths times as much of lime, by weight, as of the materials which give the lime its hydraulic properties, and to be finely pulverized after said calcination, and thereafter additions or substitutions for the purpose only of regulating certain properties of technical importance to be allowable, not exceeding 2 per cent of the calcined product.

From this definition it will be seen that the raw material for Portland cement is not limited to any particular form of material. It may be made from any combination of materials that together furnish the proper elements. In this country Portland cement is manufactured from a number of raw materials, which, with a few exceptions, may be classed under four heads:

First.—Argillaceous limestone (cement rock) and pure limestone.

Second.—Clay or shale and limestone.

Third.—Clay or shale and marl.

Fourth.—Slag and limestone.

In all cases the raw mixture is a combination of some form of clay and some form of lime, and in the first and fourth classifications the clay materials contain some lime. This simply reduces the proportion of lime material necessary for a proper mixture.

In the manufacture of Portland cement from slag and limestone the molten slag flowing from the furnaces is granulated by a stream of water, loaded into cars and transported to the cement plant, where it is dried in rotary driers and receives the first grinding; it is then mixed in automatic weighing machines with the proper proportion of ground and dried calcite limestone. These are then ground together and burnt to a hard clinker at a temperature of nearly 3000° Fahr. in rotary kilns, using pulverized coal for fuel.

This clinker, after seasoning, is crushed and ground and mixed with a small percentage of gypsum to regulate the setting time. The cement is ground to such fineness that 96 per cent passes through a sieve having 10,000 meshes, and 80 per cent passes a sieve with 40,000 meshes to the square inch. It is then conveyed to the stock house for storage prior to shipment.

It is necessary to use a flux in furnaces supplying slag for cement manufacture, a pure calcite limestone. The limestone burnt with the slag must also be a pure calcite stone. It is also essential that the ores be of a uniform and proper character.

Inasmuch as Lake Superior ores are noted for their remarkable uniformity of analysis, the resultant slag obtained from the use of these ores and a pure calcite limestone is more uniform in its analysis than any form of natural clay deposits used in the manufacture of Portland cement, and the variation in the proportions of the two raw materials used in the manufacture of Portland cement from slag is less than those of any other materials mentioned above.

In addition, the opportunity for analysis and selection of the proper ingredients through the use of an artificial material is a great advantage as compared to the necessitous use of natural materials just as they are found with their variations in analysis at different depths.

In the intense heat of the kiln, under the influence of the oxidizing flame, any sulphides in the slag are completely burned out.

The rotary kiln commonly used ten years ago was 60 ft. long and 6 ft. in diameter. This has gradually been increased in length and diameter until the modern kiln is 140 ft. to 150 ft. long and 8 ft. to 10 ft. in diameter, and there are a few even larger kilns in use. Kilns are usually set at an incline of ¾ in. to the foot. With the lining and contents the modern kiln weighs 150 tons, and in revolving upon two bearings presents interesting constructional features.

In the case of the plant at Buffington, Ind., using 26,000 hp. situated between South Chicago and Gary, Ind., electric power is supplied from the steel works at these points. Each piece of machinery is driven by its individual motor. The high-tension line is connected through the cement plants, and the gas engines at these two steel works, 14 miles apart, operate continually in parallel.

This enables the cement plant to draw its power from either source or from both sources at the same time, as may be desirable at any time.

It has happened that one of these works has supplied power to operate the cement plant and has also furnished additional power at the same time to the steel works at the other end of the line.

The method of manufacture above described is the standard method of manufacturing Portland cement from natural deposits, and the finished product differs in no way from other Portland cements in chemical analysis, fineness, specific gravity, color, nor in the operation in practical work.

It has no peculiarities whatever and has no limitations as to its applications.

There is no difference, from the chemist's point of view, between the manufacture of Portland cement from natural deposits, such as limestone and clay or shale, and its manufacture from limestone and slag. Slag is really a mixture of the clay from the ore with the lime content of the stone used as a flux in the furnace.

Our method of manufacture of Universal Portland cement does not embody any real invention, nor is it based on any patents.

It is simply an adaptation to an artificial raw material of the regular Portland cement process formerly applied only to natural deposits.

True Portland cement in which slag is used as one of the raw materials should not be confused with Puzzolan or so-called "slag cements," which are simply mechanical mixtures of slag and slaked lime ground together without burning. Such cements are suitable only for use underground and in moist locations.

The manufacture of Puzzolan cements ni this country has practically been abandoned.

The remarkable growth of the Portland cement industry is not equalled by any other manufactured article. This is due to the economy, durability and plasticity of cement and concrete work.

While the large engineering work, such as dams, bridges, and heavy reinforced-concrete buildings consume large quantities of cement, the bulk of consumption at the present day is in a multitude of small uses. It takes an average shipment of only 5 bbl. a day to take care of the average customer of a large cement company.

For example, there is a steady increase in the application of cement to new uses on the farm, such as silos, fence posts, barn floors, feeding floors, watering troughs, corn cribs, etc. There, as elsewhere, concrete is rapidly displacing all forms of wood construction, this process being hastened by the continually advancing cost of lumber.

Beautiful effects are now being obtained in concrete surface finishes and its use in decorative work is advancing rapidly.

The use of Portland cement will continue to increase until the campaign of education of the small user has reached its finality.

Most of the problems of utilization of wastes or by-products of the blast furnace have been solved, and these solutions, in addition to being highly profitable, are powerful factors toward the conservation of our natural resources. Portland cement manufactured from slag, to a large extent, replaces wood; the waste gases displace coal, and reclamation of the flue dust conserves the deposits of iron ore.

The Problems of Tungsten Concentration.--II.

By H. C. Parmelee

Treatment of Old Tailings

The Cardinal mill of the Primos Mining and Milling Company is a remodeled gold mill, formerly known as the Boulder County mill. The tailings impounded during several years' run of tungsten ore before the canvas plant was installed are now being retreated at the rate of 20 tons per day. Naturally the grade of the material is not uniform owing to irregularities in its deposition and in the grade of the ores originally treated.

Ten stamps are used to break up the pulp and prepare a uniform feed for the concentrators. There is really little work for the stamps to do, and the operation is hard on them as there is little bed of ore to resist excessive wear of shoes and dies. The pulp is discharged through a 20-mesh screen and flows directly to one Wilfley table from which a fairly coarse concentrate is obtained. All of the tailings are returned by a Frenier pump to a Callow cone which thickens the pulp for tube mill feed. No screen analyses are available to show the work of the tube mill, but an inspection of the canvas plant would indicate that the sand is not ground fine enough, and that a heavier load of pebbles should be carried and the pulp further thickened to reduce the ratio of water to solids in the tube feed.

The tube mill discharge is pumped to a V-shaped settler, from which pulp is drawn by several syphons to a distributing box for three Frue vanners. All vanners thus receive the same feed and no attempt is made to classify the pulp. The vanner tailings are treated on the canvas plant which consists of 3600 sq. ft. of canvas arranged on stationary tables.

At the head of each set of tables is an inclined launder carrying the pulp to distributing boxes. One double box is provided for each pair of tables and wooden plugs are used to stop the flow of pulp to any box. Adjustable dividing strips are placed in the launder to equalize the flow of pulp to the several boxes. From the box the pulp is further distributed across the head of the table by means of several launders of varying length, and the flow over the table is still further equalized by strips of wood notched in a saw-tooth manner. A main service pipe for wash water extends along the upper end of the tables, with a valve and lateral pipe for each table. Two parallel launders, one for tailing and one for concentrate, extend along the foot of the tables and wooden aprons are so hinged that by shifting their position the pulp flowing off the table may be diverted into one launder or the other.

Another plant treating old tailings is that of Smith and Ardourell on Beaver Creek. The tailings from earlier work at the Wolf Tongue mill are hauled two miles and presumably treated at a profit. The average grade is reported to be about 2 per cent WO_3. Twenty tons a day are treated at this mill.

From the bins the pulp is conveyed by spiral conveyor to a shaking screen for the removal of stones and rubbish. It is then classified, the coarse grade being treated on a Wilfley table and the two finer grades on Monell slime concentrators. The Wilfley sand tailing is rejected and the middling reground in a Denver quartz mill. The Wilfley slime tailing and the Monell tailings are run over canvas. There are four canvas tables, each 4 ft. by 18 ft., built with a fall of 1 in. per foot in length.

Two grades of concentrate are recovered at this plant, instead of one as at the mill just described. The Monell slimer, which will be referred to in more detail later, will deliver two grades of mineral, one high and one low. The high grade from the Monell is combined with the Wilfley concentrate making a product running from 40-50 per cent WO_3. The Monell low-grade concentrate carries 30-40 per cent, and the canvas concentrate 10 per cent WO_3. If the Wilfley and Monell tables are running well the canvas plant makes a poor recovery and at times the concentrate is freely contaminated with pyrite and grains of gangue and scarcely worth saving.

When the present campaign on tailings is finished the mill will be fitted with crushing apparatus and adapted to treat crude ore. It appears probable that stamps will be installed, and that the capacity of the mill will be about 5 tons of ore per day as compared with 20 tons of tailings at present.

Treatment of Ore.

Before describing the other mills in detail it may be well to speak of the Monell slimer, as it is used in almost all of the plants and is regarded with favor. It is a slime concentrator of the traveling belt type with a shaking movement in the direction of belt travel. Its principal features are the unusual length and slow travel of the belt, and the large flat settling area afforded for the collection of fine mineral. The belt is 5 ft. wide and the working surface is 23 ft. long. The rate of belt travel is adjustable from 3 to 27 in. per minute, and is usually set at 18 in. The number of vibrations varies from 160 to 180 per minute. Pulp is fed at one side of the belt and tailing discharged at the other. The concentrate is collected in a box at one end in the usual manner.

The feed is first received in a classifying box set about 2 ft. above the deck of the table and near one end. Pipes from the several compartments of the box deliver the pulp to distributing launders arranged along the side of the table. The coarse grade is delivered near the end of the table where it forms a bed for the collection of the finer grades that are delivered farther on. Suitable wash water boxes are provided near the discharge end to wash off the sand and leave a clean concentrate.

The belt travels on strips of redwood laid lengthwise of the table. The upper or feed edge is slightly raised to direct the flow of pulp across the belt, and the lower or discharge side is inclined downward to aid in discharging the tailing. These inclinations at the edges of the belt extend for a few inches only, and the large area between them is perfectly flat, thus affording an excellent settling surface.

Owing to the manner of distributing the feed on the belt a bed of high grade mineral forms on its upper half, and a less well defined streak of lower grade mineral on the lower half. When the belt passes through the collecting box the mineral accumulates in corresponding beds of high and low grade material and the attendant keeps the two classes separate when cleaning the box. The illustration, Fig. 1, shows a Monell slime machine in the mill of the Tungsten M. & M. Co. on Beaver Creek. The bedding of high and low grade mineral is plainly shown on the end of the belt passing down to the concentrate box. The illustration also shows a Monell concentrating table which is of unusual design. The concentrates are drawn off through slots in the deck of the table and conducted by launders to boxes at the end.

The mill of the Tungsten M. & M. Co. has a capacity of about 5 tons in 24 hours. The ore is reduced by a jaw crusher to ½-in. size and fed to a Denver quartz mill fitted with 16-mesh diagonal-slot punched screen. The discharge is then passed through a 20-mesh screen, the oversize of which is treated on one Monell concentrator. The undersize is roughly classified, the coarse portions being sent to a second Monell table and the fine to a Monell slimer. There is no canvas plant at this mill and the tailings of all concentrators are run to waste. Two grades of mineral are recovered but no data can be given as to percentage recovery as there is no systematic chemical control of operations.

The Alton mill is a new plant modeled along modern lines, but as it has not been in steady operation nothing can be given but the plan of treatment. The ore is first crushed in a Samson No. 4 crusher, elevated to a bin from which it is delivered by a plunger feeder to a pair of 14-in. by 30-in. rolls. The roll product passes through a trommel fitted with 12-mesh screen, and the entire oversize is treated without further sizing on a double compartment Harz jig, having the same screen as the trommel. The undersize of the trommel and the hutch product of the jig are combined and treated directly on a Wilfley table.

Coarse concentrate is drawn from the side gates of the jig and the tailing is reground in a Denver quartz mill fitted with 20-mesh punched screen. The Wilfley tailings also are reground in the same machine. The reground pulp is pumped to an 8-ft. Callow cone, the underflow of which is divided between a Card table and a Monell slimer. The Card and Monell tailings are combined and treated on two canvas tables of 12-oz. duck, 6 ft. wide and 26 ft. long.

FIG. 1.—SHOWING MONELL SLIME CONCENTRATOR IN MILL OF TUNGSTEN M. & M. CO.

The manager of this plant expressed the opinion that the jig would make from 25 per cent to 40 per cent of the total recovery, according to the grade and physical condition of the ore. This belief is based on the treatment of 20 tons of ore when the mill was first put in commission.

The Wolf Tongue Mining Company whose mill at Nederland is shown in Fig. 2, is one of the two large companies that have been pioneers in the tungsten industry. The mill is an old remodeled stamp mill formerly used on gold and silver ores. As a result it is not as well arranged as a new plant would be, nor is its operation as satisfactory as that of a more modern plant. Nevertheless it shows very well the possibilities of coarse crushing and jigging tungsten ore, and it is probable that should the company erect a new plant it would conform closely to modern practice in ore dressing.

The company is at present treating custom ore which on an average will carry about 7-8 per cent WO_3. Each lot is sampled and bought on comparison of assays. The ore is first crushed in a Blake crusher and then in rolls set ½ in. apart Power is applied to but one of the rolls which makes 90 r.p.m., the other running free. The roll product is elevated to a Vezin sampler which cuts out a fraction of the lot. This is further reduced by the tenth shovel method, and the portion thus obtained split on Jones riffles. The sample is then ground in a coffee mill, finished on the bucking board and divided into portions for the buyer and seller.

The reject from the Vezin sampler falls on a belt conveyor running to a trommel fitted with 16-mesh screen. The entire oversize is jigged, and the jig tailing is dewatered and sent to stamps for regrinding. The trommel undersize and the hutch product of the jig are combined with the reground tailing and classified for table treatment. The slime from the dewatered jig tailing flows directly to the canvas plant.

Ten 750-lb. stamps are used as regrinders of jig tailings. This battery formed part of an old equipment and probably is used only because it is convenient. The pulp is discharged through 12-mesh ton-cap screen and combined with the undersize of the 16-mesh trommel and the hutch product of the jigs. This mixed pulp is then classified in Flood classifiers and treated on four Card tables. These tables make a fairly coarse high grade concentrate which is dried and sacked for shipment. The middlings and tailings are reground in another stamp battery through 50-mesh screen and concentrated on a fifth table.

The slime tailing from the fourth and fifth tables and the overflow from the fourth or last Flood classifier are collected in a distributing box and sent to three Monell slimers. A lower grade concentrate is recovered from these and their tailings are pumped to the canvas plant. On account of the preliminary coarse concentration, less reliance is placed on the canvas plant in this mill than in some others. It contains only 768 sq. ft. of canvas arranged in two tiers of tables, eight in a tier, each 4 ft. wide and 12 ft. long. A cement foundation was put in for the canvas and it appears to be perfectly satisfactory provided a firm foundation is made for the concrete work. The surface is smooth and there are none of the irregularities sometimes noticed in board surfaces where the boards have been laid either too close together and buckled, or too far apart and failed to close up on becoming thoroughly wet. Twelve ounce canvas is used and the tables have the usual fall of 1 in. per foot in length. Pulp is allowed to flow for three or four hours, after which the usual method of washing and cleaning is followed.

Cement settling basins for fine concentrates, with a cocoa matting filter at the outlet, are placed in the lower part of this mill. These basins have proved valuable in saving fine floating mineral from the canvas plant and from the concentrate boxes of the Monell slimers.

The Lakewood Mill.

In marked contrast to the principal methods employed in the plant just described are those practiced at the Lakewood mill of the Primos Mining & Milling Co. Those in charge of this mill and responsible for the methods employed are likewise pioneers in the milling of tungsten ore, and it is interesting to compare their methods with those of the other old company. The Lakewood mill is new and a model of construction as regards arrangement, convenience, cleanliness and facilities for saving time and labor. The illustrations, Figs. 3, 4 and 5, will tend to bear out these assertions.

At the head of the mill is ample bin room for the numerous

FIG. 2.—THE WOLF TONGUE MILL, NEDERLAND, COLO.

small lots of ore shipped by leasers when the company is in the market for custom ore. Separate crushing and sampling apparatus is installed for this work, consisting of jaw crusher, rolls and pipe sampler. The ore is bought outright on comparison of assays, and the lot is held until satisfactory settlement is made.

Ore from the company's mines is dumped into a large bin from which it is drawn over 2-in. grizzlies, the fine passing to the crushed ore bin. The coarse is reduced in a 10-in. by

16-in. Blake crusher and combined with the undersize of the grizzlies. The crushed ore bin is of 120-ton capacity, or about three times the daily capacity of the mill. Tappet-driven Challenge feeders draw the ore from this bin to the stamps through which all ore passes before concentration begins.

The battery frames are of heavy timber construction and the mortar foundation is built up of heavy timbers 18 ft. long set on end on a concrete foundation.

Concentration is divided into two principal departments; first, the customary table work with Wilfley tables and Frue vanners, and second, the recovery of fine mineral on the canvas plant. All of the concentrating tables are arranged on one floor below the stamps, and the canvas in three tiers below the tables. Concentrates from the Wilfley and Frue machines are combined. The product assays over 60 per cent WO_3.

The pulp from each battery of five stamps flows directly without classification to a Wilfley table. A clean concentrate is cut out and the balance is sent by a Frenier pump to a spitzkasten which serves the first set of five vanners. The vanner tailings are combined and pumped to a large V-shaped box. The pulp is delivered to the box at one end through a pipe

FIG. 3.—THE LAKEWOOD MILL OF THE PRIMOS MINING AND MILLING CO., LAKEWOOD, COL.

extending some distance beneath the surface, thus giving the coarse particles opportunity to settle. There are no partitions in this box, but as the pulp flows from one end to the other there is a rough classification due to the settling of the particles with the retardation of the stream.

Six spigot products are drawn from this box; the first or coarsest being thickened, reground in a tube mill and returned, and the other five treated on Frue vanners. The tube mill is shown in Fig. 5 in relation to the V-box and the Frue vanners. No screen analyses are available, but the statement is made that 85 per cent of the tube product will pass a 200-mesh screen. Pebble consumption is 50 lb. per day, but no figures can be given as to quantity of pulp ground. The vanner tailings and overflow from the V-box flow to the canvas plant.

The Lakewood mill has the most extensive canvas plant in the district, comprising 10,320 sq. ft. of cloth arranged in three tiers of tables. An idea of the area covered can be gathered from Fig. 3, showing the mill exterior. With the exception of the concentrating table floor, the entire lower portion of the mill is devoted to the canvas plant.

The construction of the distributing and collecting launders and other features of the plant is practically the same as described for the Cardinal mill of this company. The tables are cleaned once each shift and all canvas concentrates are collected in settling boxes on the lower floor. This is practically on a level with the drying house shown at the right of the mill in Fig. 3, where the concentrates are dried on steam tables and sacked for shipment.

The labor employed consists of six men on the day shift and three at night. During the day there is one man at the Blake crusher, two at the stamps and tables, two on the canvas and one in the drying and sacking room. At night there is but one man on the stamps and tables and two on the canvas.

The mill is steam heated and electric lighted. Electric power is received at 13,000 volts from the lines of the Central Colorado Power Co., and stepped down to 440 volts. Motors are

FIG. 4.—VIEW OF STAMP BATTERY AND WILFLEY TABLES IN LAKEWOOD MILL.

distributed as follows: 15 hp, crusher; 35 hp, 10 stamps; 5 hp, 2 Wilfley tables and Frenier pump; 10 hp, 11 vanners and 2 Frenier pumps; 35 hp, tube mill.

Water is supplied from North Boulder Creek and delivered at the mill storage tanks either by a high line ditch, or by a Worthington 3-in. turbine pump direct connected to a 15-hp

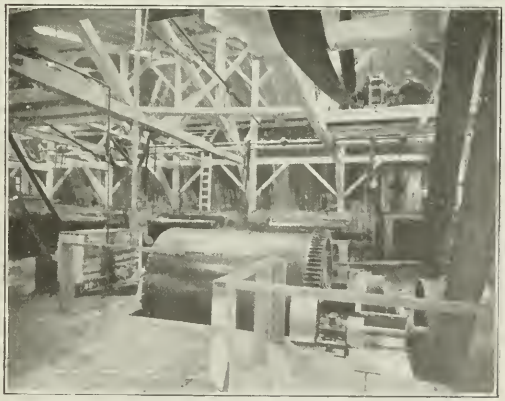

FIG. 5.—VIEW OF TUBE MILL WITH LARGE SETTLER AND VANNERS IN BACKGROUND, LAKEWOOD MILL.

motor. The pipe line from the pump to the tank house is 700 ft. long and rises 85 ft. An unusually large quantity of water is used amounting to 250 gal. per minute for the treatment of 40 tons of ore in 24 hours.

All of the Boulder County tungsten mills are fortunate in having a supply of clear water which is of advantage in all ore dressing plants, but particularly where so much fine mineral has to be recovered by means of the canvas table.

The Development of Economical Ore Dressing Systems.*

By Frank E. Shepard.

In the quest for mineral values there appear to be several phases of development, one leading into the other. The discoveries of many of our large mining sections have resulted from the placer workings in which the values are found in gravels on or near the surface of the ground. The primitive methods with pick, shovel, and hand rocker often served to develop rich deposits. Then followed the more highly developed hydraulic mining systems involving greater expenditure of capital but bringing greatly increased returns. This trail of values leads to some source and so the patient prospector finally reaches an outcrop or vein which requires deeper workings with a more elaborate plant.

The search is first for high-grade ores, for the difficulties of mine development, transportation, and treatment are great and expenses in proportion. Bonanzas, however, are rare, and then must come the patient search for ways and means of developing better methods of mining, milling, and smelting for the recovery of values from lower-grade ores. Refractory ores are found which call for more advanced methods of smelting or the grade of ore is such that milling systems must be devised for concentrating into values sufficient for commercial delivery to smelting or refining points.

While the general trend of ore values has been from high grade to lower grade, there has also been a sombre accompaniment of decreasing market prices for the metals calling for serious study in all metallurgical systems. Ten years ago, manufacturers of machinery for ore reduction processes, in the Rocky Mountain section, were devoting much attention to the details in smelting machinery for the treatment of high-grade ores. To-day there is less call for smelting systems and the demand appears for improved ore dressing machinery for the recovery of values from lower and lower grade ores. This change from higher to lower grade ore conditions has taken place generally throughout the fields of gold, silver, lead, zinc and copper ores.

The stamp mill, with its amalgamating plates and bumping tables for the recovery of 50 per cent to 70 per cent of gold and silver values in the earlier period, is being succeeded by the concentration and cyanide plants producing recoveries of 90 per cent and over.

Lead-iron-zinc ores are presenting more and more difficult problems, and with the mining of lower grade ores of these metals comes the demand for better methods of crushing, screening, hydraulic classification and concentration, and in this particular line of ore treatment appears the great development in electrical processes of mineral separation.

The successful mining and milling of the great porphyry copper ore deposits of a grade as low as 2 per cent and under has brought about radical changes in milling methods and concentrating mills of 10,000 tons daily capacity have been successfully developed.

The tremendous pace in modern steel production has produced such demands on the iron ore supply that commercial possibilities have been found in the lower-grade iron ore deposits of Michigan and concentration plants have been installed for the treatment of 20,000 tons of ore daily.

The call for economy and reclamation of values in the Cripple Creek District has resulted in treating the dumps formed by the discarded ores of a former period by means of modern concentration and the cyanide systems at the remarkably low cost of $1.50 per ton.

Business men making investments in mining enterprises have found that it pays to be guided by specialists in this line of work. So many mistakes are made by the mining companies rushing through the building of a mill before the mine is sufficiently developed. The professional fee of the competent geologist and mining engineer is well earned, and thorough examination and sampling of the mine should be completed to furnish sufficient data from which to design and develop a suitable mill system.

Having provided a representative sample of the ore to be treated, there are laboratories throughout the country where tests and experiments may be conducted and results obtained from which an economical system of ore treatment may be planned. The various manufacturers of mining and milling machinery offer engineering advice in the development of systems of ore treatment, and while this may be competent and the result of good practical experience, such advice depends upon data furnished by the mining company itself.

Large mining companies appreciate the value of preliminary investigations of ore conditions in a mine, and the manufacturer has competent advice from which to design and construct suitable machinery and equipment for the ore dressing system; but in the smaller mining organizations, the building of a mill oftentimes appears to be more important than the development of ore bodies and the manufacturer is called upon to furnish machinery to treat ores which may change radically in further development of the mine.

In extensive mining operations the plan is followed of erecting mills to test the practical application of the mill system determined upon, and this proves of great value in solving difficult problems of ore treatment.

In the smaller mining companies, often composed of business men without any experience in mining and milling methods, it is seldom found that sufficient funds have been devoted to these important preliminary tests and instead of employing competent technical advice some one of the directors of the company who "has a liking for machinery" assumes charge of affairs and the resulting mining and milling composition ends in minor chords. However small the proposed mining or milling installation, it is alway advisable to secure the advice of the mining or metallurgical engineer who studies the entire field of operation and the economic conditions relating to mine and mill, makes suitable examination of mine, takes sufficient samples of the ore, and after preliminary tests is prepared to submit general plans and specifications for a suitable mill system.

While the manufacturers of mining and milling machinery are by custom expected to prepare plans for milling systems, on account of the stress in business competition, such is not an economic condition, and it is better practice to have one engineer thoroughly advised on all technical matters from inception to the complete milling plant.

The manufacturer has the very important part to perform of attending to the many details of mill installation and it is his affair to keep up to the minute in all the improvements which aid in reducing costs and increasing recovery of values from the ores.

Mill design is a profession in itself. It is not necessary for the consulting, mining or metallurgical engineer of the mining company to be an expert in the details of mill construction as the machinery manufacturers make a study of these problems. The detail drawings of the mill should be intrusted to an engineer who has not only a very thorough knowledge of mill machinery details but an intimate knowledge of mill men and practice.

In the selection of mill machinery the new inexperienced mining company usually buys the cheapest grade, while the mill superintendent of long experience buys the best machinery that can be built. In a small mill treating 50 tons in 24 hours of an ore having a value of $15 per ton and assuming the mill recovers 80 per cent. of the value, a delay in operation of but one hour means a loss of $25. It is manifestly poor economy to save a few hundred dollars in the original investment at the expense of several thousand dollars in delays and repairs.

Ore crushers were formerly equipped with hard cast-iron jaw

*Presented before the Congress of Technology at the Fiftieth Anniversary of the Granting of the Charter of the Massachusetts Institute of Technology.

plates which were required to be removed every few weeks, whereas now these crushers are provided with the best crucible-steel jaw plates which last for several months. Crushing rolls were formerly equipped with cast-iron shells which gave short service and soon became grooved; now the best forged-steel, machine-finished shells are used with the result of longer service and better product.

Elevating and conveying apparatus has reached a high state of development, all tending to greatly reduce costs of handling materials. By means of these excellent modern devices the entire mill system is automatic from beginning to end, save for the adjustments of machinery.

One of the greatest if not the greatest improvement in the wet concentration of ores has been the important development in the preparation of ore pulps previous to jigging and table work as a result of the investigation of Dr. Robert H. Richards of the Massachusetts Institute of Technology.

Dr. Richards' devices for hydraulic classification of ore pulps, previous to table concentration, have produced savings in ore values over former methods amounting to hundreds of thousands of dollars annually.

If we refer to our small mill before mentioned having 50 tons capacity daily and recovering 80 per cent of values in $15 ore, an improvement in recovery of only 5 per cent will mean an additional annual saving of over $12,000. Such improvements have actually been accomplished in practical mill systems using Dr. Richards' systems of hydraulic classification.

The tube mill is an important element in modern mill systems and was adapted from cement mill practice. It takes the place of the more complicated crushing machines involving the frequent renewal of shoes, dies, screens, and various parts in roller or chilian mills and presents a simpler and more economical means for the fine crushing of ores. The development of the tube mill in connection with the stamp mill in South African practice is extraordinary; the combination effecting an increase in tons crushed per stamp from five tons, before the tube mill was introduced, to 20 tons per stamp when assisted by the tube mill.

The better understanding of the preparation of pulps previous to table treatment as well as the better understanding of the concentrating tables themselves has brought about great improvement in mill recoveries.

The development of electromagnetic and electrostatic concentrating machinery has established practical separation of iron and zinc minerals which before was most difficult or impossible.

Most interesting use has been made of the property of film tension in liquids for the purpose of separating mineral values from the attending gangue. In general the sulphides of the metals may be floated on the liquid while the gangue sinks. While the system is limited to certain conditions, it opens a fascinating field and one which may develop into great possibilities.

Even greater progress could be accomplished were it possible to obtain the earnest co-operation of mill operators. In some cases splendid triumphs have been accomplished because new devices have been given the "square deal" by intelligent and progressive mill operators. On the other hand, many a mill system is undeveloped on account of personal prejudice and lack of initiative.

Failures in mill systems are often due to neglect in making tests to determine the points where losses occur or the costs of various operations. Changes suddenly occur in the ore and if not promptly followed up with required changes in the mill system will result in serious losses.

One of the modern requirements is thorough sampling and the best mills make use of automatic sampling throughout the system.

It is most important to have the right spirit prevail among the members of the mill crew. Good team work tells here as well as in the game, and a fair attitude and attention to improved methods of milling means also thousands of dollars to the mining company.

We often see machinery advertised as "fool-proof." If the mill system is to be run by fools then we need the fool-proof machinery, but if we cannot advance beyond the stage of fool-proof machinery then we might as well give up our cherished ideas of additional recoveries in ore values. For the economical recovery of values in low-grade ores we must expect greater complication in mill systems, but if we can save $25,000 by the addition of some machine, even though not classified as "fool-proof," is not the expenditure warranted of $2,500 in wages to some millman who will be a friend to the machine?

The man who stands by the machine has the opportunity of discovering many points, possibly improvements, regarding the operation or results of that machine. If the personal equation of that man is plus and he receives proper recognition by the management, the result is a substantial increment to favorable mill devolpment. Mills are usually located in remote sites, difficult of access and in many cases at altitudes of 10,000 and 12,000 feet above seat level. It requires some financial incentive to induce good men to work constantly under these conditions and liberal wages must be offered to establish a good order of intelligence in the mill crew.

The study of mill systems has in some cases shown a high order of inventive ability among mill superintendents in the development of devices for increasing the recovery of ore values, or reducing the expense of operation. There is, however, a great amount of blind prejudice to overcome when an attempt is made to introduce improved methods in the milling systems. This is a strange condition, for one would think that any millman would be favorable to any device which would show improved results even at the expense of some extra attention, but the fact remains that it requires a bitter fight to establish new systems.

A very interesting psychological fact exists in mill conditions. If a new device or system be introduced by some one of the mill attendants and he has the care of the device, that device is certain to work successfully. Should a system be introduced by the manufacturer, even though such a system may have been proven a success, all manner of prejudice and resistance appears and a well-merited system is classed as a failure.

If our graduates of technical schools could be induced to serve a few years of apprenticeship in the splendid experience of these mill systems and devote their technical training toward assistance in the development of improved devices, instead of obstructionary measures, there would be good progress made for better ore dressing systems.

With the successful treatment of low-grade ores there must be better study of conditions, better skill in operation and a constant effort for improvement. The modern mill calls for a higher order of materials of construction; concrete and steel are now being used when a few years ago such use was designated as extravagance. Better machinery is being used and the use of higher grade materials throughout the mill construction is considered a necessity.

The opportunity for improved results in ore dressing systems is great. When we know that in the operation of 10,000-ton copper ore concentrators, the loss on every ton of ore treated is 30 per cent to 40 per cent; that in precious metal wet concentrating mills the loss is from 20 per cent to 30 per cent, the time is now at hand when the data from long lines of investigation assisting the engineer and the builder, added to the practical application of the honest millman, should produce some telling results.

The trail of the gold seeker leads along difficult paths and through discouraging obstacles. Constant search and persistent effort will be the procedure as long as there remains a quest for precious metals—but the problems call for work and work develops the man.

"Let not him that seeketh cease from his search until he find, and when he finds he shall wonder; wondering, he shall reach the Kingdom, and when he reaches the Kingdom he shall have rest."

Denver Engineering Works, Denver, Colo.

Notes on the Analysis of Tungsten Ores.

By Hugh F. Watts.

Insomuch as tungsten can be readily separated from other elements by precipitation as yellow oxide or as mercurous tungstate, and as these precipitates can be easily converted into weighable tungstic oxide, few methods depending on other reactions have been proposed for its gravimetric determination in ores.

Volumetric methods have not come into general use principally for the reason that most of the time consumed in making the assay is in getting the ore decomposed and the tungsten separated from iron and silica. Solution and titration of the tungstic acid would not, therefore, present any advantages over weighing.

An interesting method described by Ekeley and Kendall (*West. Chem. & Met., Jan.*, 1908) consists in dissolving the tungstic acid from the silica by means of a measured volume of standard ethylamine and titrating back the excess with standard oxalic acid using phenolphthalein as indicator. The method has given excellent results.

Other volumetric methods depend on the principle that tungstic acid can be dissolved in standard sodium hydrate and the excess titrated with standard acid.

For the purpose of analysis, tungsten ores can be decomposed by fusion with alkaline carbonates; by boiling in solution of sodium hydroxide; by digestion in a mixture of hydrochloric and hydrofluoric acids, or by digesting in aqua regia.

When decomposition has been effected by fusion or digestion with alkalis, it is essential that the tungsten be precipitated as mercurous tungstate. A method given in many text-books depending on the separation of the yellow oxide from solutions of alkaline tungstates by evaporation with hydrochloric acid is unreliable, as it seems to be quite impossible to recover all the tungsten in this manner even when the evaporation and boiling with acid is repeated many times.

When the separation is made by mercurous nitrate, it should, of course, be remembered that phosphorus, vanadium, molybdenum, etc., are also precipitated. Moreover, even though these interfering elements are absent, as is generally the case, the voluminous precipitate of mercurous tungstate is apt to include impurities which cannot be easily found and accounted for, so that the results are apt to be a little high. Nevertheless, this is an excellent and much used method and is probably the only one that can be used on some ores.

Hutchin and Tonks (Inst. of Min. & Met., London, May, 1909) have described a method of especial use for battery pulp and tailings, the decomposition being effected by hot caustic alkali solution. The charge taken may be from 5 grams upward, which is digested in a porcelain dish with 25 cc of a 25 per cent solution of caustic soda. From this point the assay is finished as though the decomposition had been made by fusion. The method is not applicable to ores containing scheelite.

A mixture of equal parts of hydrochloric and hydrofluoric acids will decompose tungsten ores, sometimes to an almost complete solution. If now an excess of hydrochloric acid is added and the hydrofluoric acid expelled by evaporation, the yellow oxide will be precipitated on the addition of water. (Method of O. P. Fritchle.)

Conflicting statements can be found regarding the solubility of tungstic acid in hydrochloric acid. The unignited precipitate is certainly soluble to considerable extent in strong hydrochloric acid. Upon dilution with several volumes of water the tungsten is completely precipitated on standing. If subjected to filtration with the proper precautions in washing and the filtrate is perfectly clear and bright, no tungsten can be found therein or at the most in but very slight amounts.

Tungstic acid cannot be washed with pure water as it forms a pseudo-solution and causes the filtrate to be turbid. The wash water must contain acid or a solution of some salt. Similarly, in separating tungstic acid from silica with ammonia, much silica is carried through in a turbid stream when ammonia water is used alone. The presence of a little ammonium chloride prevents this in a great measure, but not to the extent, however, of making a complete separation, as silica is appreciably soluble in ammonia. The use of ammonia is, nevertheless, a most convenient means of separating all the tungstic acid from the bulk of the silicious residue.

When it is expected to use ammonia in the separation, care must be taken not to carry the assay to hard dryness as the tungstic acid is thus rendered difficultly soluble. Even prolonged heating on the water bath makes its solution uncertain.

Tungstic acid and silica may be separated by evaporation with hydrofluoric acid, the addition of sulphuric acid being unnecessary.

A Bunsen or Teclu burner can be safely used to ignite tungstic acid for weighing. The use of a blast lamp is inadmissible since tungstic acid is slowly but steadily volatilized at such temperatures. (Wells and Metzger, *J. Am. Chem. Soc.*, Vol. 23, No. 5.)

When working with material so intractable as tungsten ores, whatever method of analysis is adopted, it is absolutely essential that the sample be finely agate-ground.

Having regard for some of the foregoing principles, the methods in practice are carried on about as follows:

Fusion Method.

From ½ to 1 gram of the sample is thoroughly fused in a platinum crucible with 4 or 5 grams of sodium carbonate. The melt is dissolved in hot water, a little sodium peroxide added, and the iron and manganese separated by filtration. The tungsten passes into the filtrate as sodium tungstate.

Acidify the filtrate slightly with nitric acid, make slightly alkaline with ammonia, boil and filter from the usually slight precipitate. To the filtrate add a few drops of methyl orange and titrate with nitric acid, contained in a burette, until just acid. Heat and add an excess of a clear solution of mercurous nitrate. Now add a few drops of a strong solution of sodium carbonate to precipitate a little mercurous carbonate. Remove from the heat and allow to settle for a few minutes. Filter on a 12-cm filter paper and wash well with hot water.

Without drying the precipitate further than can be done on the filter pump, transfer it with the filter to a platinum crucible. Char the paper at a low heat and finally ignite, in a good hood, over the flame of a Teclu burner. Cool the crucible, moisten the contents well with hydrofluoric acid, dry, reignite and weigh as tungstic oxide.

Aqua Regia Method.

Usually 1 gram of ore is used for analysis. If extremely high grade or a concentrate, ½ gram is sufficient, while for mill tailings, etc., 2 grams or more may be taken. For high-grade ores 50 cc aqua regia are used, for low grade 30 cc. The decompositions are made in 4-oz. covered beakers. The degree of heat should be such that there is a gentle action of the acid on the mineral, but the solution should not actually boil. The assay should be occasionally well stirred up to prevent caking. When the solution has evaporated to 10 cc or 15 cc it is removed from the hot plate and diluted with 50 cc hot water and allowed to stand for half an hour. Decant the clear solution through a good filter paper. The residue settles readily and can be decanted close. Wash the residue twice more by decantation, using each time 50 cc hot water, which has been acidulated with hydrochloric acid, keeping as much of the residue in the beaker as possible.

Add about 20 cc ammonia solution to the beaker to dissolve

the tungstic acid and decant the solution through the filter. The ammonia wash solution is made by mixing 200 cc strong ammonia with 1000 cc distilled water and adding 10 cc hydrochloric acid to form a little ammonium chloride. The residue of silica is now brought on the filter and washed thoroughly with the ammonia solution, which is most conveniently used in a wash bottle.

The resulting silica should be white; if it shows any particles of undecomposed mineral, as may sometimes occur in the high-grade ores, from the protecting action of the separated tungstic acid, instead of bringing on the filter, wash two or three times by decantation and treat again with aqua regia, using 15 cc or 20 cc, which will generally complete the work in a short time. One trial is all that is usually necessary with the ordinary run of ores.

The ammoniacal solution is now evaporated to dryness in a weighed platinum dish, ignited gently at first to drive off ammonium salts and finally at the full power of the burner. Cool, moisten with hydrofluoric acid and again evaporate to dryness and ignite. Weigh as tungstic acid.

The aqua regia method is the one used in the writer's laboratory for the valuation of ores from the Boulder district and has been found to work well on any of our western ores. Two time-saving devices are used to facilitate the work, a McKenna mechanical agate grinder, which is a most efficient machine, and a special air bath for evaporating the ammoniacal solutions, constructed so that each dish has its own receptacle. Each receptacle is heated from beneath with a small Bunsen burner and overhead is furnished with a glass tube through which a current of air is made to impinge on the surface of the liquid. When removing a dish the tube may be turned to one side out of the way.

The time that this arrangement saves by hastening the evaporation is very material, and insomuch as the evaporation can be started while the washing is still in progress, this part of the operation is really very short. The air is furnished from the blast arrangement of a Richard's filter pump.

Tungsten ores are paid for by the unit of tungstic acid, consequently the weight derived from the assay gives at once the figure without calculation further than reduction to percentage. If metallic tungsten is wanted the factor is 0.7931.

A simple qualitative test can be made by boiling a little of the finely ground mineral with 10 cc strong sulphuric acid in a test tube. When cold the liquid assumes a deep blue color. The addition of tin or other reducing agent is needless.

The papers cited in these notes will be found of value to any one interested in tungsten analysis.

Boulder, Colo.

Progress in Mexican Metallurgy During the Century of Independence.*

By A. Grothe.

On reaching the patio we find a scene vastly different from that of the morning. A large cavalcade has arrived and the dismounted riders are busy examining the numbered ore heaps. It is the day appointed for the ore sale or "rescate" and the visitors are the owners or managers of the many reduction works in the valley near town, all intent upon purchasing ore for their "haciendas." Notebook in hand they proceed from heap to heap, judging the weight by the eye and the contents by panning in a small lacquered gourd (jicara). They are wonderfully expert at the operation (tentadura) when dealing with ore of which they have experience.

The art of assaying is hardly practised as yet (any more than that of mine surveying) and in consequence grievous mistakes occur occasionally; as, for instance, when some years later ore was found in abandoned workings in the upper levels of Valenciana which had the look of compact iron pyrites and gave no indication of silver in the tentadura. Nevertheless it was found by fire assay to contain from 22 to 24 marcos of silver per "montón" (3.5 to 4 kg per ton). Still these mistakes are the exception, and ordinarily the estimate of weight and contents is astonishingly correct.

When all are ready with their calculations the manager of the mine (administrador) takes his position near one of the heaps and invites bids for this number. The competing buyers approach him one by one and make their bids in whispers. The proprietor of the mine or his representative do the same as a protection against possible collusion among the rescatadores. When after the auctioneer's solemn: "No hay quien diga más?" no further offer is forthcoming, the name of the highest bidder and the price to be paid are announced, and the group moves on to the next montón until all are sold. In this manner thousands of dollars worth of ore are sold every week. Losses are made, and great bargains secured, and it seems that this gambling nature of the method makes it so attractive to those interested that it has survived in Guanajuato to until the end of the last century, when the San Cayetano Company still sold the production of its mines in this manner. And, crude as the system was, perhaps no great injustice resulted to either buyer or seller.

The writer had the ore offered for sale by those mines in 1888 carefully weighed and assayed and found that at the end of the year the computation of the value on this correct basis differed only 2 per cent from the price realized, the latter being the higher. He thereupon published his figures on the day before the rescate and sold the ore on the basis thereof. This put an end to the picturesque but risky proceeding of former times.

At the conclusion of the rescate the mules which have to convey the ore to the reduction works swarm in, and the arrieros proceed to load the ore in leather sacks, while their masters sit down to a sumptuous lunch, after which the tables are cleared for a friendly game of cards, which is often prolonged far into the night, in the course of which many of the purchased heaps of ore change hands.

Not being possessed of the gambling spirit, we shall rather follow the ore to the reduction works.

At the hacienda it is weighed, without, however, a determination of the moisture being made. This and other inaccuracies make the returns as to results obtained not quite so trustworthy as might be desirable. The coarse ore (grueso) is then crushed to pea size in crude wooden stamps or equally primitive roller mills with stone runners, and, after being mixed with the smalls, is fed to arrastres, where it is ground to impalpable slime under addition of water.

The arrastre is a circular stone tub of about 9 ft. diameter half sunk below the floor and provided with a bottom of hard basalt or porphyry, the stones being placed on end. The grinding stones are large pieces of the same material suspended by chains from cross-bars fixed to a vertical shaft, to which a mule imports a rotary motion. Eighty or more arrastres are placed in a row in a large shed or galera. The bottom of the arrastre is covered with a thin layer of silver or copper amalgam to which the fine particles of metallic silver and gold contained in the ore adhere.

Every morning the arrastres are emptied of the ground pulp, which goes to the "patio" for further treatment. The capacity of an arrastre is from 7 to 8 cargas (1100 to 1300 kg) per day, according to the degree of softness of the ore. Every two to three months a "raspa" is made; that is, the amalgam is removed from the bottom and joints. The scrapings are thinned

*In the days of rapid progress in the twentieth century it is difficult to recall or imagine some of the conditions which existed a century ago, or the crude methods then employed for the valuation and treatment of ore. At a recent meeting of the *Concurso Cientifico y Artistico del Centenario*, held in Mexico on Feb. 25, 1911, Mr. Albert Grothe represented the Mexican Institute of Mining and Metallurgy, and read a paper showing the progress of metallurgy in Mexico during the past century. In a delightfully interesting manner he contrasts the conditions existing at the Mellado and Rayas mine at Guanajuato in the year 1809 with those of the present day. His full address, of which the following is an abstract, appears in the *Bulletin* of the Mexican Institute of Mining and Metallurgy, Vol. 2, No. 2.

out with mercury, filtered and the remaining mercury distilled off in vertical iron retorts or "capellinas." The resulting bullion, which is very rich in gold, is then melted in charcoal furnaces, cast into bars and taken to the mint, where it is assayed and parted—that is, the two metals are separated, and obtained in an almost pure state. By this process about one-half of the gold contained in the ore is recovered, the other half remaining in the pulp is lost, as we shall see.

The pulp is collected in flat heaps, called "tortas," each containing about 100 tons of ore, on the flagged floor of an open yard, called the "patio," from which the name of the whole process is derived. It was invented by Bartolomé de Medina and first practised by him in Pachuca in 1557. It was admirably adapted to the available resources and the requirements of the country, and, crude as it may appear to the modern metallurgist, has been of incalculable benefit to the mining industry.

The proper proportion of common salt is then added to the torta and thoroughly mixed with the pulp (repaso) by the action of twenty-four horses held on lines by the "tortero," round whom they circle, while he himself continually changes his position so that all parts of the torta are eventually reached. Before 1793 this work was done by hand.

The next operation consists in the admixture of "magistral," an impure sulphate of copper obtained by the calcination of copper pyrites containing variable quantities of iron. Lastly the torta is incorporated—that is, mercury is spread over its surface in a fine spray produced by filtration through porous cloth. After each addition of ingredients, and afterwards every other day, a repaso is given.

In from twenty to thirty days, according to the size of the torta and the weather, the chemical action is complete and the torta is said to be "rendida." The silver and gold have combined with the mercury to fluid amalgam, from which the pulp is washed by a liberal addition of water and stirring in large cylindrical vats. It is now only necessary to filter the excess of mercury off the solid amalgam, distill the latter in the manner described before the gold amalgam, and melt.

The product is very pure. Its fineness is determined in the mint and expressed in thousands of the gross weight. Impurities are deducted and it should be noted that if gold is present in less proportion than three-one-thousandths it is not only not paid for, but even deducted from the silver as an impurity. Small wonder that Mexican pesos of this period from the gold-bearing districts are subjected, at a good profit, to parting in London and Paris.

The patio process is a purely empirical one and requires great practice on the part of those who carry it out. It would lead us too far were we to attempt a detailed description of all the operations in connection with it, or to mention the various vicissitudes to which a torta may become subject, and the means for diagnosing and correcting them. The only guide for the "azoguero" is that afforded by frequent tentaduras.[1]

From time to time improvements, based upon chance discoveries, have been introduced and local modifications demanded by peculiarities of the ore have been made, but the history of the process is free from the often absurd nostrums frequently used during the earlier times of Californian panamalgamation. Altogether Medina's discovery was an admirable one and much more perfect than the mining methods in use at the beginning of the nineteenth century, which have been described above, for no other process until the advent of cyaniding has been able to oust it.

We have tried to produce an impressionist picture in broad traits of the methods employed in Mexican mining and metallurgy at the beginning of the century, in the years immediately preceding the outbreak of the revolution which ultimately liberated the country from the oppression under which it had been ground for more than two centuries and a half. It was the most productive period of Mexican mining, with which the general prosperity of the whole country had naturally kept pace.

Another discovery which gave an immense impulse to Mexican mining was the method of extraction of the precious metals from their ores by means of weak solutions of potassium cyanide. There has been much controversy over the question as to who was the real discoverer of the principle underlying this operation. We shall not enter into it here. Uncontrovertible, however, is the fact that since the introduction of the process by the McArthur-Forrest interests millions of tons of ore which formerly had to be considered as of no value can be treated profitably, in consequence of which the economic conditions of the mining industry have been radically changed and much foreign capital has been attracted.

Mexico was somewhat slow in adopting this method, possibly on account of the fact that as at first practised it was more applicable to gold than to silver ores.[2]

In our description of the process we can be much more concise than we were in that of the earlier methods, if for no other reason than that Rayas in 1808 is immeasurably farther from us than, for instance, Pachuca in 1911. Any of the modern reduction works there can be readily visited by those desiring some knowledge of this newest branch of metallurgy of the precious metals. Such a visit will afford convincing evidence of the great importance of this method of ore treatment and will show that, while Mexico entered the field long after other countries, once the start was made it has not only kept pace with them, but, certainly as regards the treatment of silver ores, is ahead of most.

Briefly, the process is carried out as follows: As in any other wet method of extraction, the ore is finely triturated in stamps, Chilean mills and tube mills, cyanide solutions being added from the beginning. The separation of sands from slimes, which a few years ago was considered indispensable to successful cyanide practice, has been superseded in all modern plants of this country by the "all-sliming" method, in which the sand is all ground as fine as possible, or, rather, as fine as necessary to obtain the best economic results.

The pulp, consisting of finely ground ore and cyanide solution, is then agitated by means of mechanical stirrers or by compressed air, the latter now being the rule in Pachuca When the cyanide has completed its chemical action on the gold and silver of the ore, these substances are found in solution as double salts with sodium cyanides. This solution must now be separated from the worthless tailings by means of vacuum or of pressure filters of various construction, of which new forms are almost daily brought out. The clear, filtered solutions are then brought into contact with zinc shavings or zinc dust, on which the precious metals are precipitated at the expense of the zinc.

The solutions, after having been brought to their original strength by the addition of fresh sodium cyanide, enter again into circulation by being returned to the grinding apparatus. The black precipitate obtained by the operation, consisting chiefly of gold, silver, finely divided zinc, lime, alumina and other impurities, is then washed in filter presses, dried, melted with suitable fluxes, and finally cast into bars of about 30 kg, which are exported. The product is not of the same purity as that from the patio process, rarely being above 950 fine, but, on the other hand, the extraction is above 90 per cent of the silver and 98 per cent of the gold, and the process requires only as many days as formerly weeks, and the cost is less than one-fourth.

A description of the mechanical details of the appliances used in the cyanide process would fill volumes and not be pertinent

[1] The old system of tentaduras as a guide in the patio process was gradually replaced by assays of the amalgam, proposed in 1875 or 1876 by Manuel Maria Contreras, M. E. The art of making correct tentaduras has well-nigh been lost among the younger generation of engineers.

[2] In 1894 the McArthur-Forrest Company installed a movable plant for the treatment of tailings in the State of Sonora which they shifted from one point to another. This was followed by stationary plants in Guanajuato, El Oro, Pachuca and other mining centers. In Pachuca the new plants followed each other rapidly. The last mill which has been reformed is that of Purisima Grande, where centuries ago the system of Bartolomé de Medina had originated and where it was practised until very recently.

to the purpose of this paper, which is to draw attention to the great and beneficent change in methods since the time when Mexico obtained its independence, especially during the last thirty years, when continued peace made it possible to devote all the available energy to the development of the industry.

It must be noted that since the introduction of cyaniding all efforts have been directed toward improvements on mechanical lines, in which certainly wonderful progress has been made. Our knowledge of its chemistry has, however, not advanced at the same rate and is still very much as it was when McArthur-Forrest first advocated and practised the principle involved, with the important exception, however, that it was found that in the treatment of silver ores the extremely weak solutions used on gold have hardly any effect, but have to be considerably strengthened, a fact which was not known at that time. Before this was known successful treatment of silver ores by cyanide was considered impracticable.

Various other chemicals in combination with cyanide have been proposed and tried, as they were supposed to accelerate or intensify the action, but the largest number of them have no effect or are only of use with certain classes of ore. Mention should, however, be made of Clancy's proposal to add to the straight cyanide solution calcium cyanamide, an alkaline sulphocyanide and an alkaline iodide, and passing a low-voltage current through the agitated pulp. The process has not as yet been fully tried on our Mexican ores, refractory on account of containing part of the silver in combination with manganese.

If successful on these, many ores not amenable to straight cyanide treatment could be profitably worked in this manner. According to the experiments of the inventor even in ordinary ores a saving of cyanide is obtained as the solutions are regenerated at the expense of a less costly substance and a trifling expenditure of electrical power. If the claims made for this process are substantiated by results on a working scale, new prospects for the industry will doubtless be opened.

We approach the end of our task, which was to indicate in broad lines the difference between the methods in use at the beginning of the century of independence and those now practised. Some of the manifest faults of our sketch are due to the disproportion between the space at our disposal and the great mass of material which imperatively seemed to demand consideration. This caused a constant conflict between the desire for completeness and the necessity for brevity, which perforce made the work fragmentary. We have dwelt more minutely on the early part of the period under consideration than on more recent occurrences. The knowledge of these early times is rapidly being obliterated; in none of the splendid and valuable treatises on old Mexican mining history is it presented in a connected form, being generally overlaid by a wealth of statistics and detail, which to the non-technical reader is not calculated to increase clearness.

We are safe in concluding with the statement that, especially during the period of peace and security of the last thirty years, the progress has been enormous and in expressing the hope and conviction that under a continuance of these conditions the industry will gain in importance at the rate justified by the large mineral wealth of the country.

Asbestos of Commerce.

The asbestos of commerce includes fibrous minerals of several species, but all may be included under amphibole and serpentine. Fibrous amphibole is properly called asbestos, fibrous serpentine is chrysotile, and the especially fine silky form of both amphibole and serpentine is known as amianthus, but in the trade all are included under the general term asbestos. Like auriferous quartz and the ores of other precious metals, asbestos generally forms veins, but in some places where it is of low grade it makes up the whole mass of the country rock. The three types of asbestos, cross, slip and mass fiber, are distinguished by the form of aggregation.

Treatment of the Anode Sludge in Electrolytic Refineries.

From lecture notes prepared for the School of Mines, Columbia University, by Edward F. Kern, Ph.D.

Anode sludge is the residue of the anode, formed during the electrolytic refining of metals. It consists mainly of the associated impurities which stand lower in the E.M.F. series than the metal which is being refined.

Analyses of copper anode sludge vary between:

15.0 to 55.0% Cu (as Cu: Cu_2S: $CuSO_4$: Cu_2Se: Cu_2Te: etc.)
2.0 to 8% Sb (as Sb_2O_3: $(SbO)_2SO_4$: $Cu_2O.Sb_2O_6$: etc.)
1.5 to 6.0% As (as $As_2O_3.H_2O$: $Cu_2O.As_2O_6$: etc.)
0.2 to 8.0% Bi (as Bi_2O_3: $(BiO)_2SO_4$).
0.5 to 6.0% Pb (as $PbSO_4$).
0.5 to 12.0% S (as Cu_2S).
0.5 to 1.5% Fe (as $FeO.FeSO_4$).
0.1 to 2.5% Se (as Ag_2Se: Cu_2Se).
0.1 to 3.5% Te (as Ag_2Te: Cu_2Te).
5.0 to 50.0% Ag (as Ag: Ag_2Se: Ag_2Te).—1,500 to 15,000 oz/T.)
0.017 to 0.70% Au (as Au) = (5 to 10 oz/T).

Typical analyses of sludge from Montana copper:

40.% Ag (12,000 oz/T): 2.% Au (600 oz/T): 25% Cu:
5.% Se & Te: 10% As + Sb: 18% $PbSO_4$, S etc.

Analyses of lead anode sludge vary between:

6. to 18% Pb (as Pb, PbSe, PbTe, oxide).
5. to 25% Cu (as Cu, Cu_2Se, Cu_2Te, oxide)
5. to 70% Sb (as Sb or Sb_2O_3).
2. to 50% As (as As or As_2O_3).
0. to 20% Bi (as Bi or Bi_2O_3).
0. to 2% Sn (as Sn or SnO_2).

} The OXIDES formed during drying of the SLUDGE.

0. to 3% Se (as Cu_2Se, Ag_2Se, etc.).
0. to 4% Te (as Cu_2Te, Ag_2Te, etc.).
10. to 40.% Ag (as Ag, Ag_2Se, Ag_2Te, etc.) = (300 to 12,000 oz/T).
0. to 1% Au (as Au) = (0 to 300 oz/T).

Typical analyses of sludge from trail, B.C., lead:

32% Ag (9,600 oz/T): 0.3% Au (90 oz/T): 9.0% Cu:
27% Sb: 7.% As: 14.% Pb: 11.% moisture, O., etc., and
19.% Ag (5,700 oz/T): 0.1% Au (30 oz/T): 11.% Cu:
31.% Sb: 9.% As: 16.% Pb: 14.% moisture, O. etc.

A characteristic of lead anode sludge is that the constituents are present principally as metals or oxides, whereas the constituents of copper anode sludge are present principally as basic sulphates, sulphates and oxides.

A reason that basic sulphates are the predominant constituents of copper anode sludge is that the principal impurities (Pb, Sb and Bi) of crude copper stand above copper in the E.M.F. series, so are dissolved along with copper, but forming stable sulphates and basic sulphates they are precipitated and collect in the sludge as such.

The impurities of base bullion (crude lead) stand below lead in the E.M.F. series, they, therefore, are not attacked, but remain as metals, forming the sludge. The oxides form during drying.

Preparing Anode Sludge for Treatment.

The sludge, on being received at the "silver house," is first poured through a copper screen (about 10-20 mesh) in order to remove any nodules, or crystals, of metal. The screenings are washed and returned to the refinery, and melted down with the next lot of metal to be cast into anodes.

In case the material is copper anode sludge, after it is screened, it is poured upon a filter of muslin and filtered by suction or put through a filter-press to remove excess of electrolyte, which is returned to the refinery. The filtered sludge is washed with water, well drained, placed in sheet steel pans and dried in an oven. When dry, it is sampled and the sample sent to the assay office. The dry sludge is then treated for metal content by one of the following methods.

If the material is lead anode sludge, after it is screened, it is well washed with hot water by decantation, then filtered by suction on a muslin filter. The solution and wash water is evaporated in copper pans to about 1.15 Sp.Gr. and returned to the refinery. The washed sludge is placed in pans and dried and partially oxidized in an oven, and finally treated by one of the following methods.

Treatments.

A. Direct Cupellation: (Method followed when copper refinery is run in connection with the Parkes' or Pattinson's desilverizing plant). Used for treatment of copper anode sludge: The dry sludge placed in heavy paper bags holding 10 to 15 lb. and charged on the molten metal in a cupelling furnace. The Cu, Pb and Bi are oxidized and collect with the litharge on the surface of the metal as scoria, which is skimmed off and sent to smelting furnace, where added along with regular furnace charge. The As, Sb, S, Se & Te are oxidized and volatilized, and partially enter the scoria. Difficult to remove all of the Se & Te from the resulting Doré bullion.

The Doré bullion, assaying 900+ fine, is cast into suitable slabs, and parted either with boiling concentrated H_2SO_4, or else by electrolysis.

B. Fusion Methods.—For treatment of copper and lead anode sludge: The washed and dried sludge is mixed with a flux of soda ash (crude Na_2CO_3) and small amount of KNO_3 and smelted in a basic lined (magnesite) reverberatory furnace, producing a slag which contains the Sb, As, Se, Te, S and most of the Cu and Bi. The slag is sent to the ore smelting furnace and added along with regular charge. The bullion remaining on the hearth is cupelled to Doré bullion (alloy of Ag, Au, Cu, etc.), and the resulting scoria of Bi_2O_3, PbO, Cu_2O, etc., is skimmed and sent to the smelting furnace. The Doré, assaying 900 to 975 fine, is cast into suitable plates and parted either with hot conc. H_2SO_4 or by electrolysis.

C. Fractional Scorification in Basic Lined Reverberatory Furnaces.—For sludge which contains small amount of copper, such as electrolytic lead refining sludge. The sludge, after washing and drying, is scorified (oxidizing atmosphere above melting point) in the "antimony slagging" furnace till the arsenic and antimony are mostly removed. The scoria is skimmed and subsequently treated in another furnace for the production of hard-lead. The metal is withdrawn from the scorifying furnace and placed in a second basic lined furnace and rescorified for the removal of the bismuth as Bi_2O_3. When most of the bismuth is scorified, the scoria is completely skimmed and subsequently treated for the bismuth by chemical leaching methods. The metal remaining in the furnace is withdrawn and finally rescorified in a third basic lined furnace to remove the remaining lead and most of the copper, leaving Doré bullion. The lead-copper oxide scoria is smelted along with the regular charges in a lead blast furnace, recovering the copper as matte and the lead as base bullion. The Doré bullion is cast into thin plates, and parted, either with concentrated H_2SO_4 or electrolytically.

When high grade bullion is treated by either of the above methods, precautions must be taken to *collect the flue dust.* This is done by passing the gases through sheet-steel flues 100 to 350 ft. long, then through a series of dust chambers and finally catching the finely suspended particles by filtering the gases through long flannel bags, suction draft being used, or else passing into spray-towers, or under water.

The flue-dust from these furnaces is returned to the smelting furnaces, or else treated the same as sludge. If much As_2O_3 present in the flue dust, it is recovered by subliming twice in a muffle furnace or in a reverberatory furnace using coke fuel. The residue is mixed with next treatment of sludge.

In some plants, where the treatment is carried out by either A. or C., the scoria removed during the latter part of the treatment runs high in silver, so is kept separate from that which is produced during the first part of the operation. The first scorias, in this case, are sent to the smelting furnace, and that which runs high in silver is added along with the next charge of sludge to the furnace, and its silver content collected.

D. Direct Parting with Boiling Conc. H_2SO_4.—Not used at present, as much acid is lost due to formation of SO_2. (Not suitable for sludge containing much As or Sb).

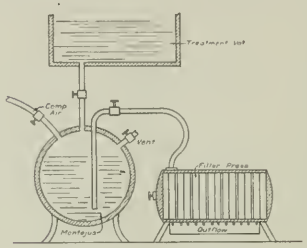
$Cu + 2H_2SO_4 = CuSO_4 + SO_2 + 2H_2O.$

$Ag_2 + 2H_2SO_4 = Ag_2SO_4 + SO_2 + 2H_2O.$

$M + 2H_2SO_4 = MSO_4 + SO_2 + 2H_2O.$

This treatment is similar to the parting of Doré bullion with boiling conc. H_2SO_4 in iron kettles.

E. Mix the washed and dried sludge with a calculated amount of conc. sulphuric acid (sufficient to dissolve the copper, antimony, etc., but not enough to dissolve the silver), forming a thick mud. It is then heated in iron kettles till SO_2 is expelled, and silver begins to dissolve. A small amount of fresh sludge is added to precipitate the silver, then the residue is leached with water to remove the sulphates. The solution is treated by the usual method of crystallization, or by passing over iron, for recovery of the metals. The residue after leaching is scorified to Doré bullion, which is finally parted. The scoria is smelted in a lead smelting furnace along with regular charge.



FILTER PRESS AND MONTEJUS.

The cement metal, formed by precipitation of the sulphate solutions with iron, is smelted for its metal content.

F. Treatment with Hot Dil. H_2SO_4, Air and KNO_3.—The washed sludge is placed in a lead lined vat containing dilute H_2SO_4 (1 acid : 2 + water), and heated to boiling, and agitated by means of injected steam and air, and hard-lead stirrers. A small amount of KNO_3 (saltpeter) is added at intervals in order to assist in the oxidation and more rapid solution of the copper, etc. This treatment lasts from 20 to 30 hours, during which time most all the copper and some Ag is dissolved, and Bi and Sb changed to basic sulphates, and Pb to $PbSO_4$. The Ag in solution is precipitated by suspending strips of copper in the tank at the end of treatment, and collecting it with the residue of Au, Ag, $PbSO_4$, BiO_2, SO_4, $Sb_2O_3SO_4$, etc., or else by adding a small amount of fresh sludge.

The Cabell Whitehead process is a modification of the above treatment, using Ag_2SO_4 residues from the parting kettles in place of KNO_3 to get the Cu, Bi, etc., in solution. Process formerly used at plants where the Doré was parted with boiling conc H_2SO_4.

Reaction.—$Cu + Ag_2SO_4 = CuSO_4 + 2Ag.$

$2Bi + 3Ag_2SO_4 = Bi_2(SO_4)_3 + 6Ag.$

$M + Ag_2SO_4 = MSO_4 + 2Ag.$

In case of Bi and Sb, their sulphates are decomposed, forming insoluble basic sulphates ($Bi_2O_3 . SO_4$ and $Sb_2O_3 . SO_4$).

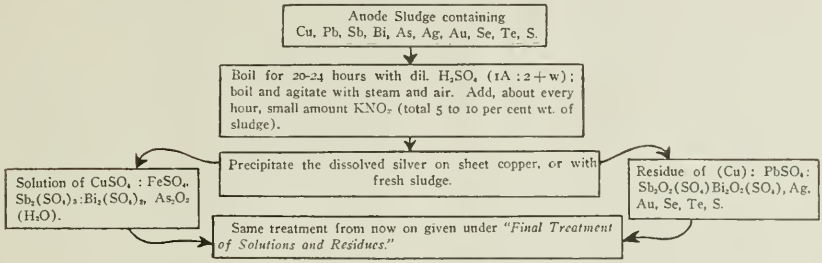
The use of the Ag_2SO_4 residue from the H_2SO_4 parting kettle reduces the time of treatment six to eight hours. These residues consist principally of anhydrous Ag_2SO_4 and $CuSO_4$, which form on the side of the kettle during the parting of Doré bullion.

The vats in which the treatments are carried out are made of heavy pine boards lined with sheet lead. Dilute H_2SO_4 solutions do not dissolve metallic lead after it is coated with a thin layer of $PbSO_4$.

The vats used for evaporating or for boiling *dilute sulphuric acid* solutions are made of hard sheet lead (containing 4 to 6 per cent Sb), the heating being done by means of hard lead coils through which steam is passing.

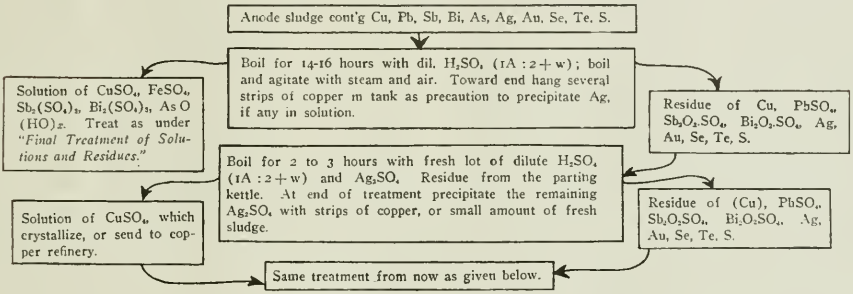
Tree of Treatment of Anode Sludge with Dilute H_2SO_4 (F).

1. *Use of KNO_3 as Oxidizing Agent.—*



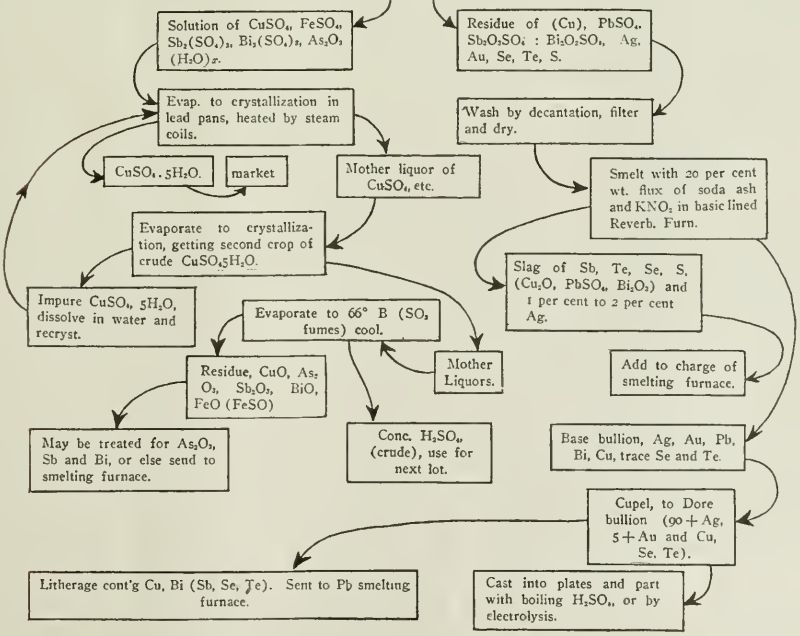
Anode Sludge containing Cu, Pb, Sb, Bi, As, Ag, Au, Se, Te, S.
Boil for 20-24 hours with dil. H_2SO_4 (1A : 2 + w); boil and agitate with steam and air. Add, about every hour, small amount KNO_3 (total 5 to 10 per cent wt. of sludge).
Precipitate the dissolved silver on sheet copper, or with fresh sludge.
Solution of $CuSO_4$: $FeSO_4$, $Sb_2(SO_4)_3$: $Bi_2(SO_4)_3$, As_2O_3 (H_2O).
Residue of (Cu): $PbSO_4$: $Sb_2O_2(SO_4)$ $Bi_2O_2(SO_4)$, Ag, Au, Se, Te, S.
Same treatment from now on given under "Final Treatment of Solutions and Residues."

2. *Cobell Whitehead Process—Use of Ag_2SO_4 as Oxidizing Reagent.* (F).



Anode sludge cont'g Cu, Pb, Sb, Bi, As, Ag, Au, Se, Te, S.
Boil for 14-16 hours with dil. H_2SO_4 (1A : 2 + w); boil and agitate with steam and air. Toward end hang several strips of copper in tank as precaution to precipitate Ag, if any in solution.
Solution of $CuSO_4$, $FeSO_4$, $Sb_2(SO_4)_3$, $Bi_2(SO_4)_3$, As O (HO)$_x$. Treat as under "Final Treatment of Solutions and Residues."
Residue of Cu, $PbSO_4$, $Sb_2O_2SO_4$, $Bi_2O_2SO_4$, Ag, Au, Se, Te, S.
Boil for 2 to 3 hours with fresh lot of dilute H_2SO_4 (1A : 2 + w) and Ag_2SO_4. Residue from the parting kettle. At end of treatment precipitate the remaining Ag_2SO_4 with strips of copper, or small amount of fresh sludge.
Solution of $CuSO_4$, which crystallize, or send to copper refinery.
Residue of (Cu), $PbSO_4$, $Sb_2O_2SO_4$, $Bi_2O_2SO_4$, Ag, Au, Se, Te, S.
Same treatment from now as given below.

Final Treatment of Solutions and Residues.



Solution of $CuSO_4$, $FeSO_4$, $Sb_2(SO_4)_3$, $Bi_2(SO_4)_3$, As_2O_3 (H_2O)$_x$.
Residue of (Cu), $PbSO_4$, $Sb_2O_2SO_4$: $Bi_2O_2SO_4$, Ag, Au, Se, Te, S.
Evap. to crystallization in lead pans, heated by steam coils.
Wash by decantation, filter and dry.
$CuSO_4.5H_2O$.
market
Mother liquor of $CuSO_4$, etc.
Smelt with 20 per cent wt. flux of soda ash and KNO_3 in basic lined Reverb. Furn.
Evaporate to crystallization, getting second crop of crude $CuSO_4.5H_2O$.
Slag of Sb, Te, Se, S, (Cu_2O, $PbSO_4$, Bi_2O_3) and 1 per cent to 2 per cent Ag.
Impure $CuSO_4.5H_2O$, dissolve in water and recryst.
Evaporate to 66° B (SO_3 fumes) cool.
Mother Liquors.
Add to charge of smelting furnace.
Residue, CuO, As_2O_3, Sb_2O_3, BiO, FeO (FeSO)
May be treated for As_2O_3, Sb and Bi, or else send to smelting furnace.
Conc. H_2SO_4, (crude), use for next lot.
Base bullion, Ag, Au, Pb, Bi, Cu, trace Se and Te.
Cupel, to Dore bullion (90 + Ag, 5 + Au and Cu, Se, Te).
Litherage cont'g Cu, Bi (Sb, Se, Te). Sent to Pb smelting furnace.
Cast into plates and part with boiling H_2SO_4, or by electrolysis.

The boiling of *concentrated sulphuric acid* is done in cast iron or cast steel pans, heated by flame underneath.

The *filter presses* used for filtering sulphuric acid, or sulphate solutions, are made of hard lead (containing 8 per cent Sb), the filtering medium being closely woven cloth. The solutions are forced through the filters by either pumps or montejus, which are made of iron lined with hard lead. A montejus is an air-tight siphon vessel, used for lifting liquids by means of compressed air. The solutions are run into the montejus by gravity and afterward forced out through a pipe extending to the bottom, the supply pipe being closed. This apparatus is more suitable than a pump, as it has no working parts which are exposed to the acid solutions.

The *crystallizing vats* for $CuSO_4 . 5H_2O$ are made of wood and lined with lead. Strips of lead are suspended in the vat and form the nucleus for the crystals of $CuSO_4 . 5H_2O$. The hot saturated solutions are run into the vat and allowed to cool, giving a crop of crystals, which, if pure, are collected, washed, dried and stored. If the crystals are impure they are dissolved and recrystallized. The final mother liquors are passed over scrap iron to recover their copper content and the solutions run to waste. The cement copper is added to the copper furnace.

The *scorifying furnaces,* in which the acid-treated sludge is brought to Doré bullion, have hearths 5.5 to 5 ft. wide and 6 to 8 ft. long, capacity of 60,000 to 150,000 Troy ounces of Doré per charge. The hearths are made of either magnesite or chromite bricks, which are not corroded by the scoria. The furnaces are usually fired by oil and blast. Ordinarily two charges of Doré bullion are completed and cast per week.

A comparatively cheap, but still very satisfactory, material for making hearths of scorifying and cupelling furnaces is made of dolomite concrete, which is prepared by mixing about four parts of crushed dolomite and one part Portland cement. This is thoroughly mixed with sufficient water to give a good "setting" mass, then tamped into place, allowed to "set," and thoroughly dried by a fire of gradually increasing intensity.

The workmen, before they are allowed to leave the "silver house," are required to change their clothes and wash. The waste wash water from the sinks is run into settling tanks where the slimes collect. The slime is removed from the settling tank at stated intervals and is treated along with the anode sludge. The old cloths are burnt, and the ash treated as sludge.

Notes on Chemistry and Metallurgy in Great Britain.

(Continuation, from our last issue, of the report of the Iron and Steel Institute.)

Mr. J. E. Stead's paper on "Notes on the Welding-Up of Blowholes and Cavities in Steel Ingots" was next read.

Professor Arnold spoke of the remarkable effect of a small proportion of aluminium in preventing blowholes. For many years it had been an annual experiment at Sheffield University to cast two ingots of the same weight, one without aluminium and the other with 0.01 per cent of aluminium, and the latter was entirely free from blowholes.

Mr. S. H. Ridsdale said that hollowness in forgings was often caused by working at too low a temperature in order to save re-heating. He had seen blooms which showed splits in the forged ends and middle, but were proved, by polishing and etching, to be quite sound in the unforged parts which, under proper conditions, yielded thoroughly sound forgings. He could not concur in Mr. Stead's statement that blowholes were least objectionable when well within the surface. Rails with a very solid exterior almost always had a spongy interior, while if the surface were spongy and shelly the inside was almost invariably sound.

Dr. W. Rosenhain remarked that the fact of a hole not reopening was not proof that it had been welded up. The time during which pressure was exerted on the steel was an important factor. There was an inward diffusion of air apart from pressure. He could not accept as proved the author's statement that a coating of iron oxide on the interior of a blowhole was a bar to welding, because he had evidence that where the skin of oxide could be broken through welding might occur.

Mr. W. H. Ellis referred to a case of an internal cavity in a large 30-ton fluid-compressed ingot. Apparently when the walls attained a certain thickness a cavity formed. He had forged down such an ingot, cut it into lengths and found that it welded satisfactorily. He believed that the reason was that the interior of the cavity was free from oxide.

A paper by Messrs. E. F. Law, W. H. Merett and W. Pollard Digby, "Some Studies of Welds," followed. Opening the discussion, Mr. A. E. Tucker said he was anxious that it should not go forth that defects such as were detailed in the paper were insuperable or even serious in practice. Gas welding had already been largely adopted with complete practical success. He produced a sample to illustrate what might be done by cutting steel with the oxy-hydrogen flame in discovering defects in the body of the metal which seemed undiscoverable in any other way. The two surfaces were very interesting. The first, cut with pure oxygen, was but little inferior to one obtained with a rough milling cutter, while the second, cut with a 96 per cent oxygen, was ragged and heavily oxidized.

Professor Turner said the microscope afforded an easy means of determining which process was best adapted for the production of a particular kind of welding. There were defective weldings by the acetylene process or by the resistance process, but that only meant that the operations were not properly carried out. He believed that those welds by modern processes when properly effected were perfectly satisfactory, as was shown by the tensile strength and working properties. At the same time the authors were doing a public service in drawing attention to certain possibilities of failure.

Sir Thomas Wrightson remarked that only certain metals could be welded. The melting of two metals together was not the same thing as welding. Many years ago he had made experiments at the Mint with Roberts-Austen which demonstrated that in the case of iron there was a distinct fall of temperature at the moment of solidification, when the pressure came on, and not an evolution of heat. He mentioned this as an explanation of the welding properties of certain metals.

Mr. H. Le Chatelier (Bessemer Medallist) said the inevitable defects of welds were all known and it would never be possible to entirely obviate them. The most pressing problem of the day was to find some means of ascertaining the quality of a weld without at the same time destroying it. Possibly the electric, magnetic or acoustic properties of the material might afford an index of even internal defects.

Dr. J. E. Stead quite agreed with the authors that it was possible to tell the method of welding by the microscope. His own experience had often confirmed the fact.

The following papers were discussed together: "The Action of Aqueous Solutions of Single and Mixed Electrolytes Upon Iron," by Dr. J. Newton Friend; "The Corrosion of Metals," by Mr. P. Longmuir, and "The Influence of Impurities on the Corrosion of Iron," by Mr. J. Cobb.

Professor Arnold remarked that one interesting point in Mr. Longmuir's paper was the mechanical deterioration of metals as a consequence of corrosion by sulphurous or sulphuric acids. This was a matter deserving attention.

Mr. E. H. Saniter fully appreciated the value of Mr. Longmuir's insistence on the importance of studying the effects of atmospheric corrosion as well as local corrosion set up by electrolytic action. He considered that in many cases laboratory tests on corrosion were quite misleading.

Prof. H. C. H. Carpenter read a paper on "The Growth of Cast Irons after Repeated Heatings." This was a continuation of his paper on the same subject last year.

Mr. J. E. Stead opened the discussion and said he had examined a stove pipe which had been heated for several years at a constant temperature of about 750° C., and the microscopical, physical and chemical results obtained led to the important conclusions which might modify some of Dr. Carpenter's tentative conclusions. Mr. Stead exhibited micrographs of the structure of the pipe before and after heating. Gas penetrated the metal very easily, but the pipe had not been heated above 750° C. and all the pearlite in the area of ferrite was globulized, while the central parts of the dark areas consisted of laminæ of graphite. When broken the cleavage was through the graphite, and, although about 25 per cent of slag was present, the fracture of the pipe was just the same as that of the original pig. He was of opinion that the shape of the sample was a factor in the longitudinal expansion. If the bars had been round different results would have ensued. Dr. Carpenter naturally assumed that silicon steel was more easily oxidized, but steel containing no silicon had been proved to oxidize to the greater extent.

Professor Arnold said that Dr. Carpenter classed as steel a material which was something between steel and pig iron. The material specified with 2.5 per cent of carbon was a special steel which commanded a high price in Sheffield. He suggested that the material Dr. Carpenter proposed to substitute was not cast iron, but a hard and probably brittle steel.

Mr. Saniter was not able to accept Table V. An expansion of 11 per cent in vacuo of one alloy could not be altogether attributed to dissolved gases.

Professor Turner highly appreciated Dr. Carpenter's work and congratulated him on being able to indicate the composition of an alloy which would not expand on heating. An alloy containing 2.66 per cent of carbon with 1.5 per cent of manganese should run quite well. He did not agree with Professor Arnold's remarks as to Sheffield steel, Professor Arnold called it steel, but he called it cast iron for the addition of a little phosphorus gave it almost exactly the composition of pig. The irons experimented on were very complex materials and could be heated to such temperatures as would cause absorption of the pearlite and diffusion and absorption of phosphorus. Some volume changes seemed to result from alteration in the silicon-iron-carbon compounds.

Mr. Edwards considered the author's explanation of growth the only one reconcilable with observed facts. Oxidation could not take place under those conditions. There might be alloys of various compositions evolving different gases, but growth might be due to the nature of the gas and not to its volume.

Mr. Adamson agreed in the author's view of the effect of manganese and phosphorus on growth. He had proved its correctness several years back with castings required to stand high temperatures in working. Dr. Carpenter was, doubtless, right in his contention as to the influence of sulphur under those conditions of test, but when sulphur in the form of acid was brought into contact with iron castings, such as gas retorts, a deposit resembling pyrites resulted, with destruction of the iron. Consequently the less sulphur such iron contained the longer was the working life of the casting. There has not yet been brought to light any proof that such destructive action of sulphur was connected with the growth of cast iron.

In the discussion on the paper by Professor A. McWilliam and E. J. Barnes, "The Influence of 0.2 per cent. Vanadium on Steels of Varying Carbon Content," Mr. J. Kent Smith said vanadium toughened steel by scavenging from it the suboxides and nitrides. The products were fusible and formed with the vanadium a solid solution in ferrite. The great strength of vanadium steel was due to the formation of complex carbides. With regard to cast iron he was able to confidently assert that the scavenging action followed on the use of vanadium. Notable advantages of vanadium cast-iron were high resistance to abrasion and freedom from porosity.

The Metallurgical Future of India.

The development of the natural resources of India and their resulting industries is, and must necessarily be, more a matter of judicious government encouragement than in countries where private enterprise is more in accordance with political conditions. The existence of various intricate systems of established rights renders interference with existing customs a process of grave importance, and one which cannot always be entrusted to a commercial body with more prospect of permanent success than can the public safety be handed over to the care of the half-educated amateur imported politician.

Previous to 1899 the complications caused by a fluctuating exchange made the extension of mining concessions impracticable, the financial return being too uncertain to form a steady inducement to private enterprise. The regulation of the coinage question which came into effect in that year, however, permitted the Indian government to take the matter up and frame regulations which offered more scope for private enterprise.

Some idea of local conditions, and the care which must be exercised in making alteration, however slight, in the usages of centuries, can be gathered from the comprehensive and instructive paper recently read before the Indian section of the Society of Arts by Prof. Sir Thomas H. Holland, formerly director of the Geological Survey of India. Amply qualified as he is to deal with the question from a scientific point of view, Sir Thomas is compelled by his subject to treat occasionally of the social or political aspect of the matter, as in the paragraph on relative safety of European and Indian mines. The superiority of the Bengal mines he attributes, in a great measure, to the fact that the Bengal collier retains, so far, a sense of discipline "that has now been all but destroyed by our education authorities in this country." Possibly a consequence of controlling instruction by those who are most in need of it.

While so many of the finest intelligences are thus engaged in directing the affairs of a portion of the empire which does not govern itself automatically, there is every hope that the mineral resources of the country will develop in conjunction with its other activities.

Taking the products in the order given them by Sir Thomas Holland, coal naturally leads in importance. We learn that during the past 25 years the production of coal has risen from 1¼ million to 12 million tons a year, and still increases, the best being that obtained from the Giridih field. This field is estimated to contain about 70 million tons. The author of the paper considers that a considerable impetus could be given to the industry in Central India by the construction of a broad gage railway extension from Nagpur to Itaisi, which would tap also a rich cotton-producing country, as well as the principal manganese mines.

The coal fields of Assam are at present worked principally for the local market, expense of transport cutting them off from Calcutta, as well as the quality of the coal, which is friable and liable to spontaneous combustion, and thus not easily carried for long distances.

The development of this industry depends very largely upon railway extension, both as providing a market and a means of transport. The available foreign markets, says this paper, are comparatively small, the principal consumption being due to locomotive wants. It seems possible, however, that a market for shipping might be cultivated where the quality of coal permits. At present, and since 1900, the exports of coal largely exceed the imports, which latter have been generally limited to small quantities to meet local and temporary variations in the demand for special coals. The exports have, on an average, been over half a million tons per annum.

With regard to petroleum the difficulties due to ancient customs for a considerable time hindered the development. When

these were overcome the output increased rapidly, rising during the past ten years from 37¾ million gallons to over 233½ million gallons (1909). Certain of the fields, however, show signs of exhaustion, the Twingon, in Upper Burma, for instance. On the other hand, three promising properties remain to be developed in Burma, the Khodaung, Singu and one on the other side of the Irrawaddy.

At present the indigenous production is insufficient to meet the country's requirements in kerosene and petrol, of which 90 million gallons are imported annually.

The production of iron is at present low in the peninsula, only one company operating with favorable results (the Bengal Iron & Steel Company), although another (the Tata Iron & Steel Company) has now been floated with a capital of £1,500,000 sterling to exploit the hematite ore deposits of the Mombhanj State in Orissa. The new works will be within forty-five miles of the principal ore supplies and 180 miles from the collieries. The ore in the Mombhanj is rich, carrying over 60 per cent of iron, and exceptionally easy to work, standing in hills above the general plain. In a period when rich ores were in demand they might thus be worth the attention of European furnaces.

Data of other fields do not seem available, although iron is known to exist, in small quantities at any rate, throughout the peninsula.

Turning to minerals raised chiefly or entirely for export the author finds that gold is only mined in Mysore and at Hutti in the Nizam's dominions. The principal opening for development appears to be on the upper reaches of the Irrawaddy, where dredging operations for alluvial gold have been carried on for the past nine years. The production in 1909 was valued at £32,730.

Manganese is a flourishing industry and appears capable of considerable and rapid expansion whenever the market provides the necessary encouragement, as shown by the output in 1907, which expanded from 571,500 tons to 902,291 under this stimulus. The falling off in steel manufacture and lower prices have since caused the output to drop to 600,000 tons.

In mica the country has a valuable product, which only needs control by organized limited liability companies to become of first-class importance. Even under present circumstances the production is equal to 61.78 per cent of the quantity produced by the three principal mica-bearing countries—India, Canada and the United States. The present methods of winning are hampered by the disadvantages consequent on divided effort and may be regarded as mere prospecting. Numerous deposits still lie untouched.

The further development of India in this connection may bring forward copper as a potential product. Copper ores are known to occur, and, in the past, have been considerably worked in the Nellore district of the Madras Presidency, in Rajputana, in Chota Nagpur, and at various places along the lower Himalayas from Kulu in the northwest to Sikkim and Bhutan in the east. Operations are now in progress by the Cape Copper Company to test the probable value of a copper-bearing country in Bengal. Prospecting operations are also in progress in the Darjeeling district and adjoining parts of the Sikkim State.

Lead, zinc and silver ores are known to exist and are being prospected on a considerable scale in upper Burma. Pitchblende and wolfram are also found, the latter in some quantity. Corundum is widely distributed in various forms, but it is possible that, in face of competition from natural and artificial abrasives in the countries of principal consumption, it would not pay at present to develop the Indian mineral for export to Europe and America.

The principal requisite for further development in the production of minerals in this country appears to be means of transport, a question which will have the consideration of those interested. The opening up of any particular field is almost invariably stimulated, in the first instance, by a brisk market. Unfortunately the period of high prices is very apt to terminate just as the preparations for opening up a new mine are ended, and it is in this connection that mercantile foresight becomes as valuable to the country as to the individual.

The continually urged objection to investment of political unrest the author does not consider grave. The results are temporarily sensational without having any widespread or permanent significance, like the political speeches of some home enthusiasts, while they serve to rouse to a stricter sense of duty those whose patriotism is not so case-hardened as to render them incapable of belief in sedition.

Recent Metallurgical and Chemical Patents.

Gold and Silver.

Silica Sponge Filters.—In two recent United States patents Mr. E. G. Spilsbury, of New York City, describes the use of a commercial product known as silica sponge for the purpose of filtering liquids or gases.

The treatment of gold and silver ore by the cyanide process involves methods of agitation and filtration which the inventor believes can be advantageously performed by the medium of a porous septum of mineral composition, such as silica sponge.

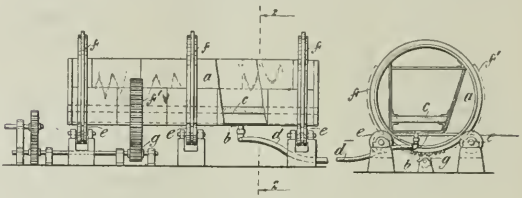


FIG. 1—SILICA SPONGE FILTER IN CYANIDE PROCESS.

As shown in Fig. 1, he proposes to place a septum of porous material *c* in a revolvable tank *a*, operated as shown in the figure. Beneath the septum is the bottom of the tank *b*, which is connected with a source of vacuum, compressed air and water by means of the flexible tube *d*.

The process of treating a charge of ore would be as follows: The ore having been crushed to the requisite degree of fineness and mixed with the cyanide solution would be charged into the tank *a*. For agitation of the pump compressed air would be admitted through the tube *d*, and when that operation was completed the air would be disconnected and vacuum applied through the same tube. This would draw off the pregnant solution from the ore, which could then be washed by water introduced through the tube *d* and filtered again as before. In this way the porous septum of silica sponge would act as a means of securing thorough agitation and aeration as well as filtration. When it is desired to discharge the filter cake the tank is rotated and the cake allowed to fall off by gravity, assisted by compressed air or water. (994,281, June 6, 1911.)

In applying the silica sponge to the filtration of gases, such as blast furnace gases from the smelting of lead and copper ores, the inventor proposes to use it much after the manner of using cotton and woolen bags in bag-houses. The mineral substance, however, will have the advantage that it will not be affected by the heat or acid nature of the fumes. The construction of a building for filtration of gases would be much the same as used in bag-houses, with a large chamber below and the filtering medium above, except that the bags would be replaced by a cell structure composed of a series of vertical cells alternately open and closed at the top, those cells which are closed at the top being open at the bottom, as shown in Fig. 2, which is a vertical section of the upper part of the filtering arrangement. The advantage of this arrangement is that the furnace gases will pass upward into those cells which are open at the bottom, filter through the porous walls of the

cell and escape to the air through the cells which are open at the top. When it is desired to clean the cells of the accumulated solid cake of fume, air can be forced in a reverse direction to the flow of furnace gas and cause the adhering cake to fall from the cell walls and down into the chamber beneath. This is an interesting modification of the present bag-house system and may have a bearing on the future operation of smelters in relation to agricultural interests which object to the discharge of noxious gases and fume. (994,282, June 6, 1911.)

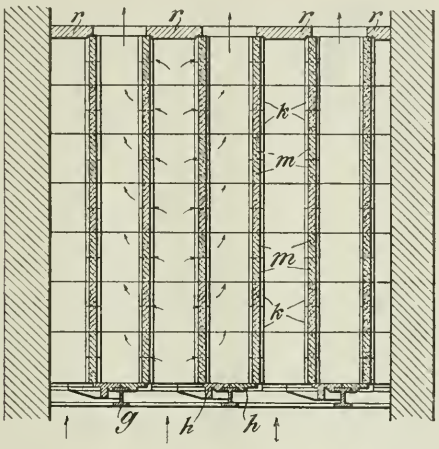

FIG. 2—FILTRATION OF GASES WITH SILICA SPONGE FILTER.

Rotary Filter.—A modification of the type of revolving filter commonly used in the United States has been patented by MR. ALEXANDER J. ARBUCKLE, of Johannesburg, Transvaal, South Africa. In the Oliver and Portland revolving filters used in this country the filtering medium is on the outside of the drum only, but in the Arbuckle filter it is proposed to make use of both the outside and inside surfaces of the drum for filtering purposes. The drum is divided into sections which, by means of a three-port valve located in the hub of the drum, are brought successively into connection with a vacuum for forming the cake, a wash and vacuum for removing the retained values and compressed air for discharging the cake. For this purpose three non-communicating spaces are provided in the hub, one for each process mentioned. Consequently, as the drum revolves in a tank of ore pulp, each section successively forms a cake on both its surfaces, which are later washed and discharged. (994,235, June 6, 1911.)

Air Lift Agitator.—In Fig. 3 is shown an improvement in air lift agitators for use in the cyanide process, patented by LEON P. HILLS of Tuolumne, Cal. The object of the invention is to provide means for bringing all the pulp in a tank into circulation, even after the ore may have settled and packed around the opening of the lift, and for securing a quiet overflow of clear solution in case of continuous treatment. The operation of the tank will be understood by reference to the figure, in which 33 is a launder and 34 a pipe for continuously introducing pulp and solution respectively. An air pipe 19 extends downward through the inner central tube, terminating in a U at the bottom. The central lift 12 is surrounded by a movable tube 20 which is operated by the hand wheel 25, this outer movable tube being shorter than the inner tube. A circular baffle 30 is placed in the upper part of the tank, as shown. The tank being full of a mixture to be agitated, the outer tube 20 is lowered into contact with the walls of the tank at the bottom, and air is admitted at the bottom of the inner tube. This will cause a circulation of the nearly clear solution, which will rise through the inner tube, spill over the apron 14 at the top and return through the annular space between inner and outer tubes, as shown at 29. When this circulation is thoroughly established the outer tube is raised gradually to admit the solid pulp at the bottom of the tank into the inner tube, and in this way the entire mass will ultimately come into circulation. The baffle 30 acts as a guide to prevent the pulp from flowing to the outer edge of the tank and directs it downward, thus preserving a quiet zone between the baffle and the wall of the tank where solution more or less free from pulp

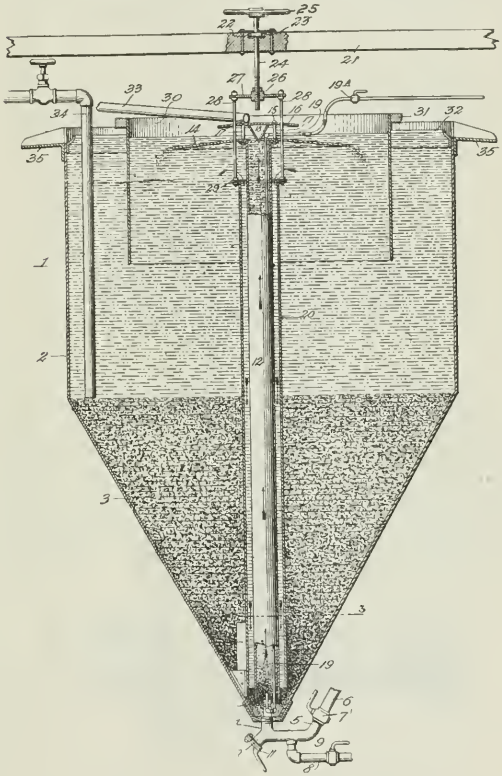

FIG. 3—AGITATOR.

can be drawn off through the circular launder 35. At the bottom of the tank a valve is provided for sluicing out the settled pulp when its values have been extracted by agitation. (994,679, June 6, 1911.)

Lead and Copper.

Fume Neutralization.—The system of fume neutralization as used by the U. S. Smelting Company at Salt Lake City, Utah, is the subject of a patent issued to MR. CHARLES B. SPRAGUE, of Salt Lake City.

Owing to the acid nature of the gases given off in the roasting of ores in converter and reverberatory roasting, it is impossible to filter those gases through bags in the manner customary with lead smelters. A system of neutralization of the sulphuric acid contained has been found possible, after which the gases can be filtered and discharged into the air, free from noxious substances, either solid or gaseous.

For neutralizing the acid in gases from converter roasters of the Huntington-Heberlein type, which are not as highly charged with sulphuric acid as those from reverberatory roasters, zinc oxide has been found efficient. Powdered lime, how-

ever, is preferred for neutralizing the gases from reverberatory roasters. In operation a furnace is built adjacent to a flue leading from the converter roasters, in which a mixture of zinc ore and coal slack is burned under a low blast. The zinc oxide produced is conducted into the roaster flue, where it mingles with the roaster gases and neutralizes the acid contained. When powdered lime is used, as on reverberatory roaster gases, it is introduced by means of a fan and eccentric feeder. The gases pass through the fan, and the feeder is set to deliver the proper quantity of lime into the gas.

Flues leading from both converter and reverberatory roasters may be united after the separate treatments have been applied and the combined gases filtered through bags as usual, the corrosive action of the gases having been overcome. (992,391, May 16, 1911.)

Roasting Furnace.—Improvements in the manner of attaching and detaching rabbles and rabble arms in ore roasters of the superimposed-hearth type have been made by Mr.

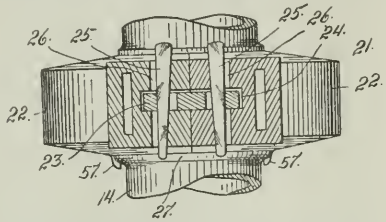

FIG. 4—DETAILS OF ROASTING FURNACE.

Chauncey E. Dewey, of Denver, Col. Figs. 4, 5 and 6 illustrate the invention. Referring to Fig. 4, the vertical central tube which carries the rabble arms in a furnace of the type described is represented by 14. The hub which carries the arms is composed of two twin members 22 which are connected by locking plates 23. As shown in Fig. 5, the hub is equipped with sockets adapted to receive the cone-shaped extremities of the rabble arms, which are fastened in the sockets by bayonet

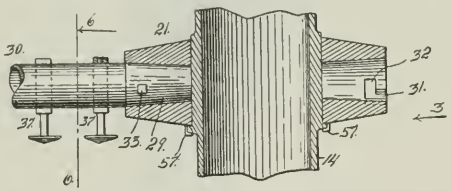

FIG. 5—DETAILS OF ROASTING FURNACE.

joints, so that when the furnace is in operation the movement of the rabble through the ore tends to hold it tightly in place. The rabbles themselves, which are shown in Fig. 6, are adapted for easy attachment or detachment. They are held in place by pins 34, which engage the perforations 35 made in the upper curved end of the rabble or plow. By means of the perforated lug 40 any plow may be removed from the rabble arm when necessary.

Alloys.

Ferrovanadium, Molybdenum and Tungsten.—The difficulty of preparing the ferro alloys of vanadium, tungsten and molybdenum usually has been that the reducing agent used remained in the resulting alloy in too large quantity. Mr. Gideon Boericke, of Philadelphia, Pa., has patented a process of reducing these alloys, which he claims eliminates the trouble experienced before. In carrying out his invention he uses a suitable form of the metals, such as vanadate of iron, which he mixes with manganese metal or alloy and a flux such as common sand. When the process of reduction is completed the products are ferrovanadium and a slag composed chiefly of the oxides of silicon and manganese. (993,338, 994,055, May 30, 1911.)

Purification of Magnesium and Alloys.—In the ordinary manufacture and refining of magnesium and its alloys more or less metallic chloride is retained in the metal, which subsequently has a deleterious action and causes oxidation of the metal in moist air. Berthold Hoffmann and Robert Suchy, of Griesheim-on-the-Main, Germany, have discovered that it is possible to readily and completely free magnesium and its alloys from this chloride by passing through the molten metal hydrogen or other reducing gas, which will drive off all traces of chloride at temperatures which are but little higher than the melting point of the chloride.

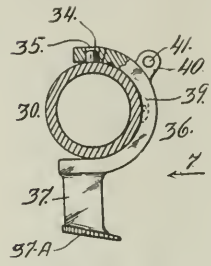

FIG. 6—DETAILS OF ROASTING FURNACE.

The process may be carried out as follows: About 8 kg of the metal are charged into a crucible fitted with a pipe through which hydrogen gas may be passed to the bottom. The current of gas is passed through the fluid metal for five or six hours at a temperature of 800° to 900° C. (993,373, May 30, 1911.)

Pyrophoric Alloy.—Metallic alloys which give sparks when scratched with a hard substance have hitherto been made by fusing together the metals of the rare earths, especially cerium, with heavy metals like iron. Adolf Huber, of Berlin, Germany, has discovered that aluminium can be substituted for iron and that the alloy thus resulting must contain not more than 50 per cent of the aluminium or other earthy metal. When the percentage of the cerium metals falls below 50 per cent the property of spontaneous ignition of the separated particles almost totally disappears. The preferable percentage of aluminium to be added is 12 per cent, at which proportion the alloy can be cast without disintegrating on cooling. The lower specific gravity of the aluminum-cerium alloy is an advantage, as is also the lower melting point. (993,908, May 30, 1911.)

Electroplating.

Cleaning and Polishing Silver Plate.—Silver plate is cleaned and polished, according to Mr. A. M. Kohler, of Brixton, London, England, by immersing in a sodium hydroxide solution in presence of aluminium or an aluminium alloy. When the articles are immersed in the solution and are in contact with aluminium, galvanic action is set up, the aluminium acting as anode and the silver articles as cathode. The anodic action is the formation of sodium hydroxide; the cathodic action is the reduction of the oxide which forms the tarnish on the silver to metal. Instead of metallic aluminium an alloy consisting of 80 parts aluminium, 10 barium, 8 calcium, 1 sodium and 1 silicon and impurities may be used. If the articles to be cleaned are greasy or very much soiled they may be immersed in a hot solution of Na_2CO_3 before placing in the solution as above described. (983,727, Feb. 7, 1911.)

Detinning.

Treatment of Old Tin Cans.—Preparatory to the removal of the tin from the iron old tin cans, etc., must be freed from everything that is neither tin nor iron. Dr. Karl Goldschmidt and Dr. Joseph Weber, of Essen, Germany, subject the tin cans to the following treatment: First, removal of the adhering organic substances by treatment with a hot 3 per cent caustic soda solution for five to fifteen minutes. Second, removal of the solder and the caoutchouc ring (which in folding the edges of the tins is placed in the fold to make the same tight) by sudden exposure of the tin cans to a temperature of from 600° C. to 800° C., the solder being melted off in five to seven minutes and the caoutchouc being destroyed at the same time. Excessive heating must be avoided, as this would cause the tin to alloy with the iron. (13,123, June 28, 1910.)

SYNOPSIS.

Gold and Silver.

Cyaniding at the Waihi Mine.—In the *Transactions* of the Australasian Inst. Min. Eng., Mr. E. G. Banks, metallurgist of the company, describes the method of treatment of an ore containing sulphides. All products are cyanided, but the sulphides are separated and treated separately from the balance of the ore.

Following rock breakers and stamps, the ore is ground in tube mills. The tubes are 18 ft. x 4 ft. 9 in., and have cast-iron liners in the shape of ribs 4 in. wide spaced at 15 in. centers. When new the ribs stand 3¼ in. above the body of the liner. They have a life of at least 18 months and represent a cost of a trifle over one cent per ton of stamp output. The consumption of pebbles is 2.6 lb. per ton of stamp output, representing a cost of about one and three-quarters cents per ton. The proportion of water to ore is kept at about 1 to 1, and each tube has a capacity of 110 to 120 tons of stamp product (10 mesh), although it grinds from 280 to 340 tons on account of the oversize returned from the sizing boxes.

Concentration follows tube milling, which is unusual practice, but justified by the author on the score that if the coarsest sulphide particles are removed it matters not if very fine sulphides escape to the cyanide plant. The sulphide concentrates are treated as follows: Grinding is accomplished in tube mills, and the coarsest of the tube product returned for further grinding. The ground pulp is thickened to 0.7 parts of solution to 1 of ore and agitated from 8 to 10 days by means of air in conical bottom tanks. Cyanide solution (NaCN) contains 0.45 per cent. of the salt, and the consumption is 16 lb. per ton, which represents 0.25 lb. per ton of original ore. The pulp is filter-pressed and the solution precipitated in zinc boxes.

The slime is thickened in V boxes and later by vacuum filtration, and is then mixed with solution of 1.2 per cent. KCN, and agitated by air in tall tanks for five days. The latest tanks built are of reinforced concrete 55 ft. high and 13 ft. diameter, erected at a cost of about $1,064, which is less than for similar sized steel tanks. No center pipe is used, slightly better results having been obtained without it. Gold is extracted in 24 to 30 hours, but a profitable extraction of silver continues up to five days. The consumption of cyanide is 1.66 lb. per ton of slime.

Vacuum filters are used to recover the pregnant solution, and zinc dust is used for precipitation. The extraction is 89 per cent. of the gold and 71 per cent. of the silver.

For several years the sulphuric acid process was used for refining, but was discarded two years ago in favor of the electrolytic method. The Doré bars run about 12 per cent. gold and 87 per cent. silver, and are separated in the stationary cathode type of cell. The output of 30 cells is about 5000 to 6000 oz. in two shifts (16 hours). The gold recovered runs 996 to 999 fine. The cost of refining is about 0.72 cents per oz. of Doré. The total cost of ore treatment is about $1.30 per ton.

Air Lift Agitation.—Writing on the subject of air lift agitation of slime pulp, Mr. Robert Allen presents some interesting data in the March, 1911, issue of the *Journal* of the Chemical, Metallurgical & Mining Society of South Africa. Referring to F. C. Brown's development of the so-called Pachuca tank, he says that the following points were found essential: The higher the tank compared with the diameter, the less the power required; the consumption of cyanide was less in tall than in shallow tanks owing to the fact that the necessary quantity of compressed air is less per ton of ore in the former than in the latter; although good agitation could be effected with slimy material in shallow tanks, yet as the coarseness or density of the material, or the specific gravity of the pulp increased, the ratio of height to diameter should be increased; the diameter of the central air lift pipe should be 1¼ in. for each foot of diameter of the tank.

On the score of excessive consumption of cyanide the author cites comparative results from the Loreto mill and the Hacienda San Francisco at Pachuca. In the former they use 30-ft. mechanically agitated tanks, with a charge of 57 tons in a thin pulp, while in the latter with Pachuca tanks agitated by air they work on charges of 112 tons of thick pulp. The cyanide consumption in the former mill is greater than in the latter and its power consumption is at least ten times as great.

Other experiments showed that Brown or Pachuca tanks consumed only 2.6 and 2.4 lb. cyanide on the same pulp on which mechanical agitators consumed 3.1 lb. cyanide per ton.

Lead.

Smelting in the Ore Hearth.—An interesting comparison of results obtained in smelting non-argentiferous galena in Scotch and Jumbo hearths at Granby, Mo., is given in the May, 1911, *Bulletin* of the A. I. M. E. by J. J. Brown, Jr., formerly connected with the Granby Mining & Smelting Company.

The ore hearth was at first a very wasteful means of reducing galena because no provision was made to recover the fume. Later this type of furnace was regarded with favor because it could be used to make a large percentage of fume or pigment, which was collected in the Lewis and Bartlett bag process. In fact, the production of metallic lead was kept down by hot blast, etc. Recently, however, a modification of the old Scotch hearth has been adopted for the reduction of lead, with a minor quantity of fume which is collected in bags, and slag which is reduced in blast furnaces.

The Granby company, however, having no blast furnace, was obliged to make as complete a recovery and leave as little lead in the slag as possible. About five years ago the system was as follows: The furnaces were water-backed Scotch hearths 2 ft. wide, using charcoal as fuel, and treating 14,000 of charge in about 14 hours, working two shifts of four men each. The men were required to convert 70 per cent. of the galena charged. 50 per cent. of the white fume, and 40 per cent. of the blue fume into pig lead. A premium of one cent per pound was given for better work than that required, but a similar penalty was charged for poorer work. Under this system about 85 per cent. of the lead in the charge was recovered, and about 2 per cent. went into blue slag, while the balance was recovered as fume and resmelted.

The author believed that better work could be done in Jumbo hearths and the result of his experiments was that all the Scotch hearths were remodeled into Jumbos. The percentages required of the operators were changed to 65 per cent. for galena, 60 per cent. for white fume, and 50 per cent. for blue fume contained in the charge, with the same premium or penalty as before. Cheaper fuel was used (bituminous coal instead of charcoal), and in a six months' run it was found that there was an advantage in favor of the Jumbo hearth of $0.6854 per ton of material smelted, or more than $1,200 per hearth per year.

The Jumbo hearths smelted a charge in less time than the Scotch hearths, the difference being about 4 to 5 hours per day. This is due to the larger fire area of the Jumbo hearth; the larger the hearth the more material can be smelted at one time provided the workmen can do the extra work entailed. A higher extraction was found on the 4-ft. than on the 5-ft. hearth, because the latter had too much fire to be worked advantageously. Pea-size ore is found to be the best.

A great objection to the ore hearth is that of small capacity. The author states that the only way to overcome this is to make the furnace mechanical in its operation instead of having it operated by hand. He states that according to designs of his own, in a patented furnace (888,582, May 26, 1908), the hearth may be from 10 ft. to 20 ft. wide, and worked by half the number of men.

Tin.

Anaylsis of Tin Ore.—Disregarding the fire assay for tin, which is regarded as inferior to volumetric methods, R. J.

Morgan gives his preferred method of estimating tin in an ore in the *Australian Mining Standard* of March 8, 1911. Six to eight grams of stick NaOH are heated in an iron crucible to expel moisture. About 5 grams of the finely powdered ore are added to the crucible after the NaOH has cooled and set. The crucible is then covered and gently heated to dull redness until fusion is complete. Allow the melt to cool, and then extract it with water in a casserole. Keep the washings as low as possible, but use enough weak HCl to wash the crucible and cover free from any adhering melt. Then cover the casserole and add HCl until effervescence ceases, and add 20 cc. strong HCl in excess. Heat to boiling and transfer to a suitable flask. There should be no undecomposed residue, save possibly some gelatinous silica.

Now add pure iron, in the shape of three horseshoe nails, to the solution and boil for 15 minutes. Filter through glass wool, washing with about 50 cc. water. To the filtrate add about 5 g. finely powdered pure antimony, heat to boiling and boil for 5 min. Cool as rapidly as possible in an atmosphere of CO_2. This can be done by dropping a small piece of marble in the flask, but a continuous source of CO_2 conducted through the flask is better. When cold the solution is titrated with standard iodine solution.

Zinc.

Flotation of Minerals.—In the *Australian Mining Standard* for April 5, 12, 20 and 27, 1911, Kenneth A. Mickle presents a very exhaustive statement of the conditions affecting the flotation of minerals in different solutions. Details are given of different experiments on many minerals and solutions under different conditions. It is impossible to present the details of the work, but the following conclusions will be interesting.

All minerals absorb gases.

Sulphides appear to naturally absorb CO_2.

The consequence of this is—

(1) Particles are not wholly wetted when immersed in water.

(2) Particles also tend to float when sprinkled on the surface.

(3) When immersed in water and heated, the air or gases dissolved in water will collect on the particles, and float or tend to float them to the surface.

(4) Saturated solutions of gases in water evolve gas which collects on all particles.

The Addition of Acids.—Metallic particles, such as sulphides and metals, when immersed in dilute acid solution, are not wholly wetted, but particles of rock materials become more readily wetted, and give off their adsorbed gas. When different dry minerals are sprinkled on the surface of dilute cold acid the tendency for them all is to float as in water. The minerals are more readily wetted by hot acid solutions than cold.

The Addition of Alkalis.—When different mineral particles are immersed in an alkaline solution, they tend to part with their adsorbed gases, and will not float even when heated. When sprinkled dry on the surface of the solution they remain for a few seconds only and then break through.

This is due to the property possessed by minerals of collecting gases on their surface in such quantity as to diminish the density of the product, to less than that of the liquid. By calculation from the decrease in density it is found that the amount collected on dry sulphides is sometimes half the volume necessary to float them at ordinary temperature. Given a starting point, any gas generated in or introduced into the solution will tend to collect on the surface of the particles. If acid is added, the gases will leave the gangue particles and collect on the sulphides; the latter, therefore, tend to float, and the former to remain under the surface of the liquid. When substances in the solution, such as carbonates, are attacked by acids, the gases evolved saturate the liquid, and commence to grow on the sulphides. Sulphuretted hydrogen, steam, air, and any other gases present either in the solution, introduced into it, or evolved from the minerals present, assist floatation, provided the sulphide particles have dry points on them for the gases to become attached to. Some sulphides naturally absorb gases, and such sulphides readily float. The bulk of Broken Hill ores may be taken as examples. Other ores require preliminary treatment, so as to alter their surface to some extent. This may be done in certain cases by merely heating to 250 deg. C., or immersing in some solution which will attack the sulphides, such as nitric acid or chlorine solution. Sulphides which condense or absorb gases well will gather together in a solution as flocculent masses, while those that do not remain individually distinct, like grains of sand.

In certain cases sulphides will float in acid solution at ordinary temperature, but for the most part with dilute acid solution flotation starts at about 80 deg. C. The explanation put forward that flotation at that temperature is due to certain carbonates, such as rhodochrosite, siderite, smithsonite being attacked and giving off CO_2, does not appear to be correct, for under reduced pressure these minerals are attacked, but flotation does not take place. The presence of silicic acid and sulphur, as stated by De Bavay as necessary for a coagulum, is not necessary in many cases of successful flotation. When minerals are treated with dilute acids, and then exposed to the air, certain sulphides absorb gases on their surface. If they are alternately wetted and exposed to the air they will become entrapped by the surface film of water which they are brought in contact with. The appearance of the film is the same as that of a bubble of gas under the surface of a solution with sulphides attached. The sulphides in both cases adhere to the surface film of the bubble or free surface of the liquid, but are mainly below the surface itself. The gas obtained in all cases from experimental work and also from samples obtained from various flotation plants was CO_2, with varying quantities of nitrogen and oxygen. There is no doubt that most of this gas is generated from gangue particles in the ore, and being more soluble in the liquid than the other gases, collects readily on the surface of the sulphides.

In all experiments with sulphides carbon dioxide was obtained on exhaustion. This gas must have been present either in the form of a compound easily decomposed by heating or by reducing the pressure, or as a gas condensed on the surfaces of the sulphides, and there retained with greater force than other gases present. It was found that the carbon dioxide was the last gas to come off.

The Effect of Oils.—The effect of oils has long been known in protecting minerals from being wetted by water owing to the oiling of their surfaces, and also the affinity of oils for metals and many metallic substances. Nearly all the minerals tried could be coated with oil either in the presence or absence of water. This seems to be connected with the absorption of gases on the particles themselves, for if the particles are deprived of their gas, then as a rule they do not become coated with it. It would therefore appear that the oiling of particles is dependent on their gaseous attachments. If the particles are oiled to a minute extent, the gases previously absorbed are retained, and if a solution is heated more gas will become attached to the particles, and flotation will ensue. An oil float may be obtained without acids. Nearly all minerals will float on water after being oiled.

The flotation is apparently due partly to the lesser density of the oil and the presence of gases absorbed on the minerals or entangled in the oil. If a large quantity of viscous oil is used gases become entangled in it, and the product is oily. In course of time the particles will drop away from it, carrying down attached globules of oil. When a lesser amount of oil is used the product becomes a coherent mass like putty, showing no apparent tendency to float. On further decreasing the quantity of oil, the product becomes firmer, and breaks up into rounded pellets. With a still less quantity of oil, when shaken up with water in presence of air the product becomes flocculent, and increases in volume. This flocculation is due to the absorption of gases. With very minute quantities of oil the flocculation becomes more pronounced, and the tendency to

float becomes greater. These results may be obtained with gangue and metallic substances. Gases collect more readily on oiled than on unoiled particles.

The Effects of Acids on Oiled Particles.—The addition of acid causes a more selective action. If oiled gangue and metallic particles are immersed in water, and acid is added, then the oil will tend to leave the gangue particles and become attached to the sulphides. The action of the oil in this respect is similar to that of the gases attached to different minerals, and probably is due to the same cause.

If an ore is treated with an acid and the acid is removed, then if the particles are oiled, the oil tends to become attached to the sulphides only. This is probably due to the removal of the gas from the gangue, which prevents oiling of the same. If acid and oil are added together, the action of the oil is selective, as in the previous case. The presence of oil on their surface does not prevent the minerals being attacked by acids.

The amount of acid required for selective flotation depends on the composition of the ore, the temperature and the pressure existing at the time. Generally it may be stated that an increase of acid will give a purer sulphide product, but flotation will take place at a lower temperature, and with a lesser amount of acid, with oil and acid than with acid alone. A selective flotation can be obtained in some cases by treatment with a chlorine solution previous to the addition of oil, and without the addition of acid.

Some of the light volatile oils cause flotation in an acid solution at a lower temperature than the heavier and thicker oils. With some Broken Hill tailings a flotation takes place at ordinary temperature with sulphuric acid and a volatile oil.

Effects of Oils and Alkalis.—Flotation can be obtained in alkaline solutions when oil is used, but in every case tried the action was non-selective. On making the solution acid the action becomes selective, only the sulphides floating.

The flotation of mineral particles appears then to depend on the particles having gas attached to them becoming entangled, or caught, by the surface film of a liquid. This film may be (1) the free surface of a liquid, (2) the surface of a bubble of gas under the surface of a liquid, or (3) the surface of a bubble of gas above the surface of a liquid. Once the particles are entangled in this film they are sustained there. That a considerable weight may be supported by this surface film is shown by the experiment of floating fine-grained mineral on the surface film of water.

The Purchase of Fuel Upon a Heat Unit Basis, in Germany and Switzerland.

By John B. C. Kershaw.

Considerable attention has been given in the United States to the methods of purchasing fuel upon a heat-unit basis, and the action of the government in arranging for the application of this system of purchase to all government contracts has given a great impetus to the movement for the use of scientific methods in the purchase and control of fuel supplies.

In view of the widespread and general interest in the subject in the United States the writer has thought that the following details of the progress of a similar movement, in Germany and Switzerland, would be found interesting.

In *Germany* considerable progress has been made during the last two years. In their report for the year 1909 the committee of the Hamburg Smoke Abatement Society state that an increasing proportion of the members of the society are taking samples and having tests made of their fuel deliveries. Over 1000 fuel tests were made at the official testing laboratories of the society in Hamburg in 1909, and it is expected this total will be largely exceeded by the figures for 1910 and 1911. The chief engineer of the Hamburg Smoke Abatement Society (Herr Nies) is firmly convinced of the value of chemical and calorific tests for checking the quality of the deliveries of fuel. This society, which had at the end of 1909 365 members and over 1300 boiler and other furnaces under its control, has arranged to undertake the regular sampling of their fuel supplies for those members who desire to be relieved of this work. This is a great step in advance, for to obtain a really fair average sample of coal or slack demands more skill and knowledge of sampling than is generally found in those who are trusted with this work, and the slow progress of the movement for more scientific control is partly due to this difficulty.

The actual testing of the fuel sample in Hamburg is undertaken by an independent fuel expert, Dr. Aufhäuser, who is head of the Thermo-chemische Prüfungs und Versuchs Austalt, or in plain English, of the Thermochemical Testing and Research Laboratory in Hamburg. The following are the details of the basis upon which the fuel is valued:

An average sample of the fuel is taken from the first or trial delivery after discharge at the consumer's works, and this is carefully tested at the official testing laboratory for moisture, ash and calorific value. The latter value is calculated on the assumption that the products of combustion of the fuel pass away in the state of vapor at 212° Fahr.—and with the aid of this result the calorific value of the combustible portion of the fuel is also calculated.

The regular samples of fuel taken to check the quality of the further deliveries are only tested for the percentage of water and ash; and from the results of these tests the calorific value is calculated by the aid of the figures obtained from the first or guarantee test. Should this calculated value deviate in either direction from the guaranteed value by more than the difference allowed by the term of the contract, an addition to, or deduction from, the price follows.

In those cases where doubt exists as to the correctness of the results, which in some cases may vary on account of a change in the calorific value of the combustible matter of the coal, the sample is submitted to all three tests, and if a different calorific value is found by the direct test, a correction is made accordingly.

It will be seen that this method of checking the fuel deliveries differs in two respects from that practiced in this country. In the first place the guaranteed calorific value of the fuel is based upon the "combustible" matter in the same, and is calculated for gasses escaping at 212° Fahr.; and in the second place, the regular samples of the fuel are only tested for moisture and ash, and the calorimeter tests are only repeated in cases of dispute.

As regards these modifications there is no doubt much to be said for the change. A fuel consists, from the practical man's point of view, of combustible and incombustible matter, the latter being made up of water and ash. If the fuel comes always from the same seam in the same pit the calorific value of the combustible portion of the coal ought to be a constant and not a variable value. The variables are the moisture and ash, and by estimating the percentage of these in each sample, and then calculating the value of the remaining combustible by aid of the value obtained in the first test, one can obtain the calorific value of the fuel actually delivered, with a minimum of time and expense.

But, this system of valuation ought to be checked, say, monthly or quarterly, by repeat tests with the calorimeter of the actual calorific value of the fuel, and the latter figure should be used until another determination is made. This will guard against errors due to the slow changes in character and quality, which undoubtedly occur in the working of some seams of coal, especially when the thickness is diminishing. It is also advisable to have some guarantee that the deliveries of fuel are from the mine and seam of coal stipulated in the contract. Mine managers often ship other coal than that bought, unless a penalty is arranged for such conduct.

As regards the assumption that the exit gases from the combustion of the fuel are always cooled to 212° Fahr, and the correction of the calorific value accordingly, this method of expressing the value is supposed to have the advantage that it

renders the calculations of the boiler efficiencies more simple, and that one can more easily judge from the calorimeter test results the actual steam-raising capacity of the fuel. As a rule, English and American calorific test results are based upon the escape of the gases at 15° C. and the value obtained in English, American and German calorific tests of fuel are, therefore, not comparable, until allowance has been made for this difference in the method of calculation. But no boiler is so efficient as a heat abstractor that the exit gases escape at a temperature of 212° Fahr. The German test results, therefore, still require correcting for the difference between 212° Fahr. and 560° Fahr., or 600° Fahr., which is generally the temperature of the escaping gases, and the simplifying of the calculations required when estimating boiler efficiencies is thus more apparent than real.

Below are a group of test results calculated on this basis obtained at the official fuel testing laboratory of the Hamburg Smoke Abatement Society and taken from the last annual report of the society:

	Percentage of			Calorific values in centigrade units.	
	Moisture.	Ash.	Combustible.	Raw coal.	Combustible.
Durham coal	1.6	2.2	96.2	7951	8273
	4.6	15.8	79.6	6339	7999
	2.6	6.9	90.5	7350	8139
Northumberland coal	1.4	13.4	85.2	6907	8115
	5.4	8.7	85.9	6840	8001
	12.1	5.5	82.4	6413	7871
Yorkshire coal	3.5	7.3	89.2	7145	8034
	6.4	4.8	88.8	6987	7912
	3.7	3.3	93.0	7526	8116

The above calorific tests require multiplying by the factor 1.8 to obtain the corresponding values in British thermal units, and it will be seen that there is a margin of 402 Centigrade units (723 British thermal units) between the highest and lowest results when based on pure coal or combustible. This difference proves that even after the two variables, moisture and ash, have been eliminated from the coal, considerable variation exists in the calorific value of the coal mined in different collieries and seams in the North of England and that the Hamburg system of valuation, if adopted, must be used with discretion and common sense.

As regards the progress of scientific methods of controlling fuel supplies in *Switzerland* the state authorities in that country established in 1907 at a cost of $10,000 a well-equipped fuel testing laboratory at Zurich, and have since 1908 based all contracts for the supply of fuel to the State railways upon calorific tests.

The principle employed here is to fix an average heat value for the fuel being delivered (in this case German and French briquetted fuel) and to deduct from or add to the price a proportionate sum for every 50 heat units (90 British thermal units) by which the calorific value as delivered differs from this standard. An illustrated description of the State fuel testing laboratory at Zurich appeared in the issue of the *Engineer* for June 12, 1908, and it was there stated that over 3000 samples of fuel had been tested in the first year of its existence.

Most of these represented German fuels, for Switzerland has to import all her coal, at an annual cost of $15,000,000. The remaining samples were of Belgian, French and English fuels.

The director of the laboratory at Zurich, Professor Coustam, has stated that this extensive examination of imported fuels in Switzerland, both for the State and private consumers, has tended to enlighten the buyers as to the qualities and economic value of the fuels from the various countries and collieries and has also contributed toward the classification of fuels according to their heating power or value.

In a recent letter to the author of the present article Professor Coustam confirms this view, and asserts that fuel testing in Switzerland is centralized at the State Fuel Testing Laboratory where practically all fuel for railway and gas-making purposes is tested regularly—i. e., a sample being taken from every twentieth car-load of coal as it arrives. In 1909 4000 samples and in 1910 4400 samples were tested calorimetrically, besides about 1000 samples of gas-coal tested for moisture, ash, volatile matter and sulphur.

All parties concerned (producers *and* consumers) appear to be satisfied with the methods of fuel testing, the former agreeing that they are thereby protected from unjustified complaints. The results of the tests are compiled monthly, and are communicated to the sellers and buyers, the monthly mean serving as basis for payment.

Liverpool, England.

Tests for Fibrous Insulating Materials.

Next to mechanical strength, the most important factor in determining the value of different types of electrical generating machinery is insulation. The size and life of dynamos and motors depends not so much on the actual current-carrying capacity of their conductors as on commutation, and the resistance of the insulating materials employed to the disintegrating action of heat, in the first place, and humidity in the second.

A dry heat need obviously only be limited in intensity by the point of combustibility of the substances employed, and it has naturally always been the aim of electrical manufacturers to employ substances as incombustible as possible. A test for inflammability under dry heat is easily contrived, and has not therefore been considered so important as one under the more onerous conditions of heat and moisture simultaneously applied.

Tests under these circumstances and the data gathered form the subject of a paper presented to the British Institution of Civil Engineers by Mr. W. Pollard Digby. This paper more particularly alludes to tests on the three well-known substances, "Press-spahn," "Leatheroid" and "Empire" cloth.

The test employed was to expose strips of the substance to be investigated, of known area and weight, to the action of a vapor bath having a temperature of 167° F. (75° C.) for periods aggregating 1 hour and 40 minutes, the weight and insulation resistance per square inch being taken every 20 minutes. The results of the test go to show how widely thin "Empire" cloth (between 4 and 5 mils thick) varies in its properties. Increases in thickness for this substance were obtained from 1.7 to 11.1 per cent., and increases in weight of from 5.9 to 7.8 per cent., the insulation resistance at the end of the test varying from 10.1 to 11.2 megohms. Thicker material (from 6 to 6.9 mils) increases in weight of from 2.6 to 6.6 per cent., were noted, and the insulation resistances on three samples were as high as 5,000 megohms per square inch. These tests showed the value of using a single thickness of, say, 12 or 14 mil material, rather than an equivalent thickness of two or more sheets of thinner material.

Press-spahn or fuller-board, unvarnished, gave, on the whole, poor results. The more satisfactory samples varied from 1.2 to 40 megohms, and other results were as low as .0001 of a megohm. The thickness seemed to make little difference. The conclusion come to was that "Press-spahn" was unsuited for any but small low voltage machines.

Leatheroid gave more satisfactory results, the poorer registering a resistance after test of 10.8, 7.7 and 4.9 megohms per square inch, while six out of nine samples gave 40 megohms per square inch, with increase in thickness not exceeding 3.4 per cent. The thicker samples (over 10 mils), however, were not so uniformly good, only three out of twenty having insulation resistances of more than 1,000 megohms per square inch. As a potential specification for this substance, the author permits the use of leatheroid, which, after the vapor bath test at 167° F. for 100 minutes, has an average insulation-resistance of over 20 megohms per square inch and an increase in weight and thickness not exceeding 5 per cent. This substance compares very favorably with press-spahn, as, for any given

increase in weight and thickness the moisture absorbed lowers the insulation resistance of leatheroid to a much less degree than that of press-spahn.

The function of these materials (press-spahn and leatheroid) is generally described as mechanical, i.e., they are used to protect the actual insulating sheaths of molded mica or woven material from abrasion in the slots. At the same time it is obviously advantageous that the most durable and non-hygroscopic material should be used.

Data on dielectric strength were only available on one specimen of leatheroid, which was tested by a manufacturing firm. The volts per mil thickness were here found to increase up to 15 mils in undried, and 21 mils in dried leatheroid, after which they apparently fell off. The highest recorded was 475 volts (on 8 mil material), and the lowest 229 volts on 21 mil.

As a result of thirty-two tests it was found that "leatheroid" might contain up to 5.5 per cent., and "Empire" cloth up to 2.96 per cent. of moisture and volatile matter, the figures for vulcanized fibre ranging up to 2 per cent.

The paper concludes with a suggestion that a formula expressing the minimum permissible resistance for motors and generators after heat-run should read: $R = Kv \div s$, where v = voltage of machine, s = estimated net iron-area of one slot, multiplied by the number of slots, and K = a constant (not less than 15). This formula would differentiate between high-speed machines with small surface and low-speed generators of large diameter.

NOTES.

The Linde Air Products Company, of Buffalo, N. Y., have just shipped a complete oxy-acetylene cutting plant arranged for six operators to the War Department for use in conjunction with the salvage of the U. S. S. Maine in Havana harbor. Much of the work involved is the cutting of 9-in. armor plate in addition to the usual structural shapes. It is interesting to note that similar apparatus to this was used with signal success in connection with the removal of the debris of the Quebec bridge.

Dings electromagnetic separators are built in low, medium and high intensity types designed for different kinds of work. The low intensity type is useful for separating metallic iron from non-magnetic material. Those of medium intensity are used for the separation of roasted sulphide ores, magnetic iron ores, etc., while the high intensity machines are applied mainly to the separation of wolframite, monazite, rutile and minerals with very feebly magnetic constituents.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in March, 1911, was 68. The total tonnage milled during that period was 2,005,526 tons of ore; 9911 stamps were in operation with an average duty of 7.62 tons per 24 hours. Tube mills in commission numbered 209. The yield for the month was 676,065 fine ounces gold. This report shows an increase of about 200,000 tons of ore milled and an addition of 47 tube mills in commission as compared with one year ago.

In the Annual Report of Phelps, Dodge & Co. appears a brief statement of the experiments on dust settling at the Copper Queen Smelter. During 1910 these experiments were carried to conclusion, and it was shown beyond question that it is possible to settle a large part of the finest dust in a comparatively short but wide chamber, in which the velocity of gases is reduced to between two and two and a half feet per second. The dust chambers are, therefore, being reconstructed by sections. The first section will handle the smoke from two blast furnaces. It is 1300 square feet in area, and it is thought this will be sufficient to settle most of the fine dust. In order to reduce the amount of gases passing through the main chamber a separate flue is being built for the converters. A calcining and reverberatory smelting plant is being built to treat fine ores and flue dust. This will be completed by the end of this year. It will consist of two reverberatories with boilers built in the furnace flues to utilize waste heat; six McDougall roasting furnaces; dust chambers, flues and stack.

Filter leaves or clarifying leaves may be bound with iron wire covered with P. & B. paint instead of the usual method of sewing them together at intervals. The wire is bound around the frame outside of the cloth and then fastened with staples passing over the wire on one side of the leaf and clinching over a wire on the opposite side. The scheme may have some advantage in cases where the threads used in sewing tend to break when reverse pressure is applied to discharge the cake.

Ferric iron may be precipitated quantitatively by a 6 per cent solution of nitrosophenylhydroxylamine, according to Biltz and Hodtke in *Zeit. Anorg. Chem.*, 1910, 66, 426-431. An excess of acid does not interfere with the precipitation, and iron may be separated from nickel, chromium and aluminium in this way.

A new classifier designed by G. A. Overstrom makes use of a rising current of water in successive sorting columns for the purpose of separating the specifically heavier particles into certain grades. The slime is removed first, and in each succeeding sorting column the rising current of water is so adjusted that successively finer grades will be raised out of the pulp, while the heavier settle to the next sorting column. The classifiers may be arranged in succession to receive and treat the specifically heaviest grade from the next preceding classifier. The system requires little clear water, as the overflow from each classifier is practically clear and is used in the succeeding machine.

The cost of silver production at Cobalt, Ontario, Canada, is indicated in the fourth annual report of the La Rose Consolidated Mines Company. During the seven months covered by the report a total of 2,569,905 oz. silver were produced at a cost of 19.11 cents per ounce. Of this quantity 401,221 oz. were produced by concentration, representing a recovery of 74.61 per cent. As a result of the large quantity of cobalt offered from this district the market is overstocked, and all payments for this metal have been discontinued.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Ore Treatment *(Continued).*

405,824, June 25, 1889, Turner D. Bottome, of Hoosick, New York, assignor to John B. Tibbits, of same place.

Gold and silver. The ore is reduced to powder and blown by steam into an atmosphere of chlorin and atomized water, the metal being thereby converted into chlorid. The chlorinated ore falls through sprays of sodium thiosulfate, to dissolve out the chlorids. The undissolved residue is filtered out and the solution is electrolyzed between electrodes of carbon and copper, the gold and silver being deposited on the cathodes.

407,386, July 23, 1889, and 410,228, Sept. 3, 1889, Jacob C. Wiswell, of Medford, assignor by Direct and Mesne Assignments, to the Electric Gold and Silver Chlorination Company, of Boston, Massachusetts.

Produces mercuric chlorid solutions for separating gold and silver from ores. A sodium chlorid solution, to which is added ammonium chlorid or hydrochloric or sulphuric acid, is electrolyzed in a tank of wood between anodes of carbon and cathodes of zinc. The resulting solution is delivered into a second electrolytic cell containing an anode of mercury and a cathode of carbon. The mercuric solution produced in this cell is employed to free the precious metals from the gangue.

415,576, Nov. 19, 1889, Werner Siemens, of Berlin, Germany, assignor to Siemens & Halske, of same place.

Copper, zinc, etc. Lixiviates the ore with a solution of ferric

sulfate, chlorid or cyanid, which dissolves the metal and is reduced to the ferrous form. Electrolyzes the resulting solution at the cathode, depositing the non-ferrous metal; then reoxidizes the residual solution at the anode to the ferric form. The operation may be carried out in one cell or in a number of cells arranged in cascade. The single cell is divided into two compartments by a cup-shaped diaphragm. The cup contains an anode of carbon, platinum or lead, and receives one leg of a syphon, which extends nearly to its bottom. The outer compartment contains a cathode-plate and a liquid supply-tube. The cup commnnicates with the outer compartment through a hole near its top. In the modification employing a series of cells, the anode and cathode compartments of adjacent cells are connected by syphons. To extract copper, the ore, for example, pulverized pyrites, is roasted until the iron therein is entirely oxidized and is lixiviated with ferric sulfate or chlorid, the resulting solution containing cupric and ferrous salts. Some free acid is added to increase the conductivity and the liquid is electrolyzed at the cathode, the copper being deposited. The solution, becoming lighter, rises in the cathode compartment and, when but one cell is used, flows through the opening at the top of the cathode-cup into the anode compartment. Here the ferrous salt in solution is reoxidized into the ferric form. In the series-cell construction, the two solutions pass successively through the cathode and anode compartments of all the cells, to secure complete deposition of the copper and oxidation of the iron. The depleted liquid from the last cathode compartment is returned to the first anode compartment. The potential difference used is 0.7 volts, and the cathode current-density 25 amperes per square meter. Zinc is similarly extracted from slightly roasted blende, the necessary potential-difference being nearly double that for copper.

415,738, November 26, 1889, Hermann A. Seegall, of Berlin, Germany.

Copper, zinc, tin. Lixiviates the ores first with ferric chlorid and then with a solution capable of dissolving the residual cuprous chlorid in the ore, for example a halogen salt or acid, or sodium hyposulfite. The second solution, plus ferrous chlorid, may be electrolyzed in an open cell, or it may be electrolyzed at the cathode in a diaphragm cell with ferrous chlorid in the anode compartment. Examples: 1. Lixiviates copper and zinc sulfid, or an alloy of the two, with ferric chlorid slightly acidulated with hydrochloric acid, until the iron is reduced to the ferrous form, the zinc dissolved as chlorid and the copper in the residue converted into cuprous chlorid and a little spongy copper. The copper is filtered and electrolyzed to recover the zinc. Copper cuttings or filings are added to the residue and it is lixiviated with ferric chlorid, slightly acidulated with hydrochloric acid and containing calcium or soldium chlorid to dissolve the cuprous chlorid. The solution is filtered to remove the freed sulfur and is electrolyzed to recover the copper. 2. Copper tin scrap is lixiviated with ferric chlorid slightly acidulated with hydrochloric acid. The tin dissolves and the solution is filtered off and electrolyzed to recover it. The residual cuprous chlorid is recovered as before. A series of electrolytic cells may be employed, the solutions passing successively through the several cathode and anode compartments, that of the last cathode compartment being returned to the first anode compartment.

418,134, Dec. 24, 1889, Henry Forbes Julian, of Johannesburgh, Transvaal, South Africa, assignor to Flavien Ernest Lezard and James Joseph Coghlan, Trustees.

Gold and silver. The ore is pulverized and agitated in a closed vessel with a solution containing bromin, chlorin or iodin or their salts. A pressure of from 60 to 80 pounds per square inch is maintained in the vessel by air or steam. When the gold has been dissolved as a haloid and the silver converted into an insoluble haloid, mercury or sodium amalgam is added to the semi-liquid mass, which is again agitated, amalgamating the gold. Or the gold in solution may be precipitated. The tailings are then run through a series of electrolytic cells, in cascade, having inclined cathode bottom-plates of amalgamated copper covered with mercury and depending anodes of carbon, platinum or lead peroxid. The remaining gold and silver are thereby dissolved and redeposited in the mercury.

452,125, May 12, 1891, Werner von Siemens, of Berlin, Germany, assignor to Siemens & Halske, of same place.

An apparatus for effecting the step of initial lixiviation in the process of his patent 415,576 (supra). The vessel is a long trough, or a series of connected troughs arranged zigzag, containing parallel shafts carrying paddles and a heating pipe.

PERSONAL

Mr. H. Foster Bain has returned to San Francisco from a trip to Colorado and will soon go to Alaska.

Mr. Thomas A. Dickson, formerly with the Colorado Iron Works Company, Denver, has gone to Goldfield, Nev., to take charge of the refinery of the Goldfield Consolidated Mines Company.

Mr. C. A. Filteau has returned to Denver from San Jose de Gracia, Sinaloa, Mexico, where he has been in charge of cyanide operations of Cia. Minera Jesus Maria y Anexas.

Mr. Franklin Guiterman, general manager of the American Smelting & Refining Company in Colorado, has left for several months' stay in Europe. He will study the progress in electric smelting with particular reference to zinc reduction.

Mr. Charles Janin, of San Francisco, was in Denver recently on a professional trip which took him through Arizona and Colorado.

Mr. William F. Kett has been appointed manager of the Mountain Copper Company, California, in place of Lewis T. Wright, who has resigned.

Mr. L. H. Norton, of Silverton, Colo., was in Denver recently on professional business.

Mr. Cooper Shapley has been appointed superintendent of the Oro Grande Company at La Luz, Guanajuato, Mexico.

Mr. George M. Taylor has been appointed general manager of the milling department of the Portland Gold Mining Company, Colorado, vice J. B. Daniels, deceased.

Mr. J. C. Welch has resigned his position as smelter superintendent of the East Butte Copper Mining Company, Butte, Mont.

Mr. Lewis T. Wright has retired from the management of the Mountain Copper Company, California, and will take up his residence in London, at least for a time.

BOOK REVIEWS.

Die Metallurgie des Zinns.—Mit spezielle Berücksichtigung der Electrometallurgie. (Band XXIX. Monographien über angewandte Elecktrochemie.) By Dr. Hans Mennicke, chemical engineer. 8vo., 196 pages, 40 illustrations, price 10 marks, bound 11.50 marks (retail price in New York $3.75). Halle a. S.: Wilhelm Knapp.

The ordinary processes of extraction of tin from ore are but briefly treated; Schnabel's "Handbook of Metallurgy" is more satisfactory on this part of the subject. The chapter on obtaining tin from tin skimmings, dross, and other chemical wastes is interesting and contains much new information. A 43-page chapter on the detinning of tin-scrap is probably the first publication of a description of some commercial plants. A 25-page chapter on the refining of impure tin, chemically and electrolytically, is most acceptable. Several short chapters follow on electroplating tin, production and consumption of tin; finally, there are 40 pages containing the full specifications and claims of important patents concerned with the metallurgy of tin. The whole is a useful and valuable contribution to the scanty metallurgical literature of an important and interesting metal.

Sintering Fine Iron-Bearing Materials by Blast-Roasting Machines.

Mr. James Gailey, who needs no introduction to our readers, has presented an exceedingly interesting paper before the June meeting of the American Institute of Mining Engineers on the sintering of flue dust on the Dwight-Lloyd system. As is well known this machine consists of a moving train of perforated iron pallets passing over a suction-box and that on this is placed the ore which is desulphurized by the blast principle of roasting. The machine resembles in appearance a short belt-conveyor.

This machine has been used successfully for the roasting of lead and copper ores. Mr. Gailey describes some experiments looking toward its application in the sintering of flue-dust and ore from the recently discovered mines of Mayari, Cuba. This proposal is to replace the sintering of the ore in long nodulizing kilns. The experiments described are favorable to the proposal. Both ores were delivered from the sintering machine with a large proportion that was coarse or granular. The percentage of iron was increased in the case of the Mayari ore from 48.53 per cent to 53.97 per cent and in the case of the flue-dust from 46.06 per cent to 57.90 per cent. The first increase is mainly due to the burning out of the coke while the second is due to the dehydration of the ore. All the pieces of the ore are described to have consumed a cellular structure like coke which is peculiarly desirable for the blast-furnace.

Experiments were made with magnetic concentrates and it is remarkable to note that the sulphur was reduced in the sintering from 1.17 per cent to 0.006 per cent. In the case of the magnetic concentrates and the Cuban ore, seven per cent of coal (presumably bituminous coal) was added. The flue-dust contained enough coke to furnish heat by its combustion for the operation. Mr. Gailey estimates the power needed for a 100-ton plant at 45 hp., the cost of repairs at 6 cents per ton. The capital cost of plant is low, as a 100-ton plant only weighs 26 tons.

We believe that this is a most important common-sense application of a machine devised for one operation to a process somewhat different in purpose but similar in modus operandi. The question of flue-dust in the smelting of Mesabi ores is most important. If the ore could be screened and the objectionable fines eliminated and sintered in a cheap efficient process a lot of blast-furnace managers would sleep better. Though we do not hear much now about blowing off the tops of blast-furnaces, yet Mesabi ores are smelted by slips and falls and the smelting is hard on the nerves.

It is very apparent from this and other proposals that the metallurgical engineer who recently proposed to amortize his plant on the ground that it would not be obsolete for twenty years was far from right. "The depreciation due to

the advance in the state of the art," should be at least ten per cent. The metallurgical profession has not given this important point the due weight that the electrical profession has.

Arbitration of the Smelter Fume Question.

The recent announcement of a suit brought by ranching interests in Nevada to restrain smelting operations on the part of the Mason Valley Mines Company, at its plant which is now in course of construction at Thompson, Nev., brings forcibly to mind the necessity for devising some means of reconciling the conflicting interests of agriculture and metallurgy. Both are of fundamental importance as original sources of wealth, and as such their interests are in a measure mutual and interdependent, especially when their several operations are carried on in the same locality. No permanent good can come from suits or injunctions, nor from resort to warfare of any sort. The settlement of the problem requires calm and impartial investigation, consideration of the interests of both parties, and, above all, extreme fairness in placing restrictions on the one or granting indemnity to the other.

That smelter fume may be and has been the direct cause of damage to vegetable life does not admit of contradiction. Three principal sources of damage are recognized, viz., sulphur dioxide, sulphur trioxide and solid fume such as arsenic. The best scientific talent in the profession has been marshalled to study the nature and extent of the damage which these substances cause and the possibility of taking reasonable steps to prevent their indiscriminate discharge into the air. It has been pretty thoroughly proved that it is possible to prevent the discharge of sulphur trioxide and solid fume, but it may be asserted that in the present state of the art no reasonable and effective method has been proposed to prevent large quantities of sulphur dioxide from escaping into the air and doing possible damage.

Sulphur trioxide may be neutralized with zinc oxide and collected in bag houses as at Midvale, Utah, and Kennet, Cal. Solid fume may be settled in flues by cooling to the proper degree of temperature and causing it to impinge on baffles as at Great Falls, Mont., and other places. But sulphur dioxide presents a different problem. It is not so much the fault of chemical knowledge that this gas is not handled as well as sulphur trioxide, but rather the difficulties encountered on the mechanical and commercial side. Many proposals have been made which undoubtedly will neutralize this gas and eliminate it as a source of damage. But what about the cost of equipment and operation of these schemes? How about the difficulty of handling large quantities of flue gas without seriously interfering with the draft on the furnaces? What shall be done with some of the neutral products obtained by these various proposals, and finally, if sulphuric acid be made from the gas, what shall be done with the acid?

Here is a problem which any sane farmer must not be too insistent in forcing the smelters to solve. The latter are fully conversant with the situation, much more so than the former, and, we are proud to say, the spirit of fairness and generosity has marked the attitude of the smelters more than that of the farmers. The larger companies, against which most of the agitation has been directed, acknowledge the possibility of damage and realize their present limitations in preventing it. It is a matter of economy with them to prevent the indiscriminate discharge of fume. Furthermore, they stand ready to pay for unavoidable damage and regard such payment as one of the expenses incident to the business; but they want the damage fairly assessed with due regard to all the conditions.

There are things which can be settled only by a fight—by a fight to a finish. It seems almost foolish to deny this. But can any sane man think seriously of a fight to a finish between agricultural and metallurgical interests? We believe that the solution of their problem lies in arbitration and that arbitration will prove in this restricted field immensely more successful than in the evasive and spectacular field of international politics. We decry suits and injunctions as being only so many expensive obstacles in the way of progress. The Anaconda Copper Mining Company and the United States government have set a good example in appointing a technical commission to consider the question as far as it relates to their several interests. This commission has arbitrary power to decide whether material damage is done to the government, and what steps, if any, the Anaconda company should take to prevent such damage. The arrangement is eminently satisfactory and is regarded on all sides as the only fair solution of the problem and one which should be adopted instead of resorting to the courts. Suits are expensive and leave one party dissatisfied. Injunctions only paralyze industry and frequently reflect injury on those who obtain them. Arbitration will be cheaper in every sense of the word, will possibly satisfy all concerned, and will surely reflect credit on the intelligence of both parties to the controversy.

The Metal Markets.

As we have pointed out several times, the increase of the productive capacity of the various metallurgical plants of the country in the past ten years was so rapid as to overrun the consumptive capacity of the country. From 1900 to 1907 there was almost without halt an increase of from 7 per cent to 10 per cent per year in the production of iron, steel, lead, copper, zinc, and the minor metals and this increase was compounded. At the present time we believe that these several basic industries are recovering from the period of mental unsettlement that occurred after the period from June, 1909, to July, 1910, when the wheels of commerce seemed to be rushing again. At present the production is going directly into consumption. As this consumption is on a hand-to-mouth basis, it is hard to see how it can be much reduced. As this situation is quite widespread throughout all industries, it would seem that the metal prices have about touched rock-bottom and the general tendency in all should be upward. There would be little doubt about this upward tendency were it not that the volume of all crops except that of cotton seems bound to be below the average of the past four years.

Sober-minded people while they may not exactly prefer a period of liquidation and retrenchment do not dread it, for that is the period when everybody works more and spends less, and when the entire spirit of inflation and speculation is curbed and chastened. This conservative policy of producers and the everywhere manifest attempt to reduce fixed charges,

to eliminate useless expenses, to improve the efficiency of plant and workmen, has put the metal industry in good shape to meet any disappointment that can result from the diminished harvests.

It also can be remarked that there are a great number of far-seeing and able inventors in this country and that their endeavors are appreciated more in periods when it is a question of a maximum of plant efficiency rather than a question of a maximum of plant capacity. Their efforts will reap a golden harvest when rightly and conservatively employed. Furthermore keen observers notice among the plain people of the United States a manifest displeasure with the attempts at "trustbusting" simply for the glory or fun that may be in it and a desire for a sane regulation of these instruments of production. When all these curative influences have done their work, we shall see a more normal growth of the metal industry. In the immediate future the outlook is not particularly promising.

Western Hospitality.

After a red-hot summer day in Omaha, to wake up the next morning in the Pullman sleeper in Colorado and see through the windows in the distance the snow-clad peaks of the Rocky Mountains, is a sensation which has given a thrill to many a traveler from the East. The stately range of peaks in the glory of their eternal snow offers the first greeting to the stranger who feels that he is entering God's country. And when on leaving the train in Denver he turns toward the city, there is the big "Welcome" Arch—that pretty and touching symbol of Western hospitality.

It has been truly said that nobody who has not seen the West and the Pacific Coast can have a full and proper conception of this country and its people. It is true, the East is mighty, and New York City is really a wonderful sight with its feverish commercial activity concentrated in such a limited space that its buildings must grow to scrape the sky. Yet the East and all its activity would be unthinkable if it were not backed up by the unlimited natural resources of our big and beautiful West. There is everything big and great in the West—the giant trees in the virgin forests, the orange groves, the wheatfields, the mines, the concentrators, the smelters. And the very men themselves—generous, cheerful, big-hearted, enthusiastic, and of a never-dying optimism. How could they have built up again a new and more beautiful San Francisco after the calamity of only a few years ago, if it was not so? Nature, bountiful and generous, is reflected in the big-hearted optimistic generosity of those empire builders of the West. And its natural expression is Western hospitality which no one who once enjoyed it can ever forget.

The Western man, whether he be a metallurgist or a mining man or anything else, always gives himself as he is. He is not afraid to show his smelter or concentrating plant to the interested visitor. There is nothing about him of that anxious secretiveness which is such a distinguishing trait of some of our Eastern and European friends. While his work speaks for him, he is not afraid to speak of his failures. He believes in the do ut des. He is always an optimist, and where old methods fail he looks out for new ones, and extends to them his hospitality.

In some parts of the West where the immense strides in agriculture have been coincident with a temporary decline in mining, the latter industry has suffered a loss of prestige as a money-making business. This has been due partly to a lack of spectacular discovery or development in new mines, and the cry has gone forth that new Cripple Creeks must be found in order to stimulate the industry. That the old spirit is still alive is shown in a broader interest and greater activity in prospecting and development, more evident now than has been apparent for some years past, and undoubtedly some good will result. But in another direction and in a far more important manner the true Western pioneer spirit shows itself now in the willingness to accept and attack new methods of metallurgical treatment.

Indeed, of greater importance than the discovery of new and rich mines, is the development of improved metallurgy for the treatment of ore already known to exist and, in some cases, already mined. As a measure of conservation of our natural resources improved metallurgy is of fundamental importance and we may look to see greater results accomplished in the immediate future by solving metallurgical problems than from the discovery of new mining districts. The most active metal-mining districts in the West to-day are those in which the metallurgical problem has been solved. The "dead camp" is the one that abounds in ore that cannot be treated at a profit. The main point is that the West is fully alive to the problem of the situation, and that means the West will solve it by its own energy and by its willingness to try new methods even if not yet completely proven. The Noble electric iron ore reduction and steel plant, now going up in California, is a true expression of this new metallurgical pioneer spirit.

In general it is evident that the limits for successful ore treatment are gradually widening. Not that any new and startling process is proving a panacea for all troubles, but accessory devices and schemes applied here and there in conjunction with well known and proved processes are raising the percentage of extraction and extending the application of the processes to a wider field. It is a fact that an old slag dump of a smelter near Denver which was dismantled not so long ago is now being treated for its metal content at a good profit.

In concentration where great waste has hitherto existed, improvement is being made by the use of flotation as an accessory process. Dry chlorination holds out some hope for the treatment of complex ores; in two western plants it will soon have an excellent chance to show what is in it of commercial success. Cyanidation is being extended by the aid of additional chemicals; and from physical chemistry the phase rule is borrowed to base on it an interesting modification of cyanide practice (as described in the suggestive articles of Mr. Lowden and Mr. Rothwell in our July issue and in this issue respectively). Electrolytic schemes are in sight which may prove of value in conjunction with present processes, while the electric furnace is anxiously awaited as one means of smelting zinc ores carrying other metals. In short, Western metallurgy is ready to make use of all latest advances in chemistry, electrochemistry, and physical chemistry. The outlook is very bright and this journal will rejoice in recording how this new phase in the evolution of Western metallurgy is carried through to success by Western hospitality.

Toronto Meeting of the American Electrochemical Society.

The twentieth general meeting of the American Electrochemical Society will be held in Toronto, Ontario, Canada, from September 21 to 23 (Thursday to Saturday).

Sessions for the reading and discussion of papers will be held on the morning and afternoon of Thursday, while a smoker with entertainment by section Q is scheduled for Thursday evening.

On Friday morning there will be a session for reading and discussion of papers, probably at some golf club. In the afternoon a golf tournament, etc., will be held, and in the evening a banquet at McConkey's restaurant.

On Saturday morning an excursion will be made to the Canadian General Electric Company's plant at Peterboro, with the return trip through the locks to reach town in time to catch the 5 p. m. boat out of town.

The full program of papers will be published in our next issue. Members having further papers to present, should notify before Sept. 1st either the chairman of the committee on papers, Mr. F. A. Lidbury, Oldbury Electrochemical Company, Niagara Falls, N. Y., or the Secretary of the Society, Prof. Jos. W. Richards, Lehigh University, South Bethlehem, Pa.

The local committee for the Toronto meeting consists of the following gentlemen: Dr. W. Lash Miller, Chairman; Wallace P. Cohoe, Chas. Danforth, Saul Dushman, Thos. C. Irving, Jr., J. A. Kaemmerer, Peter Kirkegaard, Jas. W. Moffat, L. V. Redman, Thos. D. Robertson, A. O. Tate, Geo W. Watts, O. H. Wurster, and any Niagara Falls members as is deemed advisiable.

The Iron and Steel Market.

While August has been rather a dull month as to the placing of new business in iron and steel, and has seen considerable wavering of prices, the trend of production has been slightly upward on account of the fairly heavy buying in the latter part of July and on the whole the developments of the month were reassuring, for the expectation was that this year July and August would prove very unsatisfactory. It may be well to observe that the iron and steel trade in the past two months has not been in as good condition as has been widely reported. Unusual efforts have, indeed, been made in some quarters to spread the impression that the iron trade has been rapidly improving since about June 1, when as a matter of fact there has been little real improvement and the principal cause for congratulation is that what was expected to be a very trying period has been passed without serious trouble. Production, as measured by pig iron, has decreased month by month since March, whereby production in July was at the rate of about 21,500,000 tons a year, about 4,000,000 tons less than the April rate. Late in July idle furnaces began to be put in blast and this increase in number has continued through August. On account of the high humidity always prevalent in these months, the additional furnaces have not served greatly to increase production, and indeed there is reason to infer that they were put in largely to maintain, rather than to increase, the rate of output. Under the system of individual ownership which formerly prevailed, production almost invariably suffered a large decline in the midsummer months, because individual interests could not afford to blow furnaces in and out by reason of such a temporary influence. With the United States Steel Corporation the case is different. Having so many furnaces, it always has a few which are about ready to go out, while it has others which have been relined and can readily be blown in. There is no doubt, however, that August has produced somewhat more iron than July, and it is certain that stocks, both merchant stocks and those of steel works, have been drawn upon at a fairly heavy rate. The steel works stocks are now very light, while the merchant stocks, although decreasing somewhat, are still very heavy.

Prices of finished steel products evinced more irregularity in August than in July, although there were important irregularities in the former month. Practically all the important finished products except rails have been subject to cutting, and indeed there is little semblance left of the controlled market which existed for so long.

An important feature of the market as now made is that the cutting usually proceeds by very small increments. There is no slashing of prices, but rather the order is frequently obtained by a slight concession, a relatively small fraction of a dollar per ton. A definite effort is being made by selling departments to shake off the habit of deep cutting and to substitute the method which has always prevailed in the foreign market of quoting prices very closely, allowing the fraction of a shilling or mark per ton to turn the scale. Another influence is that the cost level has been rather closely approached by the successive declines which have occurred since the market reached a top point late in 1909.

Steel bars for prompt shipment are being sold regularly at 1.20 cents, Pittsburgh, when the specifications are at all desirable, and this price is sometimes shaded slightly on the most desirable orders, the regular or nominal market being 1.25 cents. Plates are being shaded regularly $1 a ton from the regular price of 1.35 cents, and occasionally the lower figure is shaded. Structural shapes are fairly firm, 1.35 cents being only occasionally shaded. Sheets are being shaded $1 a ton in most districts, and in Ohio and Chicago territory are frequently shaded $2 a ton. Tin plates can be purchased at 10 cents per box concession for early delivery.

The mills insist that little if any forward business is being booked at cut prices, and that as order books fill up the tendency to cut will gradually disappear, although it is presumed that as the effort is made to withdraw cut prices a spell of particularly dull business may be experienced. The difficulty is that the mills are not satisfied with running somewhat heavier than a month or two ago, but are individually endeavoring to work up to full operation, and that buyers will not purchase for forward delivery as long as they see that prompt material can be purchased at a concession, so that it is far from evident that the market is really lining up for an actual restoration of the nominal quotations as the real trading basis.

Pig Iron.

Nearly all the Southern producers have withdrawn the price of $10, Birmingham, and are quoting all the way from $10.25 to $11, but there is still a little iron to be picked up at the $10 figure for early delivery, and consumers show no disposition to pay any advance, so that Southern iron has been very quiet. In the North prices are not materially changed, except that in eastern Pennsylvania basic has advanced about 50 cents. We quote: f. o. b. Birmingham, $10 to $11 for No. 2 Foundry; delivered Philadelphia; basic, $14.75 No. 2 x, $15, f. o. b. valley, 90 cents higher delivered Pittsburgh; Bessemer, $15; basic, $13; No. 2 foundry, $13.50; malleable, $13.25 to $13.50.

Steel.

There has been some shading of regular billet and sheet bar prices, which are $21 for billets and $22 for sheet bars, f. o. b. maker's mill, Pittsburgh or Youngstown. Open market sales, however, have been light, consumers being well covered by contracts. Rods are $27, Pittsburgh.

Finished Products.

Regular prices on finished steel, f. o. b. Pittsburgh, except where otherwise stated, are as follows, but are subject to considerable shading, as already noted:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, 1.35 cents for tank quality.

Shapes, 1.35 cents for beams and channels, 3 to 15-inch, inclusive, zees, and angles 3x3 and larger.

Steel bars, 1.25 cents, base; iron bars, 1.25 cents to 1.30 cents, Pittsburgh or Youngstown; 1.27 cents to 1.30 cents, Philadelphia, and 1.20 cents to 1.25 cents, Chicago.

Wire nails, $1.70, base plain wire, 1.50 cents, base.

Black sheets, 28-gage, 2 cents; galvanized, 3 cents; blue annealed, 10-gage, 1.50 cents; painted corrugated roofing, $1.40 per square; galvanized, $2.55.

Tin plates, $3.70 per base box.

The Western Metallurgical Field

Indexing Metallurgical Literature.

Engineers who appreciate the value of indexing the rapidly growing literature on metallurgical subjects will welcome the work recently published in the April, 1911, *Quarterly* of the Colorado School of Mines. The article is by Robert M. Keeney, Fellow in Metallurgy at the School, and consists of an extension of the Dewey decimal system of classification applied to metallurgy, metallography and assaying. The work is exhaustive and gives a complete system of indexing the subjects mentioned.

In the Dewey system the entire field of knowledge is divided into ten principal divisions, numbered from 0 to 9. These are, 0, General Works; 1, Philosophy; 2, Religion; 3 Sociology; 4, Philology; 5, Natural Science; 6, Useful Arts; 7, Fine Arts; 8, Literature; 9, History. Each of these main divisions is further subdivided into ten sections, and the process of decimal division is repeated as often as found necessary. This makes it possible to represent the proper classification of an article or subject by means of figures as shown in the following example: Thus, 669 means Class 6 (Useful Arts), Division 6 (Chemical Technology), and Section 9 (Metallurgy). In carrying out the system, a decimal point is placed for convenience after every third figure. To illustrate further, we have 669.145.412 (Bessemer Converter Tuyeres); 669 as already explained means Metallurgy; 669.1 the metallurgy of iron and steel; 669.14 the manufacture of steel; 669.145 the Bessemer process for manufacture of steel; 669.145.4 the Bessemer converter; 669.145.41 the construction of the Bessemer converter; and 669.145.412 Bessemer converter tuyeres.

While it is clearly impossible to include all the terms used in metallurgy, metallography and assaying, enough can be given to enable the user to assign the proper number to almost any subject that may arise. The decimal system of classification is adapted to the indexing of books, notes, clippings from journals, drawings and catalogs. In indexing current literature where the number of cards becomes large, it will be found convenient to keep the card index in order of the numbers of the decimal system rather than by alphabetical order.

Engineers can use the system in three ways: First, to keep a card index of technical literature; second, to file clippings from journals, notes, drawings and catalogs, without a card index; or third, for a combination of the card index with the filing system, so that a reference to a journal from which there is no clipping at hand can be recorded with the other references. In filing clippings, an envelope 7¾ inches long by 5¼ inches wide is a convenient size.

Mexican Labor Troubles.

Following close on the heels of the revolution, which seriously hampered mining and metallurgical operations in Mexico for several months, comes a period of unrest in labor circles which also threatens to impede progress for some time. Native peon labor is dissatisfied with several conditions under which it works. First, wages are believed to be too low, and an increase of from 25 to 100 per cent is asked from the various mining and smelting companies. The peon wage ranges from one to two pesos per day. Secondly, there is objection to some arbitrary deductions which are made from wages to cover medical attendance and hospital fees. This has been an item objected to in many other places, so that it is not surprising to find it prominent in the present Mexican troubles.

The northern part of the republic is most affected. In the state of Chihuahua there are about half a dozen camps in which serious labor strikes have occurred. The Chihuahua plant of the American Smelting & Refining Company has been closed since June 27 on account of a strike among the peons. The shut-down is apparently for an indefinite period, as the company gave its American employes thirty days' notice of discharge. The camp of Parral, Santa Barbara and Santa Eulalia also are threatened with serious strikes, and as there are many important mines and mills at these centers, the outlook is not encouraging. The opinion exists among those conversant with the country, that no definite settlement of labor conditions can be expected until after the national election in the coming October. The present dissension is not altogether unlooked for as a natural consequence of the recent revolution, and the control of the situation will be one of the problems of the reconstruction period. No doubt professional agitators will try to take advantage of the situation, but it is hoped for the good of the country and the mining industry that peaceful industrial conditions will be reached this year.

Spelter Statistics for 1911.

Statistics compiled by the United States Geological Survey show that the production of spelter or metallic zinc from ore for the first six months of 1911 was 140,196 short tons, a gain of more than 5,000 tons over half the record production of 1910. Of this production, 5,135 tons was made from foreign ore. Spelter stocks were reduced from 23,232 tons to 17,788 tons. Imports remained about the same, but exports were nearly double those of half the preceding year. The apparent consumption of spelter was 135,497 tons, an increase of more than 12,000 tons over half of 1910, but about the same as in half of 1909. The average price of spelter at St. Louis for the period was 5.36 cents per pound, the London average being 0.2 cent less per pound. During the latter part of May and the first of June the average London price was about 0.1 cent higher than the corresponding St. Louis prices. Under this stimulus the May exports of spelter, zinc ore, and dross were largely increased over those of the preceding months.

Camp Bird, Ltd.

This company, which owns the Camp Bird mine in Colorado and the Santa Gertrudis mine in Mexico, has recently made some important changes in its financial policy. It appears that at the time of the purchase of the Santa Gertrudis, in the latter part of 1909, it was necessary to raise between four and five millions of dollars rather quickly or lose the opportunity to purchase the property. In order to do this the company issued debenture stock which it was to redeem at the rate of about $500,000 per annum, with interest amounting to about $150,000 per annum. Although the terms of this issue were rather stringent, nevertheless the directors felt that the mine was too good to lose, and acceded to the terms.

Later developments in the Santa Gertrudis showed that the mine promised far greater profits than were at first realized, and the directors felt that it was too valuable a property to be subject to the mortgage represented by the debentures, and that the company should take steps to redeem the debentures at once and remove the risk of losing the property through some unfortunate circumstance during the next five years. It was therefore proposed to increase the capital of the company by the issue of 750,000 shares of one pound sterling each, being preferential shares drawing 7 per cent, and sharing with the ordinary shares in any surplus remaining after paying the usual 20 per cent on the ordinary shares. By this arrangement the company would remove the possibility of losing a valuable property for a small mortgage before the debentures were paid

in full in 1917, and the only expenditure which would take precedence over dividends on the ordinary shares would be the interest on the new stock, amounting to about $225,000, instead of $650,000 as under the present arrangement.

At a meeting of the stockholders, held in London on July 18, 1911, a majority interest voted to increase the capital as above outlined.

The latest reports from the company's properties are to the effect that the Camp Bird reserves have been increased by substantial bodies of ore, and that on July 1 there was a further profit of about $350,000 in sight. Profits are expected at the rate of about $50,000 per month for the next six months. At the Santa Gertrudis the company has developed about 1,200,000 tons of ore, which is estimated to give a net profit of nearly $6,000,000. In addition to the ore blocked out there is a large tonnage of low grade ore left in the mine as filling. This will be milled with the high grade ore.

Spelter Improvements.

It is reported that the American Smelting and Refining Company is to make improvements at the East Helena, Montana, plant, which will cost about $75,000. The lead smelting business in the West is generally in a poorer condition than in years gone by, and at the same time the competition in some states is keener. The recent entrance of the International Company into the field has stimulated the business somewhat, and other companies will have to meet the competition of a new and well equipped plant. It has been reported before that the East Helena plant was to be closed, but the recent decision to improve it effectually disposes of this rumor.

Improved Market for Lead Ores.

The entrance of the International Smelting Company into the field of lead smelting is expected to stimulate the production of that metal by reason of the reduced rates at which lead ores will be treated. Recently several good contracts have been obtained by this company, and it is certain that they have been secured only at rates advantageous to the shipping companies. The output of the Hecla Mining Company, in the Coeur D'Alene district, Idaho, is to go to Tooele for the next five years. This ore formerly went to the Ohio & Colorado plant at Salida, Col. The entire ore and concentrate production of the Monarch mine, near Murray, Idaho, also has been contracted to the International company. These two sources of lead are worth a great deal to any company engaged in custom lead smelting, as the product is steady and of good quality. The effect of the activity of the International company's agents is to place the lead producer in a more favored position than he has enjoyed for some time past.

CORRESPONDENCE

Fixation of Atmospheric Nitrogen.

To the Editor of Metallurgical and Chemical Engineering:

Sir.—I should be glad to know how Mr. John Woods Beckman can write (Vol. IX, No. 7, page 340): "Recently the Birkeland and Eyde process has been abandoned and the Schönherr process of the Badische Anilin Fabrik has been installed and is extensively operated at Notodden, Norway, where the company's factory is located."

Not a single furnace of Schönherr's system is burning at Notodden, but 35,000 kw is operated there in Birkeland-Eyde furnaces.

University of Kristiania, Norway. Kr. Birkeland.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir.—Your July number contains a letter by Mr. John Woods Beckman, entitled, "The Manufacture of Air Salpeter, a Well-Paying Industry."

While the article as a whole is quite correct, the author is misinformed on some points as regards our company, and as we are the owners of the Birkeland-Eyde patents for the nitrogen fixation process and of the only nitrate manufacturing plant existing in Norway today, we beg to make the following statements:

The Birkeland-Eyde process has not been abandoned; on the contrary, the entire plant at Notodden is employing the Birkeland-Eyde process exclusively.

Our company is capitalized at Francs 41,166,250 of which Francs 4,500,360 is preferred and the remainder common stock.

Norsk Hydro-Elektrisk Kvælstofaktieselskab.
Kristiania, Norway.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir.—With respect to the third paragraph of the letter of Mr. J. W. Beckman in your July issue I wish to make the following correction:

The several electrical furnaces of the Notodden plant which were formerly of the Schönherr (Badische Anilin und Sodafabrik type) have all been replaced recently by the furnaces of the Birkeland-Eyde (Société Norvégienne de l'Azote et Forces Hydro-Electriques) type.

In the large plant at Rjukan to be built jointly by the above mentioned firms, furnaces of both types will be installed in order to definitely determine which of the two types gives the best results in commercial service.

With reference to the chemical part of the Rjukan plant it had been decided some time ago to use the absorption towers of the Badische Company. It has been decided recently, however, that absorption towers of the Birkeland and Eyde type will be used at the Notodden plant.

It may be of interest to remark that the Notodden works, of which the present capacity is from 50,000 to 60,000 horsepower, belong entirely to the Société Norvégienne de l'Azote et Forces Hydro-Electriques, using and exploiting the Birkeland & Eyde patents.

Paris, France. A. S. Garfield.

Continuous Cyanidation.

To the Editor Metallurgical and Chemical Engineering:

Sir.—I have read with great interest Mr. Rothwell's valuable article in your issue of July, 1911, in which he suggests a continuous treatment method of cyanidation. The method he describes so clearly consists of all sliming, continuous agitation —which is apparently appreciated by all cyanide men since its introduction at the Esperanza last year—and continuous decantation.

It will probably interest Mr. Rothwell very much, and also your readers, to know that the essential features of the latter were first used in practice, I think, about nine years ago by Mr. John Randall at the Highland Chief Mill near Deadwood, S. D., and that several plants are now in operation along the same lines.

Mr. Randall grasped the most important point, which is the passing of the slime and its successive use for the dilution of the increasingly rich pulp as the solution passes toward the head of the series. This makes it necessary to precipitate the solution only after it has been several times enriched, thus reducing the amount to be precipitated to a small fraction of that otherwise required. He operated, as did the Denny brothers about the same time in South Africa, with large settling cones and attained fair technical results, although troubled with building up of solids on the sides of the cones, until the property was shut down for lack of ore.

It is unfortunate that Mr. Randall did not publish his results. The only reference I have seen to this is in a review of cyanide progress, by R. W. Gordon, in your issue of January, 1911, in which Mr. Randall is given credit for pioneer work along this line.

The advent of the Dorr thickener, which rendered continuous settling to a very thick pulp feasible, made the matter more

attractive and we suggested it to friends in 1906, but through pressure of other work it was not taken up seriously until 1910, when two plants— one to recover the values entirely by decantation, the other to use continuous decantation to reduce the values to a low point ahead of an Oliver filter—were installed and are now in successful operation.

A number of articles have appeared on the subject in the last year or two, though many writers, such as Mr. F. R. McCann, in *Transactions* of the Mexican Institute of Mining and Metallurgy, July 1909, while appreciating the advantage of continuous decanting, failed to grasp the idea of the reverse movement of the barren solution and so were perplexed as to the disposal of accumulated low-grade solution.

A short article by L. B. Eames, which appeared in the *Mexican Mining Journal* for September, 1910, under the rather misleading title of "Discussion," and which for that reason has probably not attracted the notice it merits, gives a very clear description of "Continuous Decantation." Besides a flow sheet, Mr. Eames has given an algebraic method for determining, from assumed conditions, exactly what the mechanical losses should be, which will be greatly appreciated by any one contemplating the use of this method.

Mr. Rothwell's flow sheet, covering as it does almost all conditions likely to be met in practice, is worked out so well that the cyaniding fraternity will find it of great value. I would call attention to one point, however, and that is that in the flow sheet given if the strength of solution used was two lb. or over, the mechanical loss in gold and cyanide would be less if the barren solution was added to the thickener next to the last. This loss would, of course, be further reduced by the use of cyanide solution instead of water in the batteries.

The remarkable percentage of recovery of dissolved values with the precipitation of a relatively small amount of solution, which should be obtained by this method, is well shown by the following figures, calculated from the conditions assumed:

1. Value per ton assumed to be dissolved from the ore before the pulp reaches the decantation system	$4.00	$4.00	$4.00	$8.00	$8.00	$8.00
2. Moisture in pulp discharge from thickener, per cent	37.5	50	50	50	50	50
3. Tons solution precipitated to $.02 per ton of ore	1.8	3.	4.	3.	4.	3.
4. Total thickeners used, the underflow into the last being diluted only with an equal amount of water to secure the minimum loss of cyanide	4	4	4	4	4	5
5. Loss of dissolved value per ton of ore	$ .04	$.044	$.026	$.080	$.044	$.026
6. Percentage of dissolved value saved	98.9	98.9	99.3	99.0	99.4	99.6

Undoubtedly within a short time there will be data of actual operations by this method published to show how closely the theoretical results have been attained in practice.

JOHN V. N. DORR.

Denver, Colo.

Ferro Titanium.

To the Editor of Metallurgical and Chemical Engineering:

SIR.—In your issue of July, 1911, page 348, there is an article by Dr. Hans Goldschmidt, in which he speaks of alloys produced by his aluminothermic process, and contrasts them with other alloys.

Regarding Ferrotitanium, he says: "This carbon-free ferrotitanium, containing 25 per cent of titanium, is used now quite extensively as an addition to steel for making rails and rolls. This ferrotitanium made by the aluminothermic process dissolves very easily and uniformly in the molten steel. It has a small intentional content of aluminium as this increases its solubility.

"The experience of metallurgists has shown that as a rule carbon-free metals dissolve more easily than metals containing carbon, since the latter contain carbides—that is chemical compounds with carbons."

It has been my privilege to have considerable experience with ferrotitanium alloys, in both steel and iron, which has been chiefly gained with the so-called 10 per cent and 15 per cent alloys of the Titanium Alloys Manufacturing Company. Based on this experience, these alloys can be thoroughly recommended. As is well known, these domestic alloys are not carbon-free, as they contain from 6.00 to 7.50 per cent total carbon, and so would appear to come under Dr. Goldschmidt's classification of alloys containing carbides. This, however, is not the case, for almost the whole of the carbon is present in the free or graphitic condition. The carbon in chemical combination varies from not more than 0.1 to 0.25 per cent, so that the amount of titanium carbide present, if any, must, therefore, be very small. The action of titanium, is some respects seems to be a good deal like that of silicon decomposing the carbide of iron, and precipitating the carbon as graphite.

When the 10 per cent or 15 per cent alloy is added to a bath of molten steel solution quickly takes place. Part of the graphite probably unites with iron forming carbide of iron, while a part rises quickly to the surface because of its low specific gravity, and is lost in the slag.

This opinion is supported by the results obtained in practice, for the carbon in the final steel when these alloys are used is generally slightly raised, but not to the amount expected if all the graphite were absorbed. It is extremely improbable that at the temperatures worked with, any titanium carbide is formed.

The Goldschmidt alloy when analysed shows that a considerable amount of aluminium is present and most probably unavoidably. This is present only in traces in the Niagara Falls alloys. In one sense its presence may be beneficial, but in another it is harmful. It may help the solubility of the low-carbon when added to the molten bath, and in this respect its action is necessary and helpful. After fusion, most of the aluminium will be oxidized to dry powdery alumina. This will tend to slag off, together with the oxide of titanium and other slag-making materials. Its action will be to decrease the fusibility of the slag, making it liable to be held in the metal, and so tend to defeat one of the chief advantages of using ferrotitanium, namely, a final clean solid steel or iron.

G. B. WATERHOUSE.

Lackawanna Steel Co., Lackawanna, N. Y.

Expropriation of Mining Rights.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I invite the friendly criticism of your journal on my proposed new (old) legislation permitting expropriation of mining rights (even *in invitum*) by strangers to the title in the soil. Some such legislation seems demanded and essential to the proper development of the mineral resources of States like those of the Atlantic seaboard, where obtains the ancient English common-law theory that ownership of the soil carries with it the title to the centre of the earth.

Rockland, Maine. C. VEY HOLMAN.

[As noticed in our May issue, page 278, a paper was presented by Mr. Holman at the last meeting of the American Electrochemical Society on the advantages of Maine for electrochemical industries, giving details of the available water powers and mineral resources of Maine. This paper was pub-

lished in full in Vol. 19 of the Transactions of the Society, page 351. Mr. Holman's argument is that the development and exploitation of these mineral resources seems wholly impossible under the present laws, owing to the unprogressiveness or unwillingness of their nominal owners, the holders of the land below which they lie, to undertake their proper working. For this reason Mr. Holman intends to have a bill introduced at the next session of the Legislature of Maine, providing a method by which mining of ore bodies in the lands of owners who are unable or unwilling themselves to develop them can be legally undertaken by strangers to the title who are willing to assume the risks. It is interesting to note in this connection that in his address on the mining industry and the public lands, delivered on Aug. 9 at the Michigan College of Mines, the Director of the U. S. Geological Survey, Dr. George Otis Smith, recommended that there should be made possible by legislation "the separation of surface and mineral rights wherever the two estates have values that can be separately utilized."—Editor.]

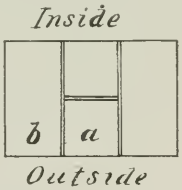
Flow of Heat Through Furnace Walls.

To the Editor of Metallurgical and Chemical Engineering:

Sir: In the recent Bulletin No. 8, by Messrs. Ray and Kreisinger, issued by the Bureau of Mines, and noticed briefly in your July issue, page 382, the conclusion is drawn from their experiments that a solid wall is a better heat insulator than one of the same total thickness having an air space not filled with any material, especially when this air space is near the hot side; also that when such an air space is filled with a loose granular material it insulates better than a solid wall.

These conclusions, if correct, seem to be quite important and valuable, although the most important one, namely, the one referring to the better insulation of loose, granulated material, is not new.

It seems to the writer, however, that the subject needs further investigation, as there are some discrepancies which seem to require an explanation. It is a well known fact, known probably to all blacksmiths, that when an iron bar which is cracked transversely is heated on one side of the crack, it may become red hot up to the crack, while it is still black on the other side. The crack may be so small as to be invisible to the eye, in the cold piece; in fact, it is believed that this phenomenon has been used to indicate the existence of invisible cracks.



This means, of course, that there is a very pronounced drop in the heat gradient at the crack, and this in turn means that the resistance to the flow of heat across the air space of the crack (or the counterpart of resistance when the heat is transmitted by radiation) is enormously greater than that of the iron. This is apparently in direct contradiction to the conclusions drawn in that bulletin. An air space is a wide crack.

A possible explanation of the discrepancy may be that the iron has such a very good thermal conductivity that the air space is poor relatively to it, and that the conductivity of fire brick is so very much poorer than iron that it is better than air. This, however, seems hardly likely, for it is evidently the air spaces in the interstices of the loose granular material that gives it its higher resistance. Moreover, the writer has an indistinct recollection having noticed that a glass rod with a crack behaved like the iron one, and the thermal resistivity of glass is of the same general order as that of refractory materials.

Moreover, the writer noticed recently in an electric furnace that the temperature of the brick at *a* in the above sketch, Fig. 1, was considerably cooler than that at *b*; the difference was so great that it was easily noticeable to the touch. This was no doubt due to the joint which separated the one from the inside of the furnace. If such a cheap and simple thing as a joint is such a good heat insulator, and this appears to be so, it would be unfortunate if the conclusions drawn in that bulletin were to be interpreted to the contrary.

It might be interesting to try heating the end of a transversely cracked fire brick or rod of insulating material to see whether it would behave like the iron bar. It would probably have to be done in the dark; moreover, the cooler end ought to be water cooled and the hot end ought to be heated quickly, for in course of time the heat would no douht find its way to the colder side by passing around the end of the crack. Mere differences of temperature alone are not measures of thermal resistances any more than voltages are measures of electrical resistances.

Fig. 2

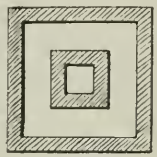


Fig. 3

If the electrical conductivity is any measure or indication of the thermal conductivity it may be of interest to note here that the writer has repeatedly drawn an alternating-current arc from the surface of a hot magnesite fire brick which formed a part of the furnace wall, the metallic charge in the furnace being the other pole of the circuit. The magnesite was scarcely visibly red.

According to the above-mentioned bulletin, filling an air space with loose granular fire brick gives that space an effective resistance which is greater than either of its two constituents, air and fire brick, would have by themselves. This seems to call for an explanation. Perhaps it lies in the resistances at the surfaces of contact of air and fire brick, as this surface is enormously greater for granular materials.

The following is another curious deduction from the formula in this bulletin which leads to apparently absurd conclusions, although they may be correct. Let Figs. 2 and 3 represent two double-walled furnaces, in the form of cubes, which are alike in every respect except that the air space within the walls in Fig. 3 is double that in Fig. 2, the thickness of each of the two parts of each of the brick walls being the same in both.

Let it be assumed for a first trial calculation that the leakage of heat is the same in both. The temperatures at the two bounding surfaces of the air space will then, of course, be the same, as the amount of heat radiated is independent of the thickness of the air space. But the cross section of the outer wall perpendicular to the flow of heat is much greater in Fig. 3 than in Fig. 2; suppose it to be twice as great in this particular case, then the drop of temperature in it would be only half as great as in Fig. 2 because the flow is the same, hence the temperature of the outside of the furnace would be considerably greater in Fig. 3 than in Fig. 2; the larger one would be the hotter. But with a higher temperature of the outside surface more heat would pass into the air; besides, the surface is now also larger, which still further increases the heat flow.

It follows, therefore, that the heat flow or leakage will not be the same in the two cases, as was assumed at the start, and that it will be *greater* for the furnace shown in Fig. 3. In other words, a larger air space insulates worse than a smaller one, which is apparently paradoxical. Yet it seems to lead to the conclusion that the thinner the air space the better the insulation; hence a joint between two abutting bricks ought to be a good insulator.

The above illustrations seem to show that it is not safe to jump to conclusions too quickly, as the problems may not be as simple as they appear at first sight.

Philadelphia, Pa. Carl Hering.

The Counter-Current of Continuous Agitation, Decantation, and Dilution Applied to the Cyanide Process

BY JOHN E. ROTHWELL.

The present practice in the treatment of a gold and silver ore by the cyanide process, when using the agitation method, requires the mixture of a barren cyanide solution with the ore at its highest value; then by the continued agitation of this mixture, dissolution of the gold and silver is accomplished and the metal transferred to the solution, the rate of dissolution proceeding more slowly as the point of chemical equilibrium is approached. Thus it is necessary to agitate the mixture for such length of time as required to obtain the highest economical transfer of the metal into solution, and in some cases it means a retreatment of the charge after the removal of the first solution, in order to obtain a satisfactory recovery of the metal content of the ore.

The ideal and logical method of continuous treatment and operation is the reverse of this method—that is, the solvent lowest in metal value and highest in free cyanide should be applied to the ore after the greater value in metal has been dissolved. This solution is then separated from the ore and applied to ore of higher value, and so back up the line of treatment until the highest grade of solution is in contact with the ore at its maximum value, after which it is separated and passed to the precipitation department, where the metal content is precipitated and recovered and the barren solution returned to the mill system to go through the work of gathering up value again in the same sequence of operations.

It is known that if cyanide solution has approached the point of chemical equilibrium on any single quantity of ore, and is then withdrawn and another solution containing free cyanide, but not necessarily barren in metal value, is brought in contact with this ore, a further dissolution of the metal takes place that it was not possible to obtain with the first solution, and that in the repetition of this sequence of operations the point of saturation is approached.

Based on this condition, which in reality is simply the application of the "phase rule," I have designed a method for carrying out these operations in a mechanical and continuous manner.

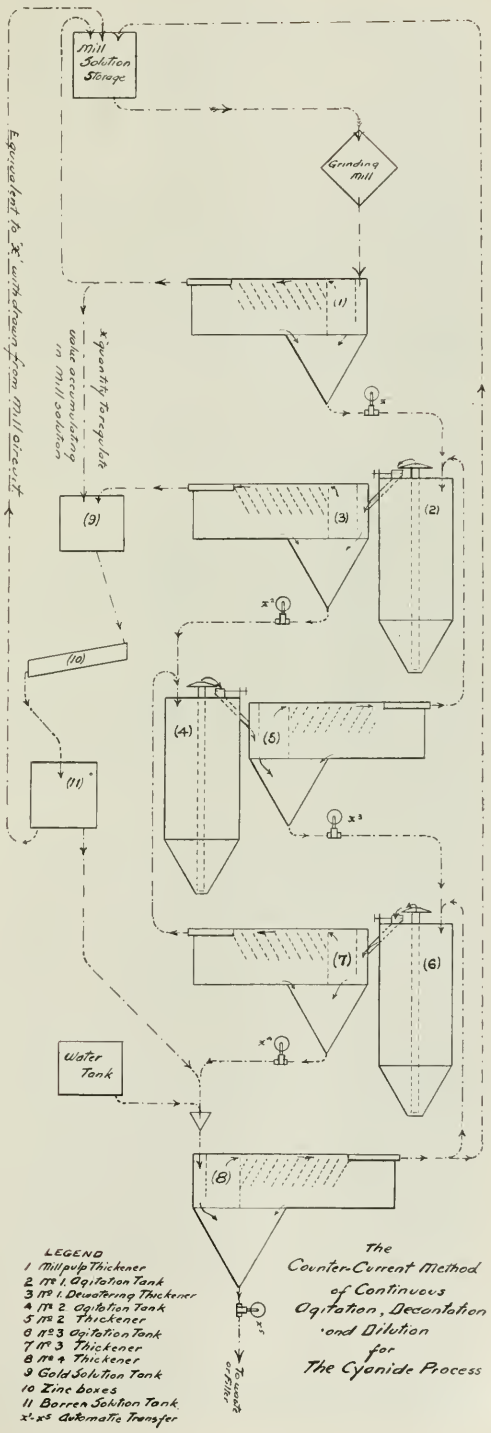
The method involves no change in the class of equipment employed in the ordinary continuous method of agitation, decantation and dilution as illustrated in a former article* of mine covering the continuous treatment of an ore, and as generally employed in mills using agitation tanks and dewatering thickeners. The only requirement is a re-arrangement of this equipment.

Reference is made to the graphic flow sheet accompanying this article, which illustrates the new arrangement, and the counter-current flow of solvent through the stream of ore. In this illustration, it will be noted that instead of placing the agitation tanks in continuous series, followed by the continuous decanting and diluting tanks, we place the agitation tank between the thickeners. The agitator then receives the thickened pulp from the thickener ahead of it, and the decanted solution from the thickener following it; thus it will be observed that the solvent is taking up value from the ore of lowest value and passing it up to the tank containing a higher value, while the ore is losing value as it passes down through each tank of the series toward the discharge.

The highest efficiency is obtained by having as thick a pulp as possible in the underflow, so that a minimum of dissolved value is contained in the moisture passing with the solids; and the greatest dilution is obtained from the counter-current flow, also the point of chemical equilibrium is removed as far as possible.

In describing the method and equipment I will not take up

*This journal, Vol. IX, No. 7, July, 1911.



the preliminary work of the preparation of the ore, as this will have to be suited to the requirements of the ore, with reference to amalgamation, concentration, fine grinding or preliminary treatment by oxidizing or other solutions to prepare the ore for the subsequent treatment in the cyanide solution.

The flow sheet shows a simple ore ground in a weak cyanide solution, and a comparatively small extraction of the metal values during the preparation.

For the operation of the counter-current method the agitation tank that can be used to the best advantage is the type in which the rising current of pulp is carried up through a central tube. At the top of this tube is a distributor, over which the flow of pulp passes, and a proportional part of this flow is cut out with a sampling vane located above the surface of the pulp in the tank. This position of the sampling vane forces the incoming flow of pulp and solution to pass from the top to the bottom of the tank before any part of it can possibly pass through the vane to the thickening tank, thus insuring a thorough mixture and agitation. The distributor may be of the rotating type or simply an inverted cone of definite diameter at the base. The sampling vane is located just below the perimeter of the cone, or in the concentric path of the rotating distributor, thus a uniform sample of the content of the tank is passed to the thickener. The adjustment feature of the vane permits of controlling the level of the pulp in the tank so the amount of outflow is equal to the inflow.

The thickener tank that works into the method is the one shown in the diagram, as it permits of a close and short connection to the agitator. This is a tank with a large cone and extended rectangular settling tank with inclined baffles that give it a very large settling area, in which the finest solids have a maximum time to settle and give a clear overflow at the weir. The weir is placed at the opposite end of the tank from the feed and the solids that settle to the flat bottom of the tank are moved to the cone by a slow-moving reciprocal rake. The large cone forms a receptacle for the storage of considerable thick pulp, thus insuring a very thick product, also a place in which any fluctuations in the flow from the grinding mill can be taken care of and the flow through the rest of the system maintained uniform.

The automatic transfer is a special type of diaphragm pump, capable of handling a very thick pulp, and may be regulated both in speed and stroke to give a definite quantity of feed in a unit of time.

In the arrangement of the series of thickeners and agitators to obtain the greatest economy in power, the tanks (2) and (3) of the series will be the lowest in the mill, the top of (4) and (5) will be about 2 ft. above the top of (2) and (3), while the top of (6) and (7) will be about 2 ft. above (4) and (5); (8) will be only high enough for the overflow to go by gravity into (6). The water tank and (11) will be located above (8); a meter placed in the outflow pipe from (11) and water tank regulates the flow of diluent into the series and registers the quantity passing. The automatic transfer takes advantage of the hydrostatic head in the thickener, thus reducing the lift necessary to discharge the pulp into the following agitator. The thickened pulp being the smallest quantity to be handled, means the minimum of power required in the system. If we figure, for example, a plant treating 100 tons a day, and the transferred pulp contains 50 per cent moisture, we then have approximately 3.26 cu. ft. flow per minute, equal to approximately 280 lb. to be raised an average height of about 6 ft. at each transfer, or 1680 ft.-lb. With the five transfers shown in the flow sheet this would be 8400 ft.-lb. Allowing 100 per cent for friction, we require very little over ½ hp for the whole transfer.

The arrangement also contemplates the overflow from (3) by gravity into (9), thence to (10) if zinc boxes are used; the barren solution is then pumped to (11). The elevation of this tank is only enough to flow back to (8) and need not exceed 30 ft. If we follow the example of 100 tons being treated, and take the quantity of solution precipitated at 3 tons for one of ore, *i. e.*, 300 tons per day, this will require, if a pump is operated continuously, 12,500 ft.-lb. per minute, which, allowing 100 per cent for friction, is about 2/3 hp.

If we take the power required to operate the air compressor for agitation in the agitation tanks at 5 hp per tank, this being about an average in the usual practice at the present time, and using three agitation tanks, we have 15 hp for this purpose. Allowing liberally for friction and contingencies, 20 hp will be ample for the whole work, or about 1/5 hp per day-ton for this department of the mill. Present practice is considerably in excess of this figure.

For the flow of the ore and counter-current flow of the solvent, reference is made to the diagram.

The following descriptive flow sheet will give the method of operation:

(1) Mill pulp thickener; receives all the flow from slime classifiers, overflow goes back to mill solution tank, except the small amount sent to (9) for precipitation if there is a tendency on the part of this mill solution to build up in value. This solution in some cases instead of being sent to (9) might be sent to (7) or (5), whichever tank should happen to contain a nearly equal amount of value per ton of solution. The underflow will be transferred in definite quantity and specific gravity to (2).

(2) No. 1 agitation tank; receives thickened pulp from (1) and counter-current solution from overflow of (5), discharges content continuously through sampling vane into (3).

(3) No. 1 dewatering thickener; receives flow through sampling vane from (2), clear overflow goes to (9), thick underflow by automatic transfer to (4).

(4) No. 2 agitation tank; receives thick plup from (3) and counter-current solution from overflow of (7), discharges content in equal quantity as received, through sampling vane, into (5).

(5) No. 2 dewatering thickener; receives flow continuously through sampling vane from (4), clear overflow goes to (2), while thickened underflow goes through automatic transfer in definite quantity and specific gravity to (6).

(6) No. 3 agitation tank; receives thick pulp from (5) and counter-current solution continuously from overflow of (8), discharges content in equal quantity as received, through sampling vane, to (7).

(7) No. 3 dewatering thickener; receives flow continuously through sampling vane from (6), clear overflow goes to (4), while thickened underflow goes through automatic tranfer in definite quantity and specific gravity to (8).

(8) No. 4 dewatering thickener; receives thickened pulp underflow from (7), mixed with barren solution from (11), plus water to make up moisture passing into the system from (1); overflow to the amount to maintain quantity in counter-current goes to (6), balance of overflow goes to mill solution storage; underflow goes by automatic transfer to waste, if sufficiently reduced in value, otherwise to an additional thickener, and this thickener would receive the flow from (11) and the water tank, instead of (8). The overflow would then go in part to (8) and the balance to the mill solution tank, while the overflow from (8) would all go to (6).

(9) Gold solution storage tank; receives overflow from (3), and delivers as required continuously to (10).

(10) Zinc boxes or zinc dust precipitating equipment; receives solution from (9), delivers barren solution to (11).

(11) Barren solution storage tank; receives solution from (10), discharges through regulating meter to (8) or subsequent thickener.

If the thickened pulp from the last dewatering thickener carries an amount of cyanide solution that would involve an excessive loss, this pulp can be washed on a pan or rotary type of vacuum filter and the cyanide solution recovered and returned to its proper place in the circuit.

The excess of cyanide can also be recovered to a high per-

centage by using two or three additional thickeners, and giving a dilution wash with water, and counter-current the wash against the solids, the overflow from the first tank going to the mill circuit to replace the amount drawn from it into the agitation circuit. A close regulation will obviate any accumulation of solution, particularly if the ore treated settles naturally to a fairly dry pulp.

There are many advantages apparent in this system as a whole over the present method of operating, the important ones of which are as follows:

The dissolved values are recovered from the system at the point farthest removed from the discharge of the tailings; thus it is impossible for a charge of pulp containing high value in solution to be thrown away by an imperfect wash or carelessness or neglect on the part of the attendant operating a filter as in the present method.

The amount of solution carried in the circuit is less than in the present method, while at the same time any unit of ore is in contact with a larger volume of solution than at present.

By proper regulation, a minimum of solution of constant maximum value is sent to the precipitation department, so that there is no occasion to carry two or more circuits for precipitation purposes.

There will be no accumulation of solutions, from which values have to be precipitated and the solution thrown away.

The power required for operating will be less and the equipment less for given tonnage capacity, thus the first cost will be less for installation per day-ton treated.

The counter-current system can be controlled in all its operation from a central point, which registers and records the exact flow at all times and sounds an alarm if any stoppage occurs or a danger point is reached that would throw the regular operation out of equilibrium.

A complete control of the process is possible by taking samples of the pulp and solutions passing, and making the necessary determinations of value considerably in advance of the time of discharge of the pulp as waste. As the mechanical operations are simple and automatic, the labor required around such a plant is a minimum, so that the personal equation plays a very small part in the whole.

The system may be applied to the treatment of ores other than gold and silver where a hydro-metallurgical method can be applied.

Denver, Colo.

New Method for the Rapid Determination of the Total Carbon in Iron, Steel and Ferro-Alloys.

By A. L. Queneau.

It is of great importance to be able to obtain rapid as well as accurate total carbon determinations in operating steel open-hearth or electric furnaces. The colorimetric method of Eggertz was formerly the quickest known, though it is not as reliable as the usual combustion method in a porcelain tube in a stream of oxygen.

The method herein described is due to M. De Noully, chief chemist of the St. Chamond Steel Works, in France. It permits of the same accuracy as the standard combustion method while giving the results in about 5 to 7 minutes. Furthermore, the apparatus used is extremely simple and can be installed independently of a regular laboratory in close proximity to the steel furnaces.

The method is applicable to the various grades of pig iron, steels and ferro-alloys; the accuracy of the results being entirely independent of the presence of nickel, chrome, tungsten, molybdenum, vanadium, titanium, sulphur or phosphorus.

Principle of the Method.—The prepared and weighed sample of the steel or ferro is burned in an atmosphere of oxygen, the combustion being started by means of a small arc flashed through the steel sample. The resulting CO_2 is absorbed in a known volume of standard NaOH solution, the excess of free NaOH being titrated by means of a standard sulphuric acid solution; phenolphthalein is used as indicator.

Solutions Used.—Alkali Solution.

NaOH	4 grams
H_2O	1000 cc.

Indicator.

Phenolphthalein	1 gram
Alcohol, 90°	100 cc.

Sulphuric Acid Solution.

H_2SO_4	4.083 grams
H_2O	to make 1000 cc. of solution

The acid solution contains 3.333 grams of SO_3 per liter; 1 cc. therefore corresponds to 1 mg. of carbon. As usual, the acid solution is standardized with a $BaCl_2$ solution.

Apparatus.—The apparatus consists of:

1. A liter Erlenmeyer flask of Jena glass, closed by a rubber stopper with 3 holes, through which pass 2 copper electrodes

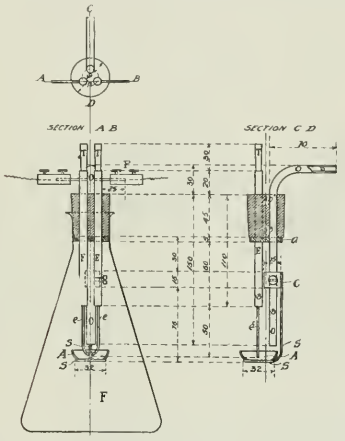


FIG. 1.—DIMENSIONS OF APPARATUS

F—Erlenmeyer Flask of 1 Liter.
B—Rubber stopper with 3 holes.
a—Asbestos disc to protect the rubber stopper from any projections during combustion.
E—Electrode supports.
e—Electrodes.
T—Fiber handles allowing to vary at will the electrode gap.
P—Current terminals.
O—Copper tube for the oxygen.
C—Adjusting sleeve with set screw.
S—Support for the asbestos boat.
A—Asbestos boat.

and a copper tube. To the copper tube is attached a copper wire; forming a loop to support an asbestos boat and a basket of copper wire cloth placed under the asbestos boat. The basket is to receive any material that may escape in case of the asbestos boat being bored by a too violent combustion of the metal sample. The copper tube terminates a short distance above the boat and serves to bring into the flask a supply of oxygen and directly over the material under analysis.

2. A glass bottle reservoir for the oxygen, which is maintained at a slight pressure, 30 to 40 cm. of water. The water is rendered slightly alkaline with KOH in order to free the oxygen of whatever traces of CO_2 may be present in the gas as supplied.

3. A small glass bottle forming a mercury trap to prevent any gas passing back from the Erlenmeyer flask in case of too intense combustion.

The asbestos boats are readily made from asbestos paper 1 or 2 mm. in thickness, from which discs, 50 mm. in diameter, are cut. These discs, slightly moistened, are pressed by means

of a bronze former, 25 mm. outside diameter, in a steel die, 30 mm. inside diameter. The boats are thoroughly dried and are also calcined in a muffle furnace to decompose any carbonates that may be present in the asbestos.

Preparation of the Sample.—Whenever possible the samples are obtained by drilling at high speed with a suitable twist drill; thin voluminous drillings are desired; dust and needle-like drillings are to be avoided if possible.

1. The hard or tempered steels are crushed and passed through 100 mesh.

2. All grades of pig iron are crushed and passed through 80 mesh.

3. All ferro-alloys are crushed and passed through 120 mesh.

For soft steels a good combustion is readily obtained without the addition of any oxidizing agents; for all other metals it is necessary to add a certain amount of PbO_2 or Bi_2O_4 to the samples, as will be shown in the table given below.

With all materials containing over 1.5 per cent of carbon in order to secure a complete combustion it is necessary to add to the sample a certain amount of fine drillings from an extra

No. 1 & No. 2—Two-throw switch with fuses.

soft and pure steel (.05 to .07 C.), due corrections being made in the results obtained for the additional carbon introduced, the determination of the carbon contents of the extra soft steel employed having been made once for all.

Materials.	Wt. of S'ple gram.	Wt. of PbO_2 gram.	W'ght of Soft Stl. gram.
Steels with less than 1.5% C....	1 or 2.	.100 or .200[1]	
Hard steels or steels with over 1.5% C.	1.	.200	
Pig iron	.500	.200	1
Ferro-chromes with 6 to 10% C.	.250	.200	2
Ferro-chromes with 1 to 5% C..	.500	.200	1
Ferromanganese	.250	.200	1
	or .500	.200	2
Ferrosilicons, 10 to 90%.....	.500	.200	1
Ferro-molybdenum	.500	.500[2]	1
Ferro-tungsten	.500	.100[3]	1

[1]With soft steels it is not necessary to add any PbO_2 unless the borings are coarse and irregular in size.
[2]With less PbO_2 some molybdic acid is volatilized and is absorbed by the NaOH solution.
[3]With more than .100 of PbO_2 the combustion is too intense and the asbestos boat becomes bored thereby.

If any extra soft steel borings are required these drillings are spread on the bottom of the boat and on top of the layer thus formed is placed the mixture of the pig iron or ferro with the lead peroxide.

The above table will enable one to obtain the complete combustion of all products, even gray iron containing a large amount of graphite.

For the analysis of all products with more than 1.5 per cent of C it is recommended that the NaOH solution be diluted to 500 cc. in order to make the end reaction more sensitive and also to bring back the pink color of discoloration by the addition of a known quantity of the NaOH solution. With high carbon contents it is also well to take 200 cc. of the NaOH solution, instead of 50 cc., in order that there may be a large excess of free alkali to absorb the last traces of the formed CO_2.

The results are not affected in the least by the presence of sulphur. A test was made with samples containing .80 per cent of S. In the same manner the presence of phosphorus is not detrimental; phosphoretic pig with 2 per cent P gave accurate results with this method. The sulphates and phosphates formed remain *in toto* in the asbestos boat, from which they may be collected and then determinations made.

Manipulations.—The asbestos boat containing the sample to be analyzed is placed upon its support, the height of the boat being so adjusted that its edge level is from 5 to 10 mm. from the level of the end of the supporting copper tube. The copper electrodes are placed with the free extremities buried in the sample and about half way therein. The rubber stopper with its adjuncts is placed in the neck of the Erlenmayer flask, a careful closure of it being made without disturbing the boat or its contents. The flask has been previously filled with oxygen gas and has also received 40 or 50 cc. of the NaOH solution. The various connections are now made and the cock *r* is opened, thus establishing communication with the oxygen reserveir *W*; the electric current is then made to pass across the gap of the electrodes by closing the double-throw switch. The resistance *R* is such as to permit, with a given source of electric current, the passage of 12 or 15 amp when the electrodes are in short-circuit.

As soon as the combustion has begun the current is cut off, the metal continuing to burn until complete combustion has taken place.

In the event of the combustion not starting properly the gap between the electrode points is changed by means of the fiber handles *T*, while the current is sent in repeatedly by operating the switch.

If the combustion is too rapid the cock *r* is closed, cutting off the access of the oxygen.

The combustion being complete, the cock *r* is closed, the flask is disconnected and it is cooled by plunging it in water; when cooled it is rapidly opened, the stopper with the boat removed and a plain stopper is substituted. The flask and its contents are thoroughly agitated for 10 seconds and the free NaOH is titrated by means of the sulphuric acid solution. As a check on the alkali contents of the NaOH solution a fresh sample is now titrated and the difference of the two titrations, the same volumes of the alkali solution having been taken, corresponds to the NaOH absorbed by the CO_2 formed. If the acid solution contains exactly 3333 grams of SO_3 per liter, 1 cc. of it corresponds to 1 mg. of C.

By taking the difference of the two NaOH titrations it is seen that no correction need be made for any carbonation which is bound to occur in the NaOH solution.*

The Arizona Copper Company, Ltd., produced during the half year ending March 31, 1911, 9,133 tons of Bessemer copper. The quantity of copper bearing material, ore and concentrate, smelted during the same period was 80,643 tons. The copper yield was 11.32 per cent on the gross tonnage treated.

Bulletin de la Société de l'Industrie Minerale, November, 1910; July, 1911.

Refining of Silver and Gold Alloys

By EDWARD F. KERN, PH.D.,
From Lecture Notes Prepared for the School of Mines of Columbia University.

One of the final products which is obtained by the treatment of anode sludge by the cupellation of retort-bullion from the Parkes desilverization process, by the cupellation of the final "mother-metal" of the Pattinson process, and by the treatment of silver-gold ores, is an alloy composed chiefly of silver and gold, and associated impurities such as copper, selenium, tellurium, and traces of lead, bismuth, etc.

If the alloy contains an appreciable amount of one or more of the following metals: lead, bismuth, antimony, arsenic, selenium and tellurium, it should be purified as completely as possible, as these metals interfere with and increase the cost of separating and purifying the silver and gold. This is accomplished by either oxidation in the cupellation furnace, or else by melting the alloy with an oxidizing flux, such as potassium nitrate.

If the alloy contains over 75 per cent of silver, it is known as doré bullion. It is refined and the gold recovered by either the acid-parting process or the electrolytic-parting processes.

If the gold content of the alloy is over 25 per cent, the direct treatment by either of these processes cannot be economically accomplished. When this is the case, the alloy is melted with a sufficient amount of impure silver (or doré bullion) so as to dilute the gold content of the resulting alloy below 25 per cent.

In order to accomplish rapid parting of the silver from the gold, the doré bullion is cast into thin plates of suitable size and shape for treatment. The thinner the plates, the more rapid the parting is accomplished.

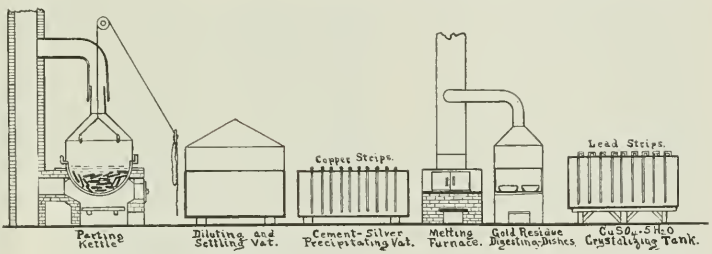

FIG. 1.—SECTIONAL SKETCH OF ACID PARTING PLANT.

Parting of Doré Bullion with Boiling Concentrated Sulphuric Acid.

The doré bullion, as thin plates containing 75 to 98 per cent silver, 25 to 1 per cent gold, and 1 to 2 per cent copper, selenium and tellurium, is placed in cast steel or cast-iron kettles and digested with boiling concentrates H_2SO_4 (66° B) for 15 to 20 hours, until only fine particles are left. (If the alloy contains over 40 per cent gold, it dissolves very slowly.) The reactions for dissolving are:

$$2\,Ag + 2\,H_2SO_4 = Ag_2SO_4 + SO_2 + 2\,H_2O.$$
$$Cu + 2\,H_2SO_4 = CuSO_4 + SO_2 + 2\,H_2O.$$

The usual capacity of the kettles is from 10,000 to 20,000 Troy oz. of doré bullion per 24 hours; 2.5 lb. of concentrated H_2SO_4 are required per 12 oz. of bullion.

As $CuSO_4$ is only slightly soluble in concentrated sulphuric acid, the copper in the doré bullion must be less than 8 per cent, otherwise crystals of $CuSO_4$ will coat the metal and prevent it dissolving. Ag_2SO_4 is, however, soluble in one-quarter its weight of boiling concentrated H_2SO_4; whereas, in dilute (5 per cent) H_2SO_4 at 90° C. it is soluble in 25 parts, and in acid of the same dilution at 20° C. one part of Ag_2SO_4 is soluble in 100 parts.

During the dissolving of the silver, a large amount of SO_2 is formed; the kettles are, therefore, covered with an iron hood which is connected with a ventilating chimney. The heating of the kettles is done by means of a fire beneath.

When the silver is all dissolved, the fire is withdrawn from under the kettle, and a small amount of cold dilute sulphuric acid (specific gravity 1.6) is added to the hot solution. The addition of the cold dilute acid causes the precipitation of some Ag_2SO_4, which carries with it any suspended particles of gold. If much copper is present, the addition of cold dilute acid is not necessary, as some $CuSO_4$ will precipitate when the solution cools, collecting the suspended particles of gold in the same manner as the Ag_2SO_4. In some plants the hot solution is ladled into a second, heated, kettle, in which the suspended finer residue is allowed to settle. This procedure gives a more rapid recovery of the major portion of the gold, as the coarser residue which remained in the digesting kettle may be under final treatment during the time that the finer particles are settling from the solution which is in the settling kettle.

The hot solution, as soon as clear, is siphoned into about 20 *times its volume of hot water* in a covered lead-lined vat. Any fine gold, which may have been carried over, is allowed to settle and the clear dilute hot solution is run into another lead-lined vat in which are suspended strips of copper, which precipitate the silver as "cement silver," $Ag_2SO_4 + Cu = CuSO_4 + 2Ag$. The solution is kept boiling by steam. The end of precipitation of the silver is determined by testing with HCl; if silver is in solution, AgCl forms.

The cement silver is washed free of copper sulphate, dried and melted. If any selenium or tellurium are present, some KNO_3 is added to oxidize and slag them. The refined silver is cast into bars weighing 1000 to 1200 Troy oz., which assay 998 + fine. The slag is added to charge in the smelting furnace, or placed on a charge of metal in the cupel furnace for the recovery of its silver content.

The $CuSO_4$ solutions are evaporated to crystallization for $CuSO_4.5H_2O$, and the mother liquors are re-evaporated to crystallization several times; the crystals are refined by dissolving in water and recrystallizing. The final mother liquors are evaporated to 55° B in lead pans, then transferred to an iron kettle and evaporated to 66° B. The concentrated acid is allowed to cool and the residue to settle; the acid is then siphoned off and used for parting doré bullion. The residue is collected and sent to the smelting furnace, or else put in the cupel furnace.

The *residue of gold* from the parting of the doré still contains some silver. It is transferred to a small iron kettle and again digested with boiling concentrated H_2SO_4 for four to six hours. The solution is poured off and added to the large parting kettle. The residue of gold is washed with hot water, transferred to a porcelain dish and digested with boiling dilute HNO_3 in order to remove the last traces of silver and copper. The solution is poured off and the silver precipitated on metallic copper. The residue of gold is well washed with hot water, dried and melted with a flux of borax-glass in a graphite crucible, and cast into bars (998 + fine). The slag is smelted, or else placed in the cupel furnace.

Some metallurgists dispense with the last HNO_3 digestion, and others digest first with boiling dilute HNO_3, after which the residue is finally digested with boiling sulphuric acid.

Electrolytic Parting of Doré Bullion.

The parting of doré bullion by sulphuric acid is rapidly giving place to the cleaner and less expensive electrolytic separation.

The parting of doré bullion containing 85 to 95 per cent of silver, 1 to 8 per cent gold and 2 to 6 per cent copper, is accomplished by making the metal an anode in an electrolyte containing from 2 to 4 per cent $AgNO_3$, 0.1 per cent to 1.0 per cent free nitric acid, and 1 to 4 per cent of $Cu(NO_3)_2$. The silver is dissolved, leaving the gold (Pt, Pd, Ir, Pb) intermixed with a small amount of finely divided silver as the anode sludge; copper, if present in the anode, dissolves along with the silver; it is not precipitated on the cathode, but accumulates in the electrolyte.

The anodes must be, as far as possible, ridded of lead, bismuth and antimony by cupellation, before the doré is cast into anodes.

The electrolytic parting of doré bullion is carried on either in the Moebius cell or in the Balbach-Thum cell, which differ in their construction. However the electrolytic principles in each are the same. The Moebius cell is the older form of apparatus.

The **Moebius cell** (Fig. 2) is a square wooden cell heavily coated with asphaltum, or an acid-proof earthenware cell (size about 24 in. by 26 in. and 22 in. deep.) In each cell are suspended four sets of four anodes (14 in. by 5½ in. by ⅜ in.) and five rolled sheet cathodes (cathode surface 18 sq. ft.).

Each set of four anodes is surrounded by a muslin bag, the purpose of which is to prevent the anode sludge becoming mixed with the deposited silver. Between each set of anodes and cathodes are two wooden stirrers, which operate back and forth for the double purpose of agitating the electrolyte, and to prevent the anode and cathodes becoming short-circuited by the long crystals of cathode silver. The stirrers knock the crystals from the cathodes, and they drop to the bottom of the cell, collecting in a wooden tray, which has a hinged bottom. The conductor bars of the anodes and the cathodes, the stirrers and the tray are all attached to a wooden frame, which may be raised from and lowered into the cell by means of a small windlass. Once or twice a day the current is shunted, the frame lifted from the cell and the silver scraped from the cathode and caught in the tray beneath. The silver is dumped from the tray, the frame then lowered into the cell and the current turned on. The refined silver is carried to the washing vat. The dried silver crystals are melted in a graphite crucible or in an oil-fired reverberatory furnace and cast into bars, assaying 999 + fine silver.

The gold sludge in the muslin bags, which contains all the gold (Pt, Ir, Pd), most of the bismuth (as $Bi_2O_5xH_2O$), and lead (as PbO_2) of the original doré bullion, and a small amount of the silver and copper, is removed every second or third day. It is refined by acid treatment, or by the Wohlwill gold refining process.*

In the course of the electrolysis of doré bullion, its copper content dissolves along with the silver and accumulates in the electrolyte, replacing an equivalent of silver (here Cu stands above Ag in the e.m.f. series). The copper in the electrolyte may amount to as much as 5 per cent, and the silver reduced to as low as 0.5 per cent without the copper being precipitated along with the silver. When the copper reaches about 4 per cent, part of the electrolyte is withdrawn from the cell, and it is replaced by a fresh lot of $AgNO_3$ solution from the treatment of the anode sludge.

*See papers by E. Wohlwill, this journal, vol. II, pp. 221 and 261; vol. VI, p. 450, and by Tuttle, vol. I, p. 157; also vol. VI, pp. 355 and 408 and vol. VIII, p. 82.

In some cases, when the copper content of the anode is low, the electrolyte which adheres to the cathode silver is ample to keep the copper in the electrolyte sufficiently low to prevent it depositing with the silver. The silver in the withdrawn solution is precipitated on sheets, or plates, of copper, giving cement silver, which is collected and melted with the washed cathode silver. The copper in the precipitated solution is recovered by either precipitating on metallic iron, or else the solution is thrown on roasted ore or matte which is to be smelted.

The Moebius cells are usually connected in multiples of five or six. The current per cell is from 350 to 450 amp. (C. D. = 20 to 25 amp. per sq. ft.) and e.m.f. per cell is 1.4 to 1.7 volt. The current efficiency is from 92 per cent to 95 per cent. The amount of silver permanently tied up as cathodes and in electrolyte is from 40 to 45 per cent of daily capacity; but by operating with higher current density, the silver permanently tied up per daily capacity of the cell is reduced. A current density of 40 to 50 amp. per square foot has been successfully employed.

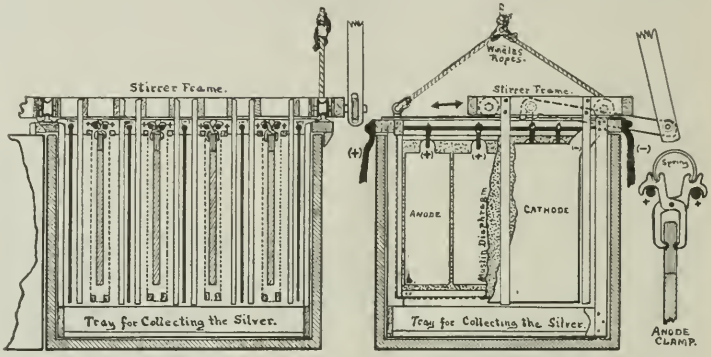

FIG. 2.—SECTIONS OF MOEBIUS CELL.

The power consumption in the Moebius cell is about 13.5 watt-hours per Troy ounce of silver deposited. Cost of refining in this cell is from ¼ to ½ cent per Troy ounce of silver deposited. The parting is rapid, as the anodes are dissolved on all sides; and when operating with high current density, the recovery of the refined silver is as rapid as by the sulphuric-acid parting process.

Dr. D. K. Tuttle (this journal, vol. IV, p. 306) and assistants, at the Philadelphia Mint, developed a method of electrolytically refining silver-gold alloys which gives solid, adherent, crystalline deposits of silver on the cathode, and thus obviates the need of mechanical stirrers, as are used in the Moebius cell. The process is in use at the U. S. Mints in Philadelphia, Denver and San Francisco.

The general arrangement of the cells and the operation of refining are similar to the refining of copper and of lead, but on a smaller scale. The cells are made of acid-proof earthenware, 20 in. wide and 11 in. deep, and hold 42 anodes (6 rows of 7 anodes side by side) and 40 cathodes (5 rows of 8 side by side), suspended vertically with 1.5-in. space between centers of electrodes. The anodes are 7.25 in. long, 2.5 in. wide and ⅜ in. thick. The cathodes are of same width and length as the anodes and are made of rolled sheet silver 0.016 in. thick. The electrodes in each cell are in multiple.

The cells are connected in series, and are operated at a current density of about 7 amp. per square foot of anode surface, and an e.m.f. of from 1 to 1.4 volt, with a current efficiency above 90 per cent.

The gold which is present in the anode in amounts between

15 and 30 per cent, remains attached to the anode as a chocolate colored mud. If the gold is present in smaller amounts, the anodes must be enclosed in muslin bags for the purpose of preventing the anode sludge floating in the electrolyte and becoming attached to the cathode.

The electrolyte contains about 4 per cent $AgNO_3$ and 1.0 per cent HNO_3. It is circulated by means of small propellers at one end of the cell, or by gravity. (The gravity cascade system of circulation gives better circulation than the propellers, and does not keep particles of the sludge in suspension so long a time as the propellers, therefore affording a higher recovery of the gold residue and the production of purer silver.)

By maintaining rapid circulation and by having present in the electrolyte 1 *part by weight of gelatine in* 8000 *to* 10,000 *parts of solution*, the silver deposits on the cathodes as a mass of solid coherent crystals, which seldom short-circuit the cell. The successful operation of the process depends upon the crystals remaining attached to the cathode and to the overcoming of short-circuits by producing smooth deposits. The addition of the gelatine is made each day as needed, which is judged by the appearance of the deposits. It is added as a solution in hot water (10 to 20 grams per litre). Too much gelatine darkens the electrolyte (due to the chemical precipitation of cement silver), and also causes the deposit to form non-coherent.

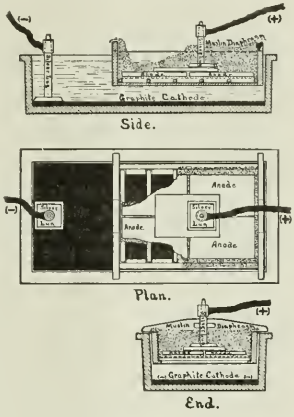

FIG. 3.—BALBACH-THUM CELL.

The cathodes, when the anodes are almost completely dissolved, are removed from the cell, washed, melted and cast into bars of 999 + fine. The gold residue is collected, washed, and treated by either the acid leaching method (when only silver is present), or else is melted, cast into anodes, and refined by the Wohlwill electrolytic process (in case Pt, Pd, and Ir are present).

The scraps of anode are remelted along with silver to be refined.

On account of the low current density which is necessary for the production of smooth, coherent deposits of silver, this process of refining cannot be economically used in the works. But as the alloys which are refined in the Mints contain from 15 to 30 per cent of gold, and as no interest is charged against the metal which is "tied up" in the cells, this method of parting silver and gold can be used in this special case.

The Balbach-Thum cell has no mechanically moving parts. It consists of a long, shallow, narrow cell about 10 in. deep by 26 in. wide by 48 in. long, made of chemical-proof earthenware. They are supported on acid-proof insulated pillars.

The cathode is made up of strips of Acheson graphite, about ¾ in. thick and completely covering the bottom of the cell. Surface, 8 sq. ft. A silver lug is used for electric connection.

The anodes of doré bullion, size 8 in. by 12 in., are suspended horizontally in the cell by being placed in a wooden or earthenware tray (24 in. by 24 to 36 in.), with muslin bottom, which is about 4 in. from the cathode. The muslin is supported on cross-bars which form the bottom of the trays. Electrical contact of the doré slabs is made by means of a slab of silver with a vertical lug.

The silver is deposited as loosely adhering crystals on the graphite slabs, and from time to time are removed with a hardwood shovel. The crystals are washed, melted and cast into bars assaying 999 + fine, and weighing 1000 to 1200 Troy oz.

The gold (and Pt), bismuth (as $Bi_2O_3.xH_2O$), lead (as PbO_2) collect as sludge on the muslin in the tray, and are removed every third day and treated in the same way as anode sludge from the Moebius cells.

The electrolyte is kept in proper condition by removing a portion, when copper reaches about 4 per cent, and replacing with same amount of fresh solution, in the same way as is done in Moebius cell.

The cells are arranged in sets of 4 to 6 in parallel, and operate with a current of about 150 amp. per cell.

The cathode surface is 8 sq. ft., giving a current density of 20 amp. per sq. ft.

The anode surface is about 4 sq. ft., giving a current density of 40 amp. per sq. ft.

The current efficiency averages 88 per cent; at times, 90 per cent.

The e.m.f. per cell ranges from 3.2 to 3.8 volts.

The power consumption in the Balbach-Thum cell is about 31.5 watt-hours per 1 Troy oz. of silver deposited.

The amount of silver permanently tied up in the cell is about 32 per cent of the daily output of the refinery.

Advantages claimed for the Balbach-Thum cell over the Moebius cell:

1. No moving parts, therefore less labor and apparatus to keep the plant operating.
2. Less silver tied up in the plant (32 per cent as against 45 per cent).
3. Less time lost in removing the silver and sludge.
4. Less wear and tear on apparatus, therefore less repair costs.
5. No anode scrap to remelt. (The anodes allowed to completely dissolve in the cell).

Advantages claimed for the Earthenware Tray cells over the Wooden Tray cells:

1. Cleaner and more permanent cell.
2. Deposited silver forms as larger crystals which are easily washed and more readily melted. (The action of the electrolyte on the wood forms organic compounds which, when present in the electrolyte, causes the silver to deposit as fine crystals).
3. Higher current efficiency (93 to 96 per cent) as against 88 to 90 per cent).

Objections claimed for the Balbach-Thum cell as compared with the Moebius cell:

1. Larger power consumption (3.5 volts as compared with 1.5 volt).
2. Large consumption of HNO_3, due to high e.m.f., forming NH_3.
3. Larger space required per given daily capacity, (about 6 times more space).
4. The anodes dissolved only on under side, facing the cathode, therefore less rapid per anodes under treatment.
5. More silver tied up in the electrolyte per given parting capacity, (larger volume of electrolyte per weight of anodes).

Advantages of electrolytic parting over acid parting of doré Bullion:

1. Production of purer silver.
2. Complete separation of selenium and tellurium (these render silver brittle).
3. Less cost of operation, due to smaller consumption of chemicals.
4. Less loss of metal, due to less handling of materials.
5. $CuSO_4.5HO_2O$ not produced as by-product.

6. The purified silver recovered in shorter time, if high current density is used.

Disadvantages of electrolytic parting, as compared with acid parting of doré bullion:

1. First cost of plant (electric generators, conductor cells, etc).

2. Time the gold residue held for parting (interest on same). It requires from 48 to 60 hours to have the gold in bars, whereas about 30 hours required when the parting is done with sulphuric acid.

Treatment of Silver Anode Sludge.

There are two methods of treating the silver anode sludge:

A.—Chemical Method. When there is not enough Pt. Pd and Ir present to pay for recovery: The sludge consists of all the gold (Pt, Pd, Ir), most of the bismuth (as $Bi_2O_3xH_2O$) and lead (as PbO_2) contained in the doré bullion, and a small amount of silver and copper. It is treated in porcelain, or acid-proof, earthen-ware bowls, which are heated by steam jackets, which conform to the bottom of the bowl, or else are heated by being placed in a sand-bath with flame underneath. The bowls are covered with an acid-proof hood which is in connection with a good draft, for the purpose of carrying off the acid fumes.

The sludge is first boiled with dilute HNO_3 (2 acid: 3 water) till no further reaction occurs; the solution is decanted, the residue of gold washed, and retreated with boiling concentrator H_2SO_4. When acid treatment is complete, the solution is decanted and the residue thoroughly washed with hot water, dried, and melted under borax glass in a graphite crucible. It is then cast into bars assaying 998 + fine.

The HNO_3 solution, containing silver nitrate and free nitric acid, is diluted and added to the silver electrolyte in the parting cells in place of the solution which is removed from time to time in order to keep the copper content down.

The H_2SO_4 solution is diluted, and the silver precipitated by boiling with sheets of metallic copper, giving cement-silver, which is melted with the cathode silver and cast into bars. The resulting $CuSO_4$ solution is either crystallized, or else sent to the copper refinery and added to the copper electrolytic tanks.

B.—Electrolytic Method. When platinum, palladium, and iridium are in sufficient amounts to pay for their recovery: The sludge is washed free of electrolyte, dried, melted under borax glass and soda ash flux, and cast into anodes, which are refined by the Wohlwill electrolytic process.

Protection of Wood Work of the Parting Plant.

All exposed woodwork of the parting plant should be well protected with several coats of an acid-proof paint (asphaltum paint, or patented P. & B. paint) in order to prevent the possibility of fire by spontaneous combustion, due to the action of nitric acid fumes on the wood. Ample ventilation for the removal of the fumes should be provided also, in order to protect the health of the workmen.

Electrolytic Refining of Gold.

The Wohlwill Electrolytic Gold Refining Process is used at the U. S. mints in Philadelphia, Denver and San Francisco for purifying gold, and for the recovery of the valuable impurities (such as Pt., Pd., Ir., and Os).

The anodes are gold bullion, of reasonable purity, running over 940 fine, and the cathodes are thin sheets of hard rolled gold.

The electrolyte contains from 3 to 4 per cent $AuCl_3$, 2 to 5 per cent free HCl (sp. gr. 1.2) and 1 to 3 per cent NaCl. If the anodes contain lead, then from 1 to 2 per cent H_2SO_4 is added to prevent the lead dissolving and being deposited with the gold; the H_2SO_4 causes the lead to enter the anode sludge as $PbSO_4$.

The conditions necessary to obtain high current efficiency and to deposit the gold in solid form are the presence of free HCl in the electrolyte, circulation of electrolyte, and temperature between 50 and 70 C. With neutral $AuCl_3$ electrolyte and at ordinary temperature, the anode is slowly dissolved, free chlorine being liberated at the anode, and hydrogen at the cathode.

The circulation of the electrolyte is accomplished by means of small propellers in one end of the cell, or else by the gravity cascade system. The former method of circulation is not so satisfactory as the latter, as it keeps the anode sludge longer in suspension, which permits particles becoming attached to the cathode. In case of the gravity-cascade system of circulation, the cells are arranged in rows of 12 or more, with ample height between adjoining cells to allow the solution flowing from the upper cell to the lower one. Porcelain pumps are used for raising the electrolyte from the sump cell to the upper cell. The circulation should be ample to maintain uniform composition of the electrolyte in all parts of the cell, which may be judged by the corrosion of the anode and the appearance of the cathode.

The cells are acid-proof earthenware, or porcelain, about 15 in. by 12 in. and 10 in. deep (or larger, depending on size and number of anodes).

A sufficient current density is used so as to allow the refining being done as rapidly as by the acid refining process, which is in 24 hr. The usual current density is between 80 and 120 amp. per square foot. The e.m.f. per cell is between 1 and 1.3 volt, with electrodes spaced about ¾ in. centers. The energy consumed is about 10 watt-hours per 1 troy ounce of cathode gold.

The heating of the cells is accomplished by having them placed on a bed of sand, which has steam coils imbedded. At a temperature of 50 to 70° C. much evaporation occurs, so water must be added from time to time to keep the volume of electrolyte constant.

The anodes of impure gold (940 + fine) are cast in iron molds, size 6 in. long by 3 in. wide and about ⅜-in. thick (24 hour anodes). The cathodes are of same length and width as the anodes, and are made of pure rolled gold sheets.

The purity of the deposited gold is 999.8 fine. It is melted in graphite crucibles and cast into bars.

The sludge contains AgCl, $PbSO_4$, Ir. and Os. If the anodes run less than 940 fine (6 per cent Ag + Pb) they become coated with the AgCl and $PbSO_4$ which are non-conductors. In this case, it is necessary to scrape the anodes when voltage of cell becomes high and current becomes low.

The silver is recovered from the sludge by fusing it with Na_2CO_3, which reduces the AgCl to metal:

$$2AgCl + xNa_2CO_3 = 2Ag + 2NaCl + CO_2 - O + (x-1)\ Na_2CO_3$$

If iridium and osmium are present in the anode, they collect with the AgCl, and are separated from the silver by the acid parting method.

If copper, platinum and paladium are constituents of the anode, they are dissolved along with the gold, replacing an equivalent of gold in the electrolyte (higher in e.m.f. series than gold), but are not deposited unless allowed to accumulate to high percentage. (Pd must not exceed 5 per cent.)

Each day, gold chloride solution must be added to the cells in order to supply the equivalent of gold which was replaced during electrolysis by Cu, Pt, and Pd. This solution is prepared either chemically or electrolytically. The chemical method of preparation is by dissolving gold in aqua-regia and evaporating off the chlorine, which is an expensive method and is very disagreeable on account of chlorine. The electrolytic method is by electrolyzing concentrated hydrochloric acid between gold anodes, and gold cathodes (in a porous cup), the anode current density 100 amp. per square foot, and the cathode current density 250+ amp. per square foot. Temperature of solution 60° to 70° C. The electrolyte around the anode becomes more and more concentrated in $AuCl_3$. The high current density of the current at the cathode prevents gold being deposited, hydrogen being liberated instead. When the solution in the anode compartment becomes suffi-

ciently concentrated in gold chloride, it is removed and replaced by the solution in the porous cup surrounding the cathode, which in turn is replaced by fresh concentrated hydrochloric acid.

The platinum (and paladium) is recovered from the electrolyte by precipitating as insoluble double ammonium chloride salts $(NH_4Cl)_2PtCl_4$. The gold must first be precipitated by a current of SO_2, the solution is filtered, then NH_4Cl added and the solution evaporated to small volume. The precipitated $(NH_4Cl)_2PtCl_4$ on ignition is reduced to metal, NH_4Cl and Cl being volatilized.

Reactions:

$$2AuCl_3 + 3SO_2 + 6H_2O = 2Au + 6HCl + 3H_2SO_4.$$
$$PtCl_4 + 2NH_4Cl = (NH_4Cl)_2\,PtCl_4.$$

If palladium is present it is precipitated along with the platinum as the double salt. It is separated from the platinum by digesting the ignited precipitate with hot conc. HNO_3, which dissolves the Pd, leaving the Pt as fine particles.

Use of a Pulsating Current for Refining Gold.

It has been found (this journal, Vol. VIII, p. 82) that when a *pulsating direct current* is used for electrolysis of gold anodes, which contain over 6 per cent of silver, the AgCl does not accumulate on the anode and stop the current. Even as much as 20 per cent silver in the anode does not prevent the electrolysis, when using pulsating direct current.

The *pulsating direct current* is accomplished by connecting a single-phase alternator in series with the direct-current generator, the voltage of the alternator being lower than the voltage of the generator, the effect being a pulsating current. The alternating current does not effect the deposition of the gold, but causes the AgCl to break from the anode, thereby avoiding mechanical scrapers for this purpose. The electrolytic effect of the alternating and direct current combination is equal to that of the direct current alone.

The effect of the alternating current on the electrolysis is: (a) it reduces the actual e. m. f. of the cell; (b) it prevents the liberation of Cl at the anode; (c) it breaks the AgCl from the anode; (d) it allows the use of a higher current density; (e) less gold is left in the anode sludge; (f) the electrolysis may be conducted at a lower temperature—25 to 35° C.

The direct current density from the electrodes is 110+ amperes per square foot.

The power consumption is the sum of both the alternating and the direct current.

In the design of the generators, figure on 1.3 volts as the maximum for the direct current generator per each cell in series, and 1.0 volt for that of the alternator per each cell in series. Since the generators are connected in series, their armatures must be so dimensioned as to withstand the heating effect of the maximum total combined alternating plus direct current. The frequency of the alternations has no practical effect on the electrolysis, the usual frequency of 60 per second is very satisfactory.

Electrolytic refining of gold is advantageous in that:

1. It recovers the Pt, Pd, Ir, and Os.
2. It gives the purest kind of gold.
3. It is cheaper than the chemical method of refining.
4. No disagreeable chlorine gas is produced.

Floor of Parting Plants.

The floor of the silver parting plant is laid with an acid-proof and solution-tight material, usually rough concrete bottom with an asphaltum topping. The floor is made with a general slope to a common sump.

At the United States Mints the floors in the gold refinery are made of concrete bottom covered with acid-proof slate slabs two inches thick, with their joints cemented with a mixture of litharge and glycerine. The sweepings from the floor and the residues from the floor washings are melted with the impure gold and cast into anodes and refined.

Cost of Power; Conversion Factors.

By Carl Hering.

Owing to the fact that the cost of power is sometimes stated in cents per hour and at other times in dollars per year, and that the year is sometimes taken at the rate of 24 hours per day and at other times 10, and that this is further complicated by the power being sometimes stated in horse-powers (and in some foreign countries in metric horse-powers) and at other times in kilowatts, the conversions from any one to another sometimes become tedious and are often liable to errors owing to the difference between a unit and a quantity measured in terms of that unit.

The following table of constants has therefore been determined accurately, giving the values of each in terms of each of the others, so that a single multiplication is all that is required for reducing a cost given in terms of one of them into any of the others, as the reciprocals of all values are always given in their proper places. The constants are arranged in the same style and order as those in the writer's "Conversion Tables" for a new edition of which they have been determined. They are in the order of size, beginning with the smallest. The approximate values, which are sufficiently accurate for many calculations, have been selected so as to minimize calculations.

Two kinds of years have been included, one the complete or full year, of 365¼ days of 24 hours each, and the other a working year of 300 days of 10 hours each, and they have been indicated by the names "full" and "working" respectively.

A horse-power-hour or year is really a measure of a quantity of energy and not of power; but as such quantities are popularly referred to as "power" this term has been used in the title, although not strictly correct.

All the values have been carefully calculated by two independent methods besides being cross checked, and it is believed there are no errors.

Cost of Energy; Charges for Power; Cost of Power During Specified Times.

(Money ÷ product of power and time: money ÷ energy.)

NOTE: A "full" year means 24 hours per day and 365¼ days per year = 8766 hours.
A "working" year means 10 hours per day and 300 days per year = 3000 hours.
Aprx. means within 2%.

1 dollar per kilowatt year (full) [$/kw-yr.]:

= 1.341 11	cts. per kw-hour.	Aprx. add 1 3.

Foreign.

The values of foreign moneys here used are those specified in the writer's "Conversion Tables" and are those used by the U. S. Treasury Dept. They are the true relative values based on gold, as determined by the U. S. Mint in terms of the U. S. gold dollar. The three fundamental values are: 1 pound sterling = 240 pence = $4.8665; 1 mark = 100 pfennige = $0.238; 1 franc = 100 centimes = $0.193. Those constants which depend upon these money values are given to only three or four significant figures; those independent of them are given to six figures, as usual. It has been assumed that the regular horse-power is the only one used in England (as in the United States) and that the metric horse-power is the only one used in the rest of Europe; when this is not the case two calculations will be necessary. One metric horse-power = 0.986-318 horse-power; one horse-power = 1.013 87 metric horse-powers: the difference is therefore about 1½%.

1 franc per kilowatt-year (full):
= 0.811 mark per kilowatt-year (full). Aprx. 4/5.
= 0.735 448 franc per metric horse-power-year (full). Aprx. 22/3 ÷ 10.
= 0.342 231 franc per kilowatt-year (working). Aprx. 34 ÷ 100.
= 0.251 693 franc per metric horse-power-year (working). Aprx. 1/4.
= 0.193 dollar per kilowatt-year (full). Aprx. 19 ÷ 100.
= 0.039 7 pound per kilowatt-year (full). Aprx. 4 ÷ 100.
= 0.011 407 7 centime per kilowatt-hour. Aprx. 8/7 ÷ 100.
= 0.008 389 77 centime per metric horse-power-hour. Aprx. 5/6 ÷ 100.

1 mark per kilowatt-year (full):
= 1.23 francs per kilowatt-year (full). Aprx. 1 8 × 10.
= 0.735 448 mark per metric horse-power-year (full). Aprx. 22/3 ÷ 10.
= 0.342 231 mark per kilowatt-year (working). Aprx. 34 ÷ 100.
= 0.251 693 mark per metric horse-power-year (working). Aprx. 1/4.
= 0.238 dollar per kilowatt-year (full). Aprx. 12/5 ÷ 10.
= 0.048 9 pound per kilowatt-year (full). Aprx. 49 ÷ 1000.
= 0.011 407 7 pfennig per kilowatt-hour. Aprx. 8/7 ÷ 100.

Recent Progress in Calorimetry.—III.

By W. P. White.

Temperature Measurement and Corrections.

Two previous papers of this series have dealt with the progress that has recently been made in eliminating various calorimetric errors due to uncertain or lagging temperatures in parts of the calorimeter, and, more especially, in its surroundings. To avoid these errors is not difficult; when this has been done the principal errors are in the temperature measurement, and are mainly accidental.

Of *mercury thermometers* for calorimetry the most sensitive are read to 0.001°, but many of the best authorities regard 0.003° to 0.002° as the maximum accuracy with which a temperature interval can in practice be reproduced by one of these thermometers. If somewhat different intervals are employed at different times unavoidable calibration errors will make the probable error appreciably greater. These sensitive thermometers seldom have a range of over 6°. Hence the maximum accuracy which could be expected with them is about 0.4 per mille. This, however, supposes that the full range of 6° is employed. Considerably shorter intervals are often recommended on the ground that Newton's law of cooling cannot be assumed to hold for intervals much over 2°. This recommendation is a mistake. The deviation from Newton's law for a 4-degree interval will not equal the thermometric error (unless the period is considerably over 10 minutes), while, on the other hand, a decrease in the interval will often increase the thermometric error almost proportionally. In fact, the effect of the deviation from Newton's law is usually quite negligible for an 8° interval, or can easily be made so by a rough correction.

The advantage of an increase above 6° is more doubtful with mercury thermometers, since several of the purely thermometric errors would tend to increase with the interval. This remark applies to the substitution of longer range thermometers for the most sensitive ones now in use. *With a given thermometer* it is probably always best, as far as the temperature measurement is concerned, to use the full range. And this has been done, up to 20°, without introducing any error chargeable to the calorimeter or the cooling.

For the best calorimetric work yet reported with mercury thermometers the mean accidental error (that is, the average variation of each determination from the mean result of the series to which it belongs) is about 0.5 per mille.

For electric calorimetric thermometers the sensitiveness and the accuracy can readily be made each 10 times the corresponding value for the mercury thermometer. That is, these electric thermometers can be read to 0.0001°, will reproduce ordinary calorimetric intervals with fair certainty to 0.0002°, and will in general yield measurements agreeing within from one ten-thousandth to one fifty-thousandth (0.1 to 0.02 per mille), their performance in this regard depending mainly on the accuracy of the auxiliary resistances. Two observers, working independently with different types of electric thermometer, have each succeeded in getting calorimetric results whose mean accidental error is one thirty-thousandth (0.03 per mille) or less. The *absolute* accuracy of these determinations may not be greater than 0.2 per mille, but this is sufficient for most present requirements and is as great as the accuracy yet attained in determining the variation in the specific heat of water itself. The electric installation is not only more accurate than a mercury thermometer, but is in some ways more convenient. The observer sitting, notebook in hand, before his galvanometer scale, within easy reach of switches which give complete control of the electrical system, can make readings with great rapidity and in great variety. His facilities in these directions will generally be of more use in the complex and varied problems of the research laboratory than in the simpler and more nearly standardized processes of commercial work. The disadvantages of the electric thermometer are three: The cost, the special electrical knowledge required, and the increased chance of occasional loss of time through slight accidents or blunders in the operation of the more complicated system. None of these disadvantages is really serious, unless the cost is. The strongest reason for not using electrical methods will probably be, in most cases, that greater accuracy than that given by the mercury thermometer is either not needed or is prevented by some cause quite outside the calorimeter, such as impurity or variability of materials.

Two forms of electric thermometer, the resistance thermometer and the thermoelement, have been used in calorimetry and have given results of (so far) about equal and very high accuracy. For some types of recording and regulating apparatus the resistance thermometer is much more sensitive than the thermoelement, but in existing calorimetric thermometers there is little difference in this direction.

The resistance thermometer has at present the advantage that a form of it, developed and now used at the Bureau of Standards, can be purchased ready made, with suitable accessory apparatus. A form accurate at least to 0.0003° in calorimetric work costs, complete with accessories, about $225. For the thermoelement also highly satisfactory accessory apparatus (potentiometers, etc.) can now be purchased, and thermoelements suitable for calorimetry require for their construction neither skill, experience, nor great labor, but they are not regularly manufactured at present. Most standardizing laboratories are better equipped for the calibration of resistance thermometers than of thermoelements, though the calibration of thermoelements is very easy wherever suitable standards are available. The chief advantage of the thermoelement appears to be the greater ease with which the thermoelectric installation lends itself to the simultaneous measurement of several temperatures, and of currents and voltages as well, if desired, but this advantage, again, is greatest in the case of the research laboratory.

The Calculation of Corrections for Cooling seems to deserve attention here because (1) it is mainly through the abbreviation of these calculations that shortening and simplification of the labor of calorimetric determinations can be secured, and (2) the customary formulas for these calculations have been misunderstood to a surprising extent, considering their age and simplicity. It will probably be sufficient, however, to give merely results and conclusions. A derivation of the two formulas here given will be found in the articles on calorimetry already referred to, those in the November and December *Physical Review* of last year. One of the formulas, also, the Pfaundler, has been often presented, though with a bewildering variety of notations, which I have made some effort to simplify.

Three kinds of data may in different cases be needed to get cooling corrections: (1) Data as to the temperature changes produced in the calorimeter by stirring and evaporation; (2) the temperatures of the calorimeter during three periods, namely, the *transfer* period, during which there is communicated to the calorimeter the heat which is to be measured, and two *cooling* periods, before and after the transfer period; (3) the rate of [temperature change of] the calorimeter during the cooling periods.

It is generally known, but sometimes overlooked, that these data may properly be much less accurate than the measurements which determine the main temperature rise, since the cooling correction is only about one-fiftieth of the whole interval. The observer who corrects his transfer period temperatures to thousandths of a degree is simply wasting time. But the rates, though needing no great accuracy in themselves, are each obtained from the difference of two temperatures, so that these temperatures need to be known with considerable accuracy. There may be, therefore, an appreciable error connected with the cooling correction, though this error is not in the cooling itself, but is an additional *accidental thermometric* error, coming in the determination of the cooling rate. Methods of diminishing or eliminating it can more conveniently be presented a little later.

Cooling correction calculations are easier to make if the rate is proportional to the temperature difference of calorimeter and jacket—that is, if Newton's law of cooling holds. The same advantages can be obtained where that law does not hold, however, by introducing the variation from it as a correction. Hence, in what follows, Newton's law will at first be supposed to apply, and the correction for deviations from it will then be discussed.

The simplest case of a complete cooling correction formula occurs where the heat of stirring and evaporation and the jacket temperature are known, for the amounts of direct cooling are then simply proportional to known temperature differences and only one cooling period is needed. For instance: Let ϕ_{tr} be the integrated temperature difference (of calorimeter and jacket) for the *transfer* period (i.e., the period when the heat to be measured is transferred to the calorimeter water), and ϕ_c the same for the subsequent *cooling* period. (The notation here is the same as in the *Physical Review* articles already referred to, except that the subscripts indicating the periods are numbers in those articles.) Let T_{tr} and T_c be the number of minutes in each period, w the heat lost by evaporation and stirring per minute (w, of course, will often be negative), $\delta\theta_c$ the observed temperature fall in the cooling period. Then $\delta\theta_c - wT_c$ is the direct heat loss in period (c), and that in period (tr) equals:

$$(\delta\theta_c - wT_c)\frac{\phi_{tr}}{\phi_c}$$

the cooling correction is, therefore, simply

$$wT_{tr} + (\delta\theta_c - wT_c)\frac{\phi_{tr}}{\phi_c} \qquad (1)$$

This can easily be manipulated into the form:

$$\delta\theta_c + (\delta\theta_c - wT_c)\frac{\phi_{tr} - \phi_c}{\phi_c} + w(T_{tr} - T_c) \qquad (2)$$

which is very convenient practically whenever the calorimeter is initially near the temperature of the jacket, for $\phi_{tr} - \phi_c$ will then be relatively small, often very small, while $T_{tr} - T_c$ will often be zero. Hence w, which is always multiplied by one or the other of these, need not be known at all accurately, and the two multiplications will give small products and so can be done by a slide rule, and usually by inspection.

Equation (1) shows how to avoid the thermometric error, mentioned above, which occurs in the determination of the cooling rate. That error comes in $\delta\theta_c$, which is multiplied by $\frac{\phi_{tr}}{\phi_c}$ hence the smaller ϕ_{tr} is, or the larger ϕ_c, the less will be the final error produced. ϕ_c can be increased by lengthening the cooling period, but this method is time-consuming and may tend to introduce other errors. ϕ_{tr}, however, can be decreased by taking the initial temperature below that of the jacket, so that the calorimeter receives heat from the jacket during part of the transfer period and gives it back again during the other part; and the total net cooling (proportional to ϕ_{tr}) is nearly zero. This is not Rumford's old rule of taking the jacket temperature *midway* between the initial and final calorimeter temperatures, but usually calls for a jacket temperature somewhat nearer the final. If this method is not used, and ϕ_{tr} nearly equals ϕ_c [as in formula (2)] the determination of the rate about doubles the maximum possible accidental thermometric error, but, in accordance with the laws of probability, only increases the probable mean error of a series by 42 per cent; hence this method of reducing the cooling correction cuts in two the maximum error, and diminishes the mean error about a third. One price which must be paid for this advantage is an exact knowledge of the value of W, the heat of stirring and evaporation, for errors in this value are no longer diminished as by formula (2).

The method just described, namely, that of diminishing ϕ_{tr}, can be used to save time as well as to gain accuracy. For since it enables us to diminish almost indefinitely the effect of errors in the value of the cooling rate, and, therefore, to get good results with rates inaccurately known, we may determine the relation of rate to temperature (the cooling factor) once for all, and then, assuming that this relation is constant, we may use it in each subsequent determination. We thus get rid of the cooling period altogether, yet with no loss of accuracy. The formula for the correction with this procedure is:

$$wT_{tr} + K\phi_{tr},$$

where K is the constant,

$$\frac{\delta\theta_c - wT_c}{\phi_c} \qquad (3)$$

Some observers have found that the cooling factors of their calorimeters were constant to ½ per cent or better, which suffices for an accuracy of 0.1 per mille even where the calorimeter is started at jacket temperature. The causes which may prevent this constancy do not seem to be fully known as yet, but it seems probable that the measurement of a cooling rate for each separate calorimetric determination will soon be generally regarded as not only a waste of time, but a detriment to accuracy.

Of the labor of getting the cooling correction there now remains only the determination of ϕ_{tr}—that is, the taking of temperature observations during the transfer period and the addition of the results. Even this labor is sometimes avoided, and the value of ϕ_{tr}, the total of the transfer period temperatures, is obtained from the initial and final values of ϕ by means of a table of some sort. The saving in this case is relatively not great, but is often easily obtained. As soon as anyone has performed a few determinations he has the material for expressing ϕ_{tr} in terms of the other temperatures. Of course, this method succeeds better the more uniform the various conditions—such as time, room temperature, material.

In many cases the jacket temperature and the heats of stirring and evaporation are not known. But *if they are constant* they can be eliminated by the use of another cooling period. The most convenient way possible of accomplishing this seems to be by the *Pfaundler formula*. The essential principle of that method is this: The proportionality between heat flow and the temperature difference (ϕ) of calorimeter and jacket cannot be used because ϕ is not known. But one consequence of that proportionality can be made useful, and that is: That the *difference between any two* cooling rates is proportional to the difference of the corresponding temperatures. Hence, not knowing the jacket temperature, we may refer our formula to any other temperature for which we know the rate and proceed much as before.

The additional cooling period furnishes the reference temperature in question. To illustrate, let this period, which comes before the transfer period, and is therefore a preliminary period, be denoted by the subscript, p. Since ϕ is not known, the *mean* temperatures of the periods will be used instead;[1] call these θ_p, θ_{tr}, θ_c. It will also be necessary to use, instead of the temperature intervals, $\delta\theta$, the rates, V_p, V_c, which equal $\frac{\delta\theta_p}{T_p}$, etc. Then the mean rate for the transfer period will be the mean rate for the preliminary period, plus the difference in rate due to the difference in temperature. The cooling correction, which equals this rate, multiplied by T_{tr}, the time of the transfer period, is, therefore:

$$T_{tr}\left\{V_p + \frac{V_c - V_p}{\theta_c - \theta_p}(\theta_{tr} - \theta_p)\right\} \quad (4)$$

which is essentially the Pfaundler formula.

Here two things are noticeable. (1) After the first term the formula is exactly like formula (1) in type, but instead of the temperatures of the two last periods there appear the differences between these temperatures and those of the preliminary (reference) period. (2) The heats of stirring and evaporation have vanished, since, being the same for all the periods, they are eliminated in the subtractions. This has always been counted one great advantage of the Pfaundler formula, and is, indeed, evident enough, but still seems to deserve emphasis, for some recent publications indicate that it has sometimes been overlooked.

As ordinarily printed the Pfaundler formula shows a summation, which is the same as the term $\theta_{tr}T_{tr}$ in the form here given. If the periods are all taken equal the computation is easier, since $\delta\theta$ can then be used instead of V. The computation is then as in formula (1), except that the three indicated subtractions must first be performed.

This formula, being like (1), can, like it, be treated as (1) was in getting (2), and thus becomes:

$$T_{tr}\left\{V_c + \frac{V_c - V_p}{\theta_c - \theta_p}(\theta_{tr} - \theta_c)\right\} \quad (5)$$

which is very convenient when θ_{tr} is nearly equal to θ_c, since then the computed term is so small that it can be obtained by approximate methods. θ_{tr} nearly equals θ_c when the calorimeter is started at about the jacket temperature, which is usually the most convenient way to do. I believe this variation of the formula is new.

The method described above of diminishing the accidental thermometric error by diminishing the final magnitude of the correction is practically useless with the Pfaundler formula. The proof is simple, and seems unnecessary here. There is, therefore, contrary to a frequently expressed opinion, little or nothing to be gained in accuracy by any particular choice of initial temperature if this formula is used, and the most convenient procedure may be employed, whatever that is. It will often be with the calorimeter temperature near the jacket temperature at the beginning, for which formula (5) is convenient. It also follows that the Pfaundler formula cannot give the highest accuracy, but its compensating advantages are often great. Where the environing temperature cannot be measured, because the environment consists of several bodies at different temperatures, the Pfaundler formula, or something equivalent, is indespensable, and this is probably the case with most existing calorimeters.

On the whole, then, the advantageous treatment of the cooling correction depends upon the observer's knowledge of conditions; the more he knows, the shorter and more accurate his work will be. If jacket temperature and heat of stirring and evaporation are all unknown the Pfaundler formula is essential, with three periods to observe. If these conditions are known the periods may be reduced to two, and accuracy may also be increased by suitable choice of initial temperature. If the cooling factor of the calorimeter is also known the periods may be reduced to one, with no loss of accuracy. If, finally, the form of the heating curve (i.e., during the transfer period) is known, the observations in that one period may be omitted, but, probably, with some loss of accuracy in many cases.

For *adiabatic methods,* also, essentially the same relation holds between the observer's knowledge of conditions and the ease and accuracy attainable. In these methods the jacket temperature, of course, must always be measured, but if the heats of stirring and evaporation are not exactly known two periods are necessary, with the same thermometric error as when formula (2) is used. The periods can be reduced to one, with thermometric error as small as with formula (3), and this requires (as for formula (3)) an exact knowledge of the heats of evaporation and stirring. The cooling factor need not be known for the adiabatic method, but this is not a matter of much importance, since a very approximate knowledge is enough in any case. The computation of the correction is saved in the adiabatic method, but an equivalent labor is substituted for it. In the "diabatic" method the observer reads certain temperatures, which he afterwards adds; in the adiabatic he duplicates these temperatures in the jacket, and must then refill the jacket and adjust it for the next determination.

Graphic methods are sometimes used for computing the cooling correction. Instead of *adding* the individual temperatures, the observer *plots* them, and then measures the plot with a planimeter. There is no question, however, that, with observations equally spaced in time, the easiest and most accurate way, by far, of getting their sum is to add them. The graphic methods are only valuable and, as a rule, have only been used in cases where the observations are taken at irregular time intervals. With such observations all the periods are of irregular lengths, and the labor of computation is considerably increased. The graphic method is merely a means of diminishing the inconvenience inherent in observations of this sort. These irregularly timed observations result from a method of reading which is often adopted with electric thermometers, but which is not in the least necessary; and is even less convenient with properly arranged apparatus. In general, therefore, they can be avoided, and with them the graphic methods which they make necessary.

The treatment of the *corrections for large intervals* remains to be considered. All the above formulas treat the cooling rate as proportional to the temperature difference of calorimeter and jacket, and owe their convenience to that proportionality. It is desirable to use the same formulas even where that proportionality no longer exists. The method of doing this can, perhaps, be best illustrated by the actual description of a simple calculation.

For this method it is necessary to know the difference of calorimeter and jacket, and this involves some measurement of the jacket temperature. But variations in the jacket temperature do not need to be known as accurately as for small intervals. And in the computation only the temperature difference is used; the absolute temperature of the system is of no importance practically.

Suppose, now, in a systematic study of the cooling of the calorimeter, the following results have been reached:

When the temperature difference was:	The cooling per minute was:
1°	0.002°
2°	0.004°
3°	0.007°
4°	0.010°
5°	0.014°

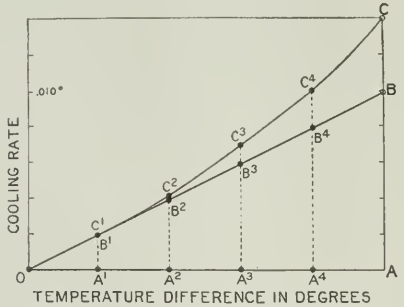
These results are plotted as in Fig. 1, where OA_1, OA_2, etc., represent the observed temperature differences, in degrees, and A_1C_1, A_2C_2, etc., represent the corresponding cooling rates of the calorimeter in thousandths of a degree.

[1] Of course ϕ may be used in the Pfaundler formula if this is desirable.

The straight line OB is now drawn through C_1. The points B_2, B_4, B_5 on it correspond to 3°, 4°, 5°. Since B is straight, and runs through the origin, the vertical distances A_2B_2, A_4B_4, etc., are proportional to th eorizontal distance OA_2, OA_4, etc.

Suppose, now, that a calorimetric determination is made, and that during it observations of temperature difference are made as follows:

1°, 3°, 4°, 5°, 5°, 5°, etc. These numbers have been obtained as a means of afterward finding the cooling that has taken place. That is their only function. It can be performed because to each number there corresponds a particular cooling rate. But a series of numbers *proportional* to the rates, if we had them, would enable us to obtain the rates more easily. Hence, if for the observed differences 1°, 3°, etc., we can substitute another set of numbers which are proportional to the desired rates, the purpose of the original observations will be accomplished and at the same time computation will be facilitated. Such numbers can be obtained from Fig. 1. Thus: the vertical distance A_1C_1 represents the rate for 1°. The ratio between rate and number is 0.002. The rate represented by A_3, C_3 does not bear the same ratio to 3°. But if the difference, 3°, is increased in the ratio $\frac{A_3C_3}{A_3B_3}$, becoming $\frac{7}{6} \times 3°$, or 3.5°, it will bear the desired ratio to the rate, for the rate is 0.007°, which is 0.002 of 3.5°. Similarly 4°, multiplied by the ratio $\frac{A_4C_4}{A_4B_4}$, or $\frac{5}{4}$, becomes 5°, which is proportional to the rate, 0.0100, which prevailed when the difference was 4°. Similarly, 5° becomes 7°, of which the 5-degree rate, 0.014°, is 0.002. And so on. Now, the condition for the



COOLING RATE AS FUNCTION OF TEMPERATURE DIFFERENCE.

cooling correction formulas given above was that rates should be proportional to temperature differences. The new temperature differences which we have just formed artificially fulfil this condition, and so they enable us to use *any* of those formulas with no further trouble.

In practice, the matter is much simpler than in the case just described, which was intended to illustrate the principle. For, (1), the curve of Fig. 1, is not used directly, but the values B_3C_3, B_4C_4, etc., are plotted in another curve on such a scale that they give at once the amounts which must be added to the temperature differences in order to obtain the proportional numbers. Thus, in the present illustration, against the abscissas 1°, 2°, 3°, 4°, 5° would be plotted the numbers 0, 0, 0.5°, 1°, 2°, and a smooth curve drawn through these points. Again, (2), the correction will almost never be needed for calorimetric intervals under 4°, and only occasionally even where the interval reaches 12°. For instance, in one case, where the cooling factor of the calorimeter increased 18 per cent as the temperature difference increased from 1° to 12°, it was nevertheless found that for determinations involving a 12-degree interval the correction for variation of the cooling factor was only $\frac{1}{20000}$ of the calorimetric interval, which, of course, is usually quite negligible. In many cases the total correction would not be negligible, as in this case, but the variations between different values of the correction would be, hence, after a few determinations had been carried through, a single constant value for the correction could be adopted, and no more computation would be needed.

The above method does not require that the cooling factor of the calorimeter remain constant from day to day. It merely supposes that the rates for different temperatures remain in nearly the same relation to each other, which will always be the case. The correction curve may be in error by 16 per cent, and usually much more, without causing perceptible error, as long as it is a smooth curve. But the different numbers obtained from the curve must not show *accidental irregularities* greater than the allowable error of the temperature difference observations, whatever this may be. This condition is easily secured by drawing the curve to a sufficiently large scale. (A discussion of the possible error in this method of correction will be found in the *Physical Review* articles already several times referred to.)

The present paper discusses (1) calorimetric thermometers. Electric thermometers, both resistance and thermoelectric, are at least ten times as accurate as mercurial, and are in some ways more convenient, though more expensive and complicated. (2) Cooling correction formulas are discussed, new forms being given which both cost less labor than the older forms and allow higher accuracy. Adiabatic methods are subject to the same principal limitations as those where corrections are used. In all, the accuracy and the ease increase with the observer's quantitative knowledge of such conditions as jacket temperature, heat of stirring, etc. (3) A method of applying ordinary formulas to large intervals is described in detail.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in May, 1911, was 68. The total tonnage of ore milled during that period was 2,051,975 tons. There were 9,978 stamps in operation with an average duty of 7.66 tons per stamp in 24 hours. Tube mills in commission numbered 218. The yield for the month was 685,951 fine ounces gold. This record is one of the best ever made on the Rand, from the point of view of high tonnage and gross yield. The plant in operation is also greater than ever before.

Chrome iron is used extensively in the manufacture of special steels, either alone or with tungsten, manganese, nickel or other steel-hardening materials. It is also used for lining metallurgical furnaces to prevent excessive corrosion. For this purpose it is used in the crude form or as chrome brick. A third use is in the making of chromium compounds, such as the metallic chromates and alkaline bichromates for use as pigments, mordants and tannages. According to reports from the U. S. Geological Survey, the production of chromite in the United States fell off in 1910, amounting to only 205 long tons, valued at $2,729, as compared with the 1909 production of 598 long tons, valued at $8,300. Almost the entire production of chrome iron ore in the United States has come from California and Wyoming, mostly from the former State. The imports from New Caledonia, Greece and other countries amounted in 1910 to 38,579 long tons valued at $415,768, as compared with 39,624 long tons valued at $460,578 in 1909. Fifty per cent chromic oxide is the basis of valuing chrome iron ores, the price per ton rising or falling with higher or lower percentages.

The Marked Influence of Copper in Iron and Steel on the Acid Corrosion Test*

BY WILLIAM H. WALKER, PH. D.

The unwarranted use which has in the last few years been made of the name of the American Society for Testing Materials in urging the validity of the so-called acid corrosion test, concerning which definite action has been taken in the report of the Committee on Corrosion of this Society at the present meeting, has made the Society unwittingly more or less responsible for two rather grave errors. These are first, that the rapidity of a given sample of iron or steel to dissolve in acid measures its tendency toward natural corrosion, and second, that a low acid test is an index of great purity of the specimen—that is, of an extraordinarily high content of iron. Enough data are now available to show the unreliability of the first assumption, and it is the purpose of this short article to show the fallacy of the second.

In investigating samples of iron and steel which had withstood corrosion for years, and which notwithstanding dissolved in acid very readily, together with samples which withstood solution in acid in a remarkable manner, and yet were rusting at the ordinary rate, it was found that the acid resistant specimens contained in every case a substantial amount of copper; that is, the presence of copper seemed to be the controlling factor in the resistance to solution in acid.

Upon examining the literature of the subject sufficient data to justify this conclusion was found. A number of investigators have studied the matter, and the results of all are fairly well presented in the Carnegie Research Report of Pierre Breuil on Copper Steels in the Journal of the Iron and Steel Institute of Great Britain for 1907. It is here found that small amounts of copper in iron or steel reduce enormously the tendency to pass into solution in acid.

In order to determine whether there is any foundation for the alleged fact so widely disseminated, that a highly acid-resisting iron or steel is also therefore a very pure product, the writer succeeded in having made a number of heats in a basic open-hearth steel furnace, under ordinary conditions, and using ordinary materials, into which metallic copper was added a little before or during tapping. The treatment of the product in the bar and sheet mills, and the annealing operation, was in every case as nearly identical as could be maintained. Although as the work developed many heats were made, the results were so uniform that but few will be here presented.

	C	Mn	S	P	Cu	Loss in weight in 20% sulphuric acid in 3 hours.
A	.08	.50	.018	.017	—	.2235 grams
A_2	.08	.50	.018	.017	.21	.0075 "
B	.10	.41	.027	.026	.19	.0082 "
C	.09	.31	.031	.063	.19	.0095 "

The influence of small amounts of copper in these heats is truly remarkable and shows conclusively that this wonderfully slight tendency to dissolve in acid is not indicative of great purity.

Inasmuch as the presence of metallic copper in contact with iron *increases* enormously the rapidity with which such iron will dissolve in acid, it at first seems surprising that in this case copper should *retard* this action. But we have a direct analogy in the case of zinc and copper. Zinc free from iron dissolves in acid very slowly; mix with it some metallic copper, however, and solution is greatly accelerated. But make an alloy of the two, namely brass, and the solvent action of the acid is negligible. So long as copper is not added to iron or steel in excess of the amount which can remain homogeneously alloyed therewith, the writer can see no reason why there may not be an advantage in its use. But such advantage cannot be ascribed to purity, but rather to what we may call a ferro-brass of small copper content. Reasoning from analogy with zinc, pure iron should dissolve in acid very slowly, but the converse is here shown not to be true, namely, that a slow-dissolving iron or steel is on this account to be considered an exceptionally pure product.

Electric Tin Smelting

A Commercial Scale Trial

BY JOHN HÄRDÉN.

Very little has as yet been said or published on the subject of electric-tin smelting; all that has been dealt with in the realm of the electrometallurgy of tin seems to refer to the detinning of tinplate. Stray notices may have appeared in transactions from time to time, but the writer has not been able to find any literature worth referring to, though this may be due to lack of opportunity.*

Even the smelting of tin in the orthodox way—by means of the reverberatory or the shaft furnace—is but scantily mentioned in textbooks, etc., and, as said in a recent editorial note in METALLURGICAL AND CHEMICAL ENGINEERING, very little is generally known, outside the circle of those directly interested in the subject, about the processes of the metallurgy of tin.

It may, therefore, be of interest to metallurgists to learn that electric tin smelting was carried out on a large scale as a commercial experiment in Cornwall, England, during last summer in a plant designed by the author and Messrs. Gröndal Kjellin Company, Ltd., London, as consulting engineers. In the following a brief report will be found of the work carried out, together with a few general remarks on tin smelting, which, of course, are not intended to embrace the whole scope of the subject.

Cornish Tin Smelting.

Tin smelting in the reverberatory furnace has been carried out in Cornwall since time immemorial, and the metallurgy of that process is, in a broad sense, very simple, though to make it an efficient one requires a good deal of minor technical details and long practice. Broadly speaking, the method is this:

The tin ore, chiefly consisting of stannic oxide, SnO_2, as mined in Cornwall, is being dressed in streams or on tables in the mines, so as to contain about 63 per cent to 64 per cent of tin. The ore is delivered in bags of about 3 cwt. each in the form of a dense, red-brown, moist powder, fairly finely ground, say about 15 to 20 mesh. After allowing to dry for some little time (depending upon the moisture, which may vary from 7 per cent to 15 per cent), the ore is mixed with the reducing agent—a low-grade anthracite called "culm"—which contains a considerable quantity of slatey clay or aluminium-magnesium silicate, etc.

The quantity of culm to be used depends, to a certain extent, upon the character of the ore. It is unusual to use one kind of ore only; indeed, the proper blending of different ores is one of the principal factors in producing an efficient melt. Bolivian or Straits tin ore is very often mixed with the Cornish ore. Generally about 20 per cent to 25 per cent of culm is used; for the first charges no other flux is added. One furnace is generally built so as to take a charge of three to four tons of ore and about three-quarters of a ton of culm; a certain portion of the culm acts as fuel. A quantity of the ores is previously mixed with culm in various proportions and smelted in a test crucible of graphite so as to give best yield.

It is very essential to conduct the smelt so that the temperature is raised gradually, especially if the ore is of a silicious nature, because if the temperature rise is too brisk tin silicate and silicides will be formed, which will go into the slag directly,

*See also: Reduction of Tin Dross in an Electric Furnace, Am. El. Ch. S., 1910, by R. S. Wile.

causing a great loss. Also volatilization must be guarded against, as the metal is comparatively strongly volatile. In more modern plants a condensing chamber is used to recover the losses. The charge is frequently rabbled with iron rakes so as to ensure an even distribution of the heat. In some plants a quantity of scrap iron is added to the charge before the melt is finished in order to cause impurities to be taken up by the slag rich in iron which is being formed.

The melt is finished after six to eight hours, when the tap-hole is opened and the metal and slag are run off together into a hemispherical cast-iron pan, which is often provided with special heating arrangements. Each pan will hold four to five tons of metal. The slag floats on the surface of the metal and is run off into iron boxes to solidify.

This first slag is generally rather rich in tin; it may sometimes contain 14 per cent to 16 per cent of tin in various combinations. It is, therefore, frequently used as an admixture to a subsequent smelt, or may be treated separately for tin. The final slag is said to contain about 6 per cent to 7 per cent of tin, and is, therefore, sometimes smelted together with lead refuse for solder tin. In more modern plants, however, the slag contains only 2.5 per cent to 3 per cent of tin.

The crude tin, as first obtained, is cast into large ingots, still containing a considerable quantity of impurities. These ingots are placed on the sole of the reverberatory furnace and remelted at slow heat and low temperature, so-called liquation process. The pure tin is thereby run off and the impurities remain behind, forming the so-called "hardhead," which chiefly consists of an alloy of tin with sulphides and arsenides of iron. The percentage of tin varies somewhat, but is always considerable, and this "hardhead" is causing the smelter considerable trouble. One of the objects of the electric smelting was to try to eliminate, if possible, the formation of this undesirable hardhead, which is so difficult to treat separately.

After the tin has been liquated it is collected in a large pan, or refining pot, heated from underneath. This tin is usually about 96 per cent to 98 per cent pure and still contains impurities of arsenic, tin-suboxides, etc. For further purification so-called "tossing" and "boiling" are employed. The former consists in scooping the hot metal in thin broad streams through the air, whereby the impurities are oxidized and float on the top. The "boiling," which is more common, consists in immersing a raw piece of wood of large dimensions in the metal, vigorously stirring the same. (Formerly it was believed that only wood from apple trees would serve the purpose properly.) A violent agitation sets in, oxidizing the impurities.

In modern plants dry steam and air are blown through the metal for the same purpose.

A small sample is ladled out from time to time and poured into the groove of the "test stone," a porous, white sandstone; the behavior of the solidifying metal, together with the fracture of the notched bar and the special sound of the "tin crying," tells the skilled smelter of the purity of his metal. Indeed, this test is so marked that an experienced smelter can tell within 0.2 per cent of the purity of the tin. Refined tin should have 99.6 per cent to 99.8 per cent of tin.

The refined tin is usually cast into 28-lb. ingots and branded with the trademark or else into strips of 18 in. and about ½ in. thick.

Electric Tin Smelting.

At a first glance it would seem that the electric furnace would not adapt itself very well to the smelting of tin ore, since the temperature of the electric furnace would appear to be unnecessarily high for the reduction, and even injurious. However, this assumption is quite erroneous. The reduction of stannous oxide by carbon requires a comparatively high temperature, especially if a good separation from impurities is to be effected. Besides, tin is readily volatile at this high temperature and in a reverberatory furnace with its wide hearth communicating directly with the smoke stack or else in the tin blast furnace where air is forced through the charge this volatilized metal is mostly lost altogether if complicated condensing devices are not provided for.

All this is mostly avoided with the electric furnace, if properly designed. Another feature is that the so objectionable formation of "hardhead" can be greatly reduced if the process is carefully conducted, as will be seen later. Finally, if the cost of power is not too high a decided economy, compared with the reverberatory furnace, is quite possible, as the experiments made have shown.

As to the losses of tin in slag, it has been conclusively shown that one has it in hand to so conduct the operation that slags containing only 0.25 per cent of tin may be produced in one melt; but it appears to be more economical to so conduct the process that a richer slag, containing, say, 14 per cent to 16 per cent of tin, is first produced, and to treat this richer slag while still hot in a second furnace as in this case the output is very much increased.

Theoretical Yield.

If tin oxide, SnO_2, is reduced by means of carbon, we may assume that the ideal equation is

$$SnO_2 + C = Sn + CO_2 \qquad (1)$$

but that part of the reaction takes place according to the equation,

$$SnO_2 + 2\,C = Sn + 2\,CO \qquad (2)$$

This is substantiated by the fact that a considerable quantity of CO can be seen burning at the mouth of the furnace; a certain amount of the CO will naturally serve as a reducer when passing through the charge piled up in the shaft, and, for reasons given before by the author in his article on "Electric Iron Reducation" (see Electrochemical and Metallurgical Industry, Vol. VII, 1909, page 16) it is of importance to so conduct the charge that the reaction (2) is predominant, though it will hardly be possible to realize this in practice to a greater extent than 50 per cent. Also the packing of the charge in the shaft, owing to the heaviness and fineness of the ore, will prevent this to a certain extent. We may therefore presume that under proper conditions, and after some hours' run, the reaction goes on according to 50 per cent of each of the equations 1 and 2.

The Heat Energy Required

According to Thomson and other investigators, 118 grams of tin (one gram-molecule) will yield 145,300 gram calories by combustion into tin oxide. This amount of energy will, therefore, be required for the liberating of 118 grams of metallic tin.

On the other hand, the combustion of 12 grams carbon into CO_2:

$$C + 2\,O = CO_2$$

will yield 96,960 gram calories,

and the combustion of 24 grams of carbon into 2CO:

$$2\,(C + O) = 2\,CO$$

will give (in round figures) 58,000 gram calories.

Assuming, therefore, that the reaction takes place according to equation (1), or $SnO_2 + C = Sn + CO_2$, we can calculate the energy requirements of the reaction per ton of metallic tin as follows: 145,300 — 96,960 = 48,340 kg calories per 118 grams of tin, or 409,661 kg calories per kilogram of tin, and as one kw-hour = 864 kg calories we have for one ton of tin:

$$\frac{409{,}661.1000}{864} = 474 \text{ kw-hours per ton of tin.}$$

In the same way we find that, if the reduction takes place according to equation (2) or $SnO_2 + 2\,C = Sn + 2\,CO$, 855 kw-hours per ton of tin are required.

Assuming that the reaction takes place to the extent of 50 per cent of either of the reactions (1) or (2), around 665 kilowatt-hours per ton of tin are required.

In addition to this, a certain amount of energy is required for the heating up of the charge to the temperature of reaction. No actual measurements of the temperature in the furnace were taken, but, judging from the appearance of the slag and the

metal tapped, it may be safe to assume that the main average of the temperature of the whole interior of the reactive zone was about 1400° C. to 1600° C.

Assuming that the ore contains 90 per cent tin oxide, we require 1280 kg of ore for each ton of tin. Experience has shown that about 16 per cent to 20 per cent of slag per ton of ore is an average, or about 220 kg of slag per ton of tin. The melting of 1 kg of slag requires, as an average, 500,000 gram calories = 0.6 kw-hour, or around 130 kw-hours for each ton of tin.

The heat capacity of the charge and the molten tin we may set at 65 kw-hours as being on the safe side.

The radiation losses through the furnace walls, electrodes and water jackets are naturally of such nature that no accurate figures can be obtained, but it seems safe to assume this loss to be equal to that consumed by the slag, or 130 kw-hours. The escaping gases, in the furnace used for our experiment, left the furnace mouth at a temperature of around 800° C.; the losses through this source may therefore be set at about 150 kw-hours for each ton of tin.

In summing up these items we therefore find that in practice it should be possible to produce one ton of tin with an expenditure of power equal to:

For the reaction	665	kw-hours
For the slag	130	"
For the specific heat	65	"
For the radiation losses	130	"
For the losses through gases	150	"
		"
	1,140	"

In the experiments carried out this theoretical figure naturally could not be obtained, as the furnace was too small, and also for other reasons given below, but a very fair result was obtained, as will be shown.

Practical Tests.

At the request of Mr. A. F. Maclaren, of London, the author was given the task of carrying out some experiments on these lines late in 1909. Some difficulty was at first experienced in finding a suitable place for the preliminary trials on a laboratory scale, but early in 1910 Dr. Walmsley, of the Northampton Institute, courteously permitted the tests to be made in the Electrochemical Laboratory of the Institute. A furnace had been designed for 800 amp and 50 volts alternating current, though only direct current of about 300 amp and 100 volts was obtainable at the Institute. The direct current is especially unsuitable for this class of work on account of the heating effect being more prominent on the positive electrode, which was fully manifest during the operation. Also electrolytic effects on the slag were to be reckoned with. In addition to this, the tests must be carried out so as not to disturb the ordinary work of the laboratory, which naturally also hampered the results.

In spite of these difficulties the following results were obtained, which proved the feasibility of the matter:

The furnace was built up in a manner somewhat resembling the one designed by Harmet for iron ore reduction. It was provided with a bottom chamber of magnesite bricks, rammed with calcined magnesite and tar, in the usual manner. A charging shaft rested on a vault or arch; the inner diameter of the hearth was about 5½ in. and the total height about 14 in.

Two lateral and inclined carbon rods about 2½ in. in diameter round were used as electrodes and reached into the center of the hearth about 2½ in. from the bottom. No cooling jacket was used, though it would have been of great assistance.

The wear and tear of these electrodes was so little, in spite of the primitive arrangement, that it could hardly be taken into account for the experiments; this was also manifested during later experiments.

A preliminary heat was made on Jan. 27, 1910. The charge consisted of:

Tin ore (about 63 per cent of tin)	20 lb.
Coke powder	5 "
Flux	5 "

Of this only 12 lb. of ore was actually reduced owing to lack of power. Totally about 40 kw-hours were spent, of which 15 were used for heating up and 25 for the reduction proper. The smelt yielded 5¼ lb. of pure bar tin and 1¼ lb. in shape of shots, thus corresponding to about 85.5 per cent of yield from ore. The slag was very irregular, as only one mutual taphole was provided for, so that some metallic tin remained in the slag. Thus the power expenditure amounted to around 4 kw-hours per pound of metal, or 8960 kw-hours per ton. Great losses of heat were experienced owing to the primitive arrangement of the furnace.

In the next trial the slag from the first melt was used as a flux. This proved to be a disadvantage, as it required a much higher temperature to be remelted, and the taphole froze very readily.

In a subsequent test 16 lb. of ore were smelted, giving 6½ lb. of pure bar tin and 2½ lb. of shots, or a total of 9 lb. of metal, equal to around 90 per cent of the metal in ore. The maximum power was 8.4 kw and the total duration of the melt two hours. The total power used, including heating up, was 19.2 kw-hours, or 2.15 kw-hours per pound, or about 4900 kw-hours per ton of metal.

The tin obtained direct from the furnace proved to be well over 99 per cent pure; it contained very little iron and no arsenic. The slag varied in appearance; if the run was smooth it flowed freely and showed a grayish glassy luster. Three average samples of this proper slag were analyzed and found to contain in the average 0.5 per cent of tin. The stiff black slag obtained in some melts contained, however, as much as 8 per cent of tin. Thus the best efficiency obtained from this little furnace, thermically, was about 25 per cent, while the metallurgical yield was as high as 90 per cent.

A test for electrolytic recovery of the tin in the slag was also made. Some slag and refuse containing an appreciable amount of metal was fused with soda (which may be carried out at once while the slag is hot). This was readily soluble in water and could be electrolyzed direct, with iron plates as cathode. A good deposit of tin was obtained, though the efficiency was not very high.

If, however, the oxide from the slag is converted into chloride of tin the theoretical power consumption would be about 1820 kw-hours per ton of metal. Assuming an efficiency of, say, only 50 per cent, this recovery may be possible, where the power price is low, with a rotating cathode and scrap tinplate as anode.

In view of the above promising metallurgical results it was decided to carry on experiments on a much larger scale on a commercial basis. A power supply of 100 kw was secured and a suitable site acquired where a galvanized iron building was erected, a tank for cooling water was built and every facility provided for a conclusive test.

The Electrical Equipment.

Current was obtained from a Diesel engine plant supplying power for a tin mining concern; the condition was that no disturbance or great fluctuation should be caused which might endanger the regular working of the pumps in the mine. The electric-power supply was three-phase, 50 cycles, 650-675 volts.

To meet this requirement a Berry three-phase transformer, oil-cooled, was installed, receiving constantly 660 volts on the primary side, in star connection, with only lightning arrester and main switch on the line; the secondary side, which was also in star connection with earthed neutral, had four tappings capable of giving either 30 volts, 40 volts, 50 volts or 60 volts The terminals ended in copper busbars on a slate panel provided with heavy copper screw plugs for obtaining the desired combinations. Each phase on the secondary side was provided with an ammeter; a voltmeter with a change-over switch served for

all three lines, while the recording and indicating wattmeters were on the primary side.

The busbars were connected with the furnace electrodes by means of each four flexible cables of suitable size arranged so as to give the least possible induction. As, however, the current was as high as about 2500 amp, a certain drop in power factor was inevitable; it was on the average about 0.90.

During the whole trial period no disturbance whatever was caused by the electrical gear, though one or two thunderstorms were experienced; the distance between power house and smelting plant was about 600 yd.

The Furnace.

The furnace used is a shaft furnace of special design. Owing to pending patent applications a detailed description of this, as well as of the details of the actual smelting process employed, will have to be deferred for a later occasion. One of the principal features in an ordinary reverberatory tin furnace is that the metal, like mercury, will percolate into the lining and brickwork in large quantities and remain lodged there until the furnace is broken up. In a large plant with a number of furnaces this means a locking up of a considerable capital for a long period, which, naturally, is objectionable. This is successfully avoided in the new design of the electric furnace, where only a minimum quantity of metal is withheld, all the metal being drawn off as soon as it is formed.

Three electrodes of carbon 8 in. x 8 in. square and 4 ft. 6 in. long, cooled by water jackets, were used. The electrodes were held by means of gripping holders extending over half the electrodes and moved upward as the ends are worn off. The holders were suspended by means of flexible steel rope and worm-gear winches, permitting of a fine adjustment.

No direct arc was permitted to be formed, as this caused a great variation of the yield and the working of the furnace. The charge formed a cone-shaped heap in the hearth, covering the reacting zone, permitting the electrodes to "burn free," forming a small space filled with incandescent gas round the ends which acted as a resistance, in which the reaction took place. This is, as is well known among furnace men, the only efficient way of properly working a furnace.

Arrangement was made to prevent the escaping of volatilized metal; only about 0.5 per cent or less of tin found its way out of the furnace.

Tapholes on different levels were provided for drawing off metal and slag separately. Sometimes the slaghole may be frozen up with a hard slag crust, especially if the ore is rich in iron which all went into the slag. In that case a small auxiliary electrode was used for burning the taphole open again, which could be made very easily, though it should be admitted that an oxy-acetylene jet would be even more handy.

The Smelting Process.

At the start of a campaign, which usually lasted 10-12 days, on account of the experimental nature of the trials, though there was no objection in keeping the furnace working for months in succession, the empty furnace was first pre-heated for about four to six hours by means of a small wood and coke fire in order to prevent cracks in the brickwork. In subsequent smelts this could be almost entirely dispensed with, since the lining had properly set.

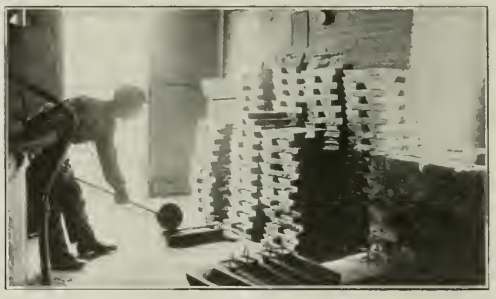
A charge of about 14 kg of culm for each 100 kg of ore, depending somewhat on the nature of the ore, was gradually filled in, while a current of about 1000 amp per phase, at 60 volts, was turned on. As the reaction commenced to set in the volts were lowered gradually to the working condition of 40 volts and 2500 amp, which was steadily maintained during the whole run. Only on special occasions, with certain ores, was 30 volts used.

The current fluctuated considerably at the beginning as the cold charge was being thrown in, but as soon as the electrodes had commenced to "burn free" properly the fluctuations ceased. Already half an hour after the first charge could the first tapping of metal take place, while the first slag was drawn after the furnace had been in proper working for a couple of hours. The appearance of the slag rendered it possible to the experienced eye to judge if the charge was of right composition or not; if of a glass-like, dark brownish green color, and freely leaving the taphole, the charge was right; if sluggish and light brown it had to be altered.

After a few hours' run, certain reagents were added at regular intervals; this successfully prevented the formation of "hard-head," causing the sulphides and arsenides of iron to enter into the slag instead of alloying with the tin. The result was that the metal, as it left the taphole of the furnace, was about 98 per cent pure, if the right blend of ore, not too much contaminated with impurities, was used. In one campaign ordinary Bolivian ore only, with only 49.5 per cent tin, and about 15 per cent of iron, was smelted solely for about ten days, and yielded over 92 per cent totally, on some days even 97 per cent of the metallic tin from the ore.

The liquid metal was accumulated in the usual way in large pots of wrought iron, heated from underneath and the sides. By means of an air-pump air was blown through the metal through a perforated iron pipe, whereafter the metal was ladled into a second tank to set properly. With this simple operation a metal of 99.75 per cent purity, and even more, was obtained, though this is well up to commercial standard.

The metal was then poured into ingots of about 28 lbs. weight, branded and stored in the usual way. The accompanying



STOCK OF INGOTS OF ELECTRIC TIN.

photograph shows a stock about 2 tons of ingots, being produced in about 1½ days.

Output, Power Consumption and Loss in Slag.

All three of these factors were found to be in close relation to each other. It was thus found that a slag containing as low as 0.25 per cent of metallic tin could easily be produced, but to do this in one operation proved to be less economical with the prevailing power price. The output was only about 6 to 8 cwt. per day, and the power consumption correspondingly high, or about 3000 kw-hours per ton of metal.

Going to the other extreme, the operation could be so conducted, by altering the composition of the charge, that a slag containing 17 per cent to 19 per cent of tin was produced. In that case the output increased to 1 ton 11 cwt. per day, with a power consumption of 1300 kw-hours per ton of metal.

As only one furnace was provided for, this manner of operation was not commercial, with such high losses of tin in the slag, although this slag could be treated again separately. It was found most economical under the prevailing conditions to operate the furnace so as to obtain a metallurgical yield of 90 per cent to 98 per cent, with a higher power consumption. The following weekly report for the week July 28 to August 4 is fairly typical:

Ore used: 21,056 lb. @ 57 per cent=	12,003	lb. metal
Scrap metal and charge refuse.... =	2,324	" "
	14,327	" "

Tin produced, 14,170 lb.
Net yield, 98.75 per cent.
Total number of kw-hours, 15,113.
To be deducted: for slag treatment (experiment), 678; for preparing furnace, etc., 500.
Total number of kw-hours used for reduction, 13,935.
Units per ton = 2220.
Electrode consumption, 28 lb. per ton of metal.

It should be noted that this figure for the power consumption was taken as an average over a single run of eight days, during which experiments with different charges were made. On single days the power consumption was only 1700 kw-hours per ton.

Conclusions.

The above figures bear out that a considerable saving in tin can be effected by means of electric smelting. If the plant is so arranged, as is so often done in other metallurgical processes, that two furnaces are working in series, the first one providing metal at a great rate continuously, and permitting the hot slag, rich in tin, to run direct into the second furnace for subsequent treatment, eventually with lead ore for solder in order to hasten the process, the power consumption should not exceed 1400 kw-hours per ton of tin (or about 55 per cent of theoretical) tin, in a sufficiently large furnace.

Even this figure may be decreased if proper blending of ores is strictly reverted to. In the above-mentioned cases single ores were mostly used, on account of the high price of the ore, which prevented the laying in of a large stock of expensive materials for experiments.

Also, it should be remembered that in a large commercial plant all the modern appliances for tin smelting should be applied, which again would help to increase the yield and lower the cost.

Another feature is of importance: The electric furnace will commence to yield pure tin already during the first hour of operation, and continue to do so without interruption, while the reverberatory furnace is intermittent in its operation.

Further, the formation of "hardhead" is materially minimized.

The amount of carbon necessary for the reduction is only 14 per cent, instead of 20 per cent to 25 per cent. Less labor is required, as three ordinary laborers per shift are quite capable to run the furnace.

Much less space is required for the electric furnace than for the reverberatory.

The consumption of electrodes is comparatively so small that it need not be regarded as an objectionable feature anywhere.

If the power can be obtained at a reasonable rate it therefore appears to be quite feasible to smelt tin electrically; especially should this be the case in the Straits Settlements, where large quantities of good ore, but not very rich in tin, are mined, and where waterfalls are said to exist in abundance, but only low grade of coal, and in small quantities. The use of charcoal, which probably would be much cheaper, should give no objection whatever.

In fact, with suitable flux, charcoal would probably work even better than culm.

Native labor could be employed under white supervision without hesitation, as practically no skilled labor at all is required. It is obvious that it would be much cheaper to ship metallic tin than an ore, which, as a rule, contains only about 55 per cent of tin. Naturally the working would at first cause a considerable amount of trouble, and would require a good deal of metallurgical and chemical engineering, but, on the whole, it seems justifiable to say that the principles of the problem are solved.

The above experiments will probably be resumed in a short time, in a somewhat modified way, by which an even greater saving is reasonably expected.

London, England.

The Right of Employer and Employee in Questions of Priority.

A recent decision in an interference case rendered by the United States Patent Office goes deeply into the legal right of employer and employee in questions of priority of invention. It is therefore of such a general and broad interest that we give here its salient features.

The case at issue was the following:

Davis E. Parker filed on May 18, 1906, serial No. 317,516, a patent which was granted him Jan. 5, 1909, bearing No. 909,017, covering an apparatus for preparing oxone.

An application covering practically the same subject was filed on Feb. 17, 1909, serial No. 478,508, by George Fred. Brindley, who was acting at the time in the interest of the Niagara Electro Chemical Company, Niagara Falls, N. Y.

To better illustrate the case we give herewith extracts of the decision rendered on June 9 a. c., which will give a clear understanding of the same, without going deeply into technical details of interest only to those immediately affected in the matter.

"This is an interference proceeding in which the subject-matter relates to an electrical furnace for fusing sodium peroxide. The fused peroxide has been given the trade name of 'oxone.' The issue, which is drawn to the details of the furnace structure, is defined in five counts . . . .

"The senior party, Parker, is a patentee, his patent No. 909,017 having been issued on Jan. 5, 1909, on an application filed May 18, 1906. Brindley's application was filed after the grant of the patent to Parker and is substantially a copy of said patent and the subject-matter of the interference is therefore the five claims of the Parker patent. The question at issue is one of originality rather than the ordinary one of priority of invention. Each of the parties has taken testimony in an effort to prove his claim as the originator of the invention in issue.

"At the time the invention in issue was originated both of the parties were in the employ of the Niagara Electro Chemical Company at Niagara Falls, N. Y. Brindley was works manager of the company and is shown to have had considerable training and experience in chemistry and metallurgy. He left the employ of the company in May, 1906. Parker was a machinist and was in charge of the machine shop of the company. He entered the employ of the company on March 28, 1904, and left in November, 1905. While both parties were in the employ of the same company, Parker's position was that of an assistant or subordinate to Brindley and the relation of the parties was therefore such as to bring them within the principles of employer and employee. In fact, there is no contention that the doctrine of employer and employee is not applicable to the case.

"The record shows that experiments for the production of fused sodium peroxide were begun by the Niagara Chemical Company at least as early as June, 1904. Brindley took up the problem at the Niagara Falls plant and during 1904 tried various kinds of apparatus. He claims to have built and tested a furnace like that shown in his Exhibit No. 1, and Parker admits having done the machine work on this furnace."

Then follow numerous quotations from the voluminous testimony taken in this case and the examiner then writes:

"These examples clearly indicate an indifference to accuracy on the part of Parker which cannot help detracting from the credibility of his testimony in a controversy of this character. It follows, therefore, that the question at issue will have to be determined largely from the circumstances of the case and the admissions of the parties together with the few facts that are not disputed or which are clearly established by the record."

The examiner goes thoroughly into the records submitted and comes to the following conclusion:

"Granting, therefore, that Parker did originate some of the features, it is not believed that he is entitled to claims covering a combination of such features with features which were admittedly originated by Brindley. In other words, if Brindley originated some of the features of the claim and Parker others, it seems clear that some claims must be regarded as the invention of Brindley and not of Parker. In fact the weight of decisions is believed to be clearly to the effect that such claims should belong to the employer rather than the employee. It is true that when an employee makes an invention which is independent of disclosures made to him by the employer and is able to prove his claim he and not the employer is entitled to the invention (Robinson v. McCormick, 128 O. G. 3289, 29 App. D. C. 98). But in no case known to this tribunal has it been held that claims to a combination made up of features admittedly furnished by an employer and others by the employee should be regarded as the property of the latter. In fact, the courts have frequently held that even where the features contributed by an employee amount to an independent invention a presumption exists in favor of the employer which can be overcome only by satisfactory proof that the independent invention was originated by the employee. On this point the Court of Appeals has said:

"What we hold is that when in the course of experiment by an employer with an invention a device is suggested for its improvement which in itself would reach the dignity of independent invention, and a dispute arises between employer and employee as to its conception, the presumption is justly in favor of the employer, and it is incumbent on the employee to overcome the presumption by satisfactory proof." (Miller v. Kelley, 96 O. G. 1038; 18 App. D. C. 163.)

"Evidently, therefore, in a case like that at bar where some of the features admittedly originated by the employer and the origin of the other features is in dispute a presumption exists that such other features were the work of the employer rather than the employee. And this presumption is strengthened when the particular facts and circumstances of the present case are considered. Brindley was admittedly the first to take up the problem of fusing sodium peroxide. He developed various forms of furnaces for this purpose before anything is claimed to have been done on the case in issue. He made the drawings (Brindley's Exhibits Nos. 3 to 10) which led up to the furnace in issue. He determined the size of the various parts which entered into the completed furnace, gave the order to build the furnace and, in fact, appears to have directed everything concerning the actual preparation of the first furnace involving the invention. Practically no evidence except the testimony of Parker himself has been introduced to show that any of the details were originated by Parker and this is not sufficient to overcome the presumption in favor of Brindley.

"Considering all the facts and circumstances of the case, it is believed that evidence presented on behalf of Brindley is sufficient to overcome the burden of proof under which he is placed and to show that the invention in controversy originated with him rather than with the senior party, Parker.

"On behalf of Parker it is contended that bar of public use exists the grant of a patent to Brindley and it is requested that, without deciding the question of priority, the examiner of interferences direct the attention of the commissioner to this fact. There appears to be no authority for the action requested. In fact, it appears to be well settled that where testimony has been taken and a case is in condition for final disposition action will not be suspended for the purpose of instituting public use proceeding (Brenizer v. Robinson, 166, O. G. 1281; Wert v. Borst and Groscop, 122 O. G. 2062; Doble v. Henry, 118 O. G. 2249). The question of priority has therefore been considered.

"The drawings made by Parker in the latter part of 1905 and the testimony relative thereto have not been discussed, as these matters appear to have little bearing on the question of priority. Likewise no reference has been made to the testimony bearing on the question of public use, although this testimony has been considered. It is not believed, however, that the circumstances of the case are such as to justify a recommendation as to public use under the provisions of Rule 126.

"Priority of invention of the subject-matter in issue is awarded to George F. Brindley, the junior party."

The case has been appealed.

Notes on Technical Analysis.

By R. S. Davis.

Analysis of Wulfenite Ores.—The Wulfenite ores found in the Southwestern States and Mexico usually contain more or less tungsten and vanadium, and as these elements exert a decided influence on the metallurgical process of extraction a practical method for the analysis of such ores was devised by the writer, as follows:

Pb. Mo. V. Treat one gram of the agate-ground sample with 10 cc. HCl and 5 cc. HNO_3, warm on hot plate and after the action has somewhat subsided add 10 cc. H_2SO_4 and evaporate to strong sulphuric fumes. Cool somewhat, dilute and heat until all is in solution excepting the lead sulphate and silica. Filter into a pressure bottle (a citrate of magnesia bottle with patent clasp stopper is well adapted for this purpose), washing with water containing a little sulphuric acid. Dissolve the lead sulphate in hot ammonium acetate and acetic acid, filter from the silica, washing well with hot ammonium acetate solution and estimate the lead by titrating with ammonium molybdate. If desired, one may add a large excess of sulphuric acid to the lead acetate solution, boil, add alcohol and determine the lead gravimetrically as sulphate.

Pass H_2S into the filtrate contained in the pressure bottle for about fifteen minutes, then stop the bottle, place in a vessel of warm water and heat to boiling for twenty minutes. If the amount of MoS_2 is small, and a preliminary test has shown copper to be absent collect the precipitate in a Gooch crucible, dry and ignite gently until there is no sulphurous odor, then heat to faint redness and weigh as MoO_3, containing 66.57 per cent. Mo. If this molybdic acid is not entirely soluble on warming with ammonia the residue should be deducted. It is safer, however, especially if there is much molybdenum, to proceed as follows:

Dissolve the MoS_2 in HNO_3, evaporate in a casserole to dryness then heat over a wire gauze to remove all sulphuric acid. Add 5 cc. ammonia and warm until the MoO_3 is all in solution (if copper is present use KOH instead of ammonia, dilute, boil, filter off the cupric oxide and estimate the copper by any convenient method). Filter if necessary, acidify with acetic acid, boil and add an excess of lead acetate. Filter and wash the precipitate with hot ammonium acetate solution to remove any trace of lead sulphate then with hot water, ignite gently and weigh as $PbMoO_4$, containing 26.15 per cent. Mo. The writer has not had much success in estimating Mo by the zinc reduction processes excepting when very little Mo is present.

Boil the filtrate from MoS_2, which will be green or blue if vanadium is present, to remove H_2S. Then add permanganate to a pink color. The amount of permanganate used will show approximately the Fe plus V present. Add an excess of permanganate and boil at least five minutes. Then add ferrous ammonium sulphate until the MnO_2 is dissolved and the liquid clear, and boil. Cool to about 70° C., add permanganate to a pink color, then run in ferrous ammonium sulphate until a ferricyanide spot shows an immediate blue color. Titrate back with permanganate until the spot shows no blue color in thirty seconds, read the burette and run in permanganate until a pink color is obtained, which persists one minute. The iron value of the permanganate multiplied by .916 gives the vanadium value. If the quantity of vanadium

is so small as to make its presence doubtful it is well to add H_2O_2 to the solution after titrating. This destroys the permanganate color and shows as little as .05 per cent vanadium by the characteristic red-brown tint.

The amount of iron present is approximately shown by deducting the permanganate used in the vanadium titration from the amount required to oxidize the iron and vanadium above.

W and Si are best determined in a separate sample. Treat one gram of the powdered ore with 20 cc. HCl and evaporate to dryness. Add 10 cc. HCl and about 100 cc. water and heat to boiling. Filter and wash by decantation with hot dilute hydrochloric acid until all lead chloride is removed from the precipitate. Add 10 cc. dilute ammonia containing a little ammonium chloride to the breaker containing the WO_3 and silica, allow to stand about five minutes and pour on to the filter, receiving the filtrate into a platinum dish. Wash four or five times using about 2 cc. of the ammonia solution for each wash. Evaporate to dryness, ignite gently until the ammonium salts are volatilized then at a moderate red heat. Do not heat excessively as WO_3 can be slowly volatilized with a strong Bunsen flame. Add a few drops of HF and a drop of sulphuric acid to the dish, evaporate, ignite, and weigh the WO_3.

Determine silica in the residue by loss with HF, and add to this result any silica found with the WO_3.

The Analysis of Ferro-Boron.—After considerable experimenting with various methods suggested for the determination of boron in metallurgical products, the writer has found the following plan to be both accurate and rapid:

Fuse one-half gram of the powdered sample with potassium nitrate and sodium carbonate in a platinum crucible. Pour the melt upon an iron plate, transfer with the crucible to a porcelain beaker and boil with just enough water to effect disintegration. Add a little sodium peroxide during the boiling to precipitate manganese. Filter into an Erlenmeyer flask and wash with hot water. Reserve the residue for manganese determination. Acidify the filtrate with hydrochloric acid and then add a moderate excess of calcium carbonate. Connect the flask with an upright reflux condenser and boil about ten minutes to remove all carbondioxide. Filter, cool to room temperature, add phenophthalein and run in deci-normal sodium hydrate to pink color; then add about one gram mannit. This destroys the color, and more sodium hydrate is added until the color is permanent, even on the addition of more mannit.

One cc. deci-normal sodium hydrate equals .0011 gm. boron. No deduction is required for blank.

One-half gram steel containing 4 per cent manganese, to which .03 gm. boron was added in the form of fused boric acid gave by this method .0299 gm. boron.

Dissolve the residue from the fusion in hydrochloric acid, add 15 cc. sulphuric acid and evaporate to strong sulphuric fumes. Cool, dilute, heat till clear and make up to 250 cc. Take 50 cc. for manganese determination by the bismuthate method, and 50 to 100 cc. for iron determination. Manganese may be made on a separate sample if desired by the bismuthate method without separating the boron.

Silica is determined in the usual way, and carbon by direct ignition in oxygen, spreading the sample over ignited asbestos in the combustion boat.

Primos Chemical Co., Newmire, Col.

The Electric Iron Reduction Plant at Trollhattan, Sweden—II.

In our July issue, page 368, was given a detailed description of the electric iron ore reduction plant at Trollhattan, Sweden, from a paper of Mr. J. A. LEFFLER, presented to the Jernkontoret (The Swedish Association of Iron Masters) at their meeting at Stockholm on May 31. The following is an abstract of the part of Mr. Leffler's paper in regard to the principles employed in the design of the furnace, analysis of materials, operating results, etc.

The Principles of the Reduction Furnace.

The fundamental principles of the construction of this furnace which was invented by Messrs. Grönwall, Lindblad, and Stalhane, is described in a communication from the Electrometals Ltd., of London, England, as follows:

1. As all known materials become good conductors at a high temperature, the construction must be such that the current does not pass away through the lining during the working.

2. The construction must be such that the charge itself protects the lining from destruction through radiation from the electric arc or through conduction; otherwise it would be necessary to employ water-cooling with consequent waste of energy.

3. The charge must not press harder against the electrodes than to permit the formation of an arc. If this condition is not fulfilled the working becomes irregular and the tension becomes unduly low, so that the electrodes and conductors would have to be of inordinately large dimensions.

FIG. 1.—FURNACE STACK.

4. In an electric furnace the carbon charged with the ore cannot burn, and in order to obtain a product of uniform quality it is, therefore, necessary to have a hearth of sufficiently large dimensions, to serve as a mixer. Otherwise every irregularity which inevitably occurs in charging will influence the carbon contents of the product.

In order to fulfil these conditions the hearth is constructed in the shape of a comparatively large crucible covered by an arched roof. When the charge sinks down into the crucible it spreads there in such manner that a free space is always formed between the charge and the brickwork of the roof. The electrodes are introduced into the crucible through the brick work at such points where it is not in contact with the

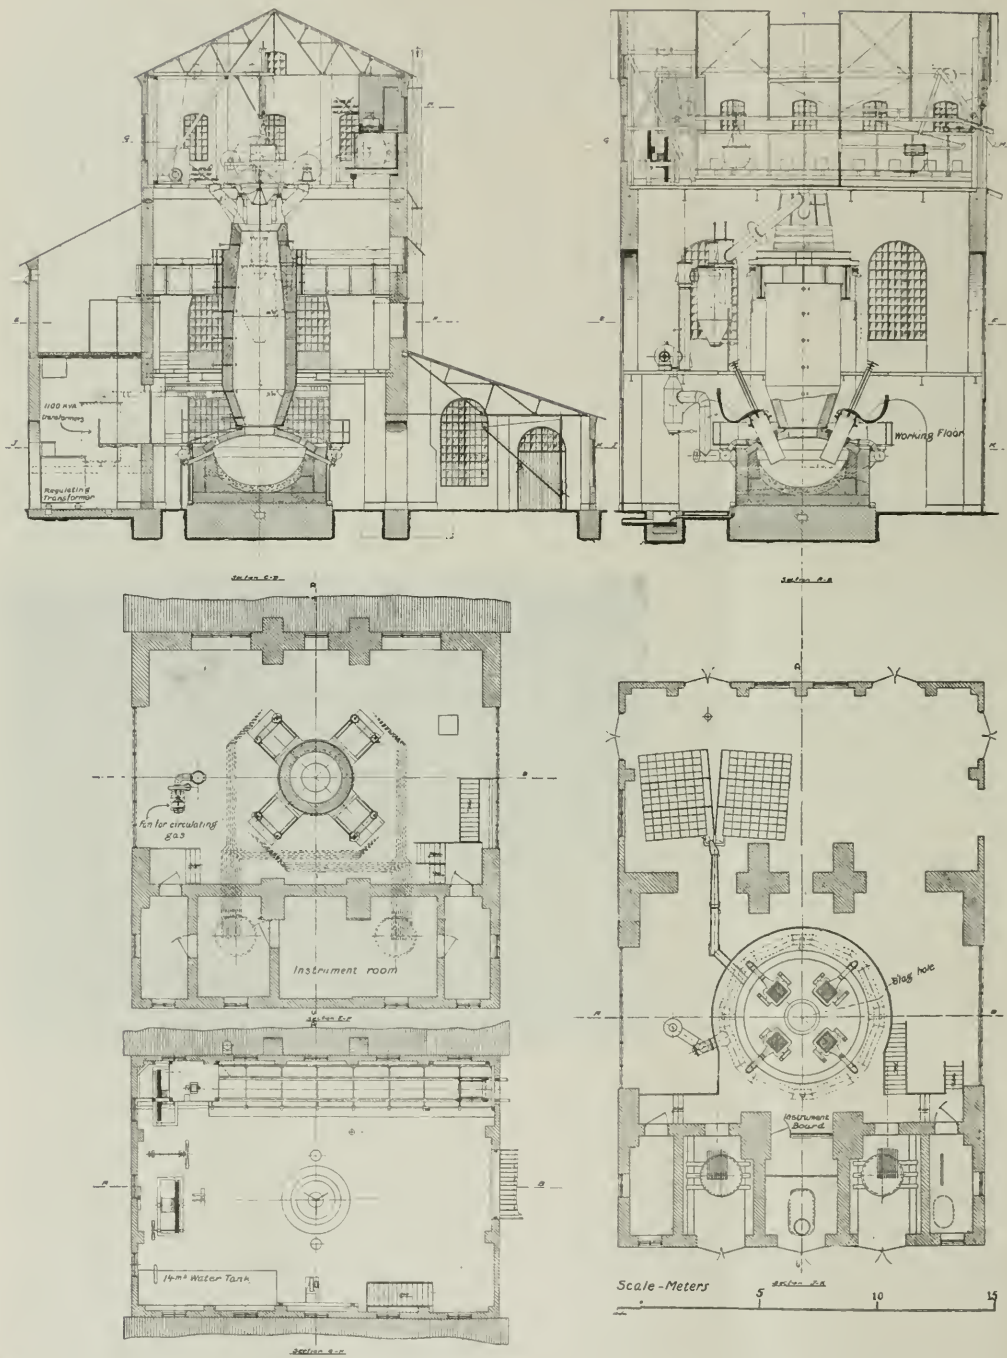


FIG. 2.—DIAGRAM OF ELECTRIC FURNACE CONSTRUCTION AND ARRANGEMENT OF ELECTRIC FURNACE PLANT AT TROLLHÄTTAN.

charge and enter the charge on the free surface exposed. By means of this construction the above enumerated conditions 1, 2 and 3 are fulfilled, and as the hearth can be made comparatively large condition 4 is also fulfilled.

Another important feature in a furnace of this kind is the regulating of the energy supply. In steel refining furnaces,

FIG. 3.—ROOF OF CRUCIBLE AND BOSH.

etc., this is done by raising or lowering the electrodes, but as a reduction furnace must necessarily work with a considerable gas pressure, this method cannot be conveniently employed, as it would be too difficult to keep the packings tight around the electrodes. Instead of this a system has been employed by which the electrodes are generally only adjusted corresponding to their wear, but all other regulating is accomplished by varying the tension of the current supply. This is done by cutting out windings on the high-tension side of the transformers and the arrangements are such that the different phases can work simultaneously with different tensions. This method for regulating the current which has been employed for the first time at Trollhättan has proved to greatly facilitate the working.

Principles Employed for Calculating the Form and Dimensions of the Shaft.

The starting point for the calculations was a manufacture of 7,500 tons of pig iron per year of 11 working months; that is about 23 tons per 24 hours. Further the calculations were based on the following assumptions:

1. 1 cu.-meter of charcoal weighs 150 kg.
2. 3 kg. of pig iron is obtained per 1 kg. charcoal.
3. For 1 ton iron 1,725 kg. ore is required, that is, 5,175 kg. per ton of charcoal.
4. One-half of the ore is contained in the interstices between the pieces of charcoal, the other half requires extra space.
5. The specific gravity of the ore is 2.5.
6. The ratio of volume of charge per day to shaft volume 1.55.

It is then found that 23 tons of pig iron correspond to a volume of 51.1 cub. meters of charcoal and an extra space of 7.9 cub. meters for the ore, or altogether 59 cub. meters. As the ratio of the volume of charge per day to the shaft volume is assumed at 1.55 the volume of the furnace should, therefore, be 59÷1.55=38 cub. meters.

This consists of the useful volume of the

crucible	12.45	cub. meters
neck	0.45	" "
bosh	3.50	" "
cylindrical portion of the shaft	11.80	" "
stack	9.80	" "
	38.00	cub. meters.

The diameter of the neck was the first dimension to be decided on, and this was fixed at 1200 mm. It appeared desirable to make it larger, but this would have made the crucible still larger and more unwieldy, as the inside diameter would have had to be increased in proportion on account of the electrodes. The depth of the crucible was determined on the strength of the experience with the Domnarfvet furnace and its bottom and sides designed in suitable form.

It is evident that with this diameter of the neck the diameter of the bosh could not be made very large. It also appeared desirable that the height of the shaft should be such that the best possible effect should be obtained from the ascending gas for the preheating and partial reduction of the ore. On the other hand, it might be expected that a too great height of the charge would cause a too great back pressure against the ascending gases. Also the cost of construction would be increased considerably, with an increased height of the shaft.

FIG. 4.—FURNACE TOP.

The problem then was how to best distribute the 25.55 cub.-meters of space that the effective portion of the shaft should contain.

A high and narrow shaft would give a good efficiency from the gas and reduce the risk of scaffolds forming in the bosh.

At the same time no undue increase of the cost of construction should be caused, and an excessive back pressure against ascending gases in the shaft must be avoided. The result of these speculations was the form shown in Fig. 1. (For convenience this is reproduced here again from our July issue.) The reasoning was that if the shaft should prove too high the remedy would be to work with a lower charge. The total height of the furnace was thus fixed at 12.7 m. from the bottom of the hearth to the furnace top. The bottom of the hearth is one m. above the floor level, and the height from the ground level to the furnace top is therefore 13.7 m.

FIG. 5.—FRONT OF FURNACE WITH TAP HOLE.

The Charcoal.

Apart from the small quantity of coke used for starting the furnace, charcoal has been used exclusively for the reduction. The charges are made by volume (0.65 cub. meters per charge), but all of the charcoal is weighed and analysis made every day.

The average composition of the charcoal is 14.58 per cent H_2O, 10.26 gases, 3.06 ash, 72.10 fixed C, 87.95 C, 2.60 H, 0.15 N, 0.61 O.

The average weight has been 168.6 kg. per cub. meter, corresponding to 144.9 kg. per cub. meter of dry charcoal. Both moisture and ash have occasionally been unduly high, in the latter case owing to stones and gravel mixed with the charcoal.

The average results of the daily analysis of the ash give 39.1 per cent SiO_2, 7.3 $K_2O + Na_2O$, 19.55 CaO, 3.85 MgO, 23.1 $Fe_2O_3 + Al_2O_3 + Mn_3O_4$, 0.95 P_2O_5, 3.3 SO_3, 0.6 Cl, 1.0 CO_2.

Besides the regular daily routine analyses a number of special analyses were also made.

The average of 99 special analyses of the ash gave 38.02 SiO_2, 6.1 $K_2O + Na_2O$, 19.52 CaO, 3.59 MgO, 22.69 Fe_2O_3, 3.88 Al_2O_3, 1.89 Mn_3O_4, 1.01 P_2O_5, 0.93 SO_3, 1.35 CO_2.

The analyses have also shown that the volume of gas obtained per gram of charcoal (dry and free from ashes) in in heating to 900 deg. Cent. was 170.35 cu. m. in average. The loss in weight of charcoal (dry and free from ashes) in heating to 900 deg. Cent. was 12.65 per cent. The weight of the gas was 9.22 per cent of the charcoal, and its composition in per cent of weight was as follows:

CO_2	CO	CH_4	H
22.47	38.03	30.47	9.03

Ore and Limestone.

The ore and limestone are broken up in a Blake crusher. This machine is large and powerful, as it was expected that

principally unroasted ore in large lumps would be crushed. Such has also generally been the case.

As the crusher delivered a coarser product than desired, a plate was fitted under one of the jaws so that the ore which at first had been of egg size was reduced to nut size.

The following are a few of the analyses of the limestone and ore used:

Limestone from Gasgrufvan: 54.32 CaO, 0.24 Fe_2O_3, 0.35 MnO, 0.31 MgO, 1.68 SiO_2. Loss on ignition 42.94.

Iron ore from Tuolluvaara: 91.05 Fe_3O_4, 1.41 Fe_2O_3, 0.16 MnO, 1.12 MgO, 0.28 CaO, 0.16 Al_2O_3, 0.10 TiO_2, 3.42 SiO_2, 0.050 P_2O_5, 0.011 S.

Iron ore from Langban: 89.85 Fe_2O_3, 2.49 FeO, 0.18 MnO, 0.85 MgO, 0.99 CaO, 0.42 Al_2O_3, 5.08 SiO_2, 0.014 P_2O_5, 0.007 S.

The chapters of Mr. Leffer's paper, dealing with the behavior of the electrodes and the general working results, will be given in our next issue.

A Plea for an Inventory of the Coal Supplies of the World*

By Prof. Joseph W. Richards.

I will take a few minutes of your valuable time to speak on this subject from the standpoint of the metallurgist—the man who uses the ore which the geologist describes and which the mining engineer takes out of the ground.

I cannot agree with some of the detailed conclusions of the very valuable report presented to the Congress upon The Iron Ore Reserves of the World. For instance, the 250,000,000 tons of Lake Superior iron ore carrying between 35 and 50 per cent of iron are placed neither in the actual reserves nor even in the potential reserves and yet this enormous quantity of ore, averaging much better than the "Minette" of Luxembourg, should in my opinion be placed under the actual reserves of ore in the United States. The reason for this statement is that this ore is not now worked simply because we have, at present, all we need of the richer ore, on which we make a larger profit, but if we did not have this richer ore we would certainly be working 40 to 50 per cent ore, and working it at a profit. I believe that within twenty years this immense quantity of ore, which the report does not consider as ore at all, will be the principal supply of iron ore in the United States, and will furnish us ore for many centuries to come.

Aside from the above criticism, I wish to support the points raised by M. de Launay and Professor Kemp, to the effect that metallurgists are continually improving their methods, and that the improvements which are certain to be made as time passes will enable metallurgists to work poorer and poorer ore at a profit. In twenty years we will be making pig iron from 40 per cent ore as cheaply as we now make it from 50 per cent ore; this is very certain and so I believe that improvement in metallurgical processes will more than compensate for the decreasing richness of the ores.

This very valuable report on iron ores of the world has therefore made it very clear to the metallurgist that there will never, in all the future history of the world, be any scarcity of iron ores for the metallurgist to work upon. Certainly, some localities will become exhausted, and the centers of production may change from place to place, but there will always be enough iron ore in the world to supply its needs.

A much more important question is the quantity of coal in the world with which to reduce this ore. This necessary material will be the real criterion of our future iron supply. Even at the present time the countries which have the most coal are dominating the iron supply of the world.

As already indicated by Prof. Kemp, the International Geological Congress would perform a very great service if it would call upon eminent geologists in all countries to make a careful inventory of the actual and potential coal reserves of the world. Such a report would not be more difficult to make than the present report on the iron ores, but probably less difficult, and it would be a splendid and highly valuable supplement to the report before us, giving us more real information about the future supply of iron and its localities of production. I wish the Congress would take up this task, and give the world this much-needed information.

However, in the distant future, when coal is exhausted, the world must produce iron by the use of the energy of waterfalls and electrical reduction, with charcoal from wood as the reducing agent. Here in Scandinavia, with no coking coal, you have already begun this era, you have been the first to show the world the economic possibility of producing pig iron electrically, using only water-power and charcoal. With your very pure ores, cheap water-power and abundant supply of wood, you will develop in Scandinavia a large electro-metallurgical iron industry. It is not a matter of the distant future for you, but within twenty years your iron industry will have been revolutionized and have become electrical. I congratulate Scandinavia on being in the lead in this new era of metallurgy, just as it has always led the world in the production of the purest commercial iron.

*An address delivered before the International Geological Congress in Stockholm, Sweden.

Notes on Chemistry and Metallurgy in Great Britain

(*From our London Correspondent.*)

The Chemical Society's Faraday Lecture.

The Fundamental Properties of the Elements.

On June 14 Prof. Theodore William Richards, of Harvard, delivered this year's Faraday lecture at the Royal Institution, and was afterwards presented with the Faraday medal. The following is an abstract of the lecture:

The lecture concerns the methods and results of some extended series of investigations designed to add to the foundations of human knowledge by careful experiment. Among quantities worthy of exact measurement the properties of the chemical elements are surely some of the most fundamental because the elements are the vehicles of all the manifold phenomena within the range of our perception. Weight is one of the most significant of these properties, and in the determination of atomic weights each substance employed must be free from all suspicion of impurity. Volume is also important. Twelve years ago the quantity b in Van der Waals' equation seemed to the author to be not really constant but subject to change under influence of temperature and pressure. This quantity is supposed to be dependent on the space occupied by the molecules, and if it be changeable are not the molecules themselves compressible?

If changes in the bulk of molecules are to be inferred even from gases, may not expansion and contraction of solids and liquids afford a much better clue to the relative expansion and contraction of these molecules? The ordinary conception of a solid has always seemed to me little short of an absurdity. A gas may be imagined with moving particles far apart; but could a rigid body like steel have such an unstable structure? The evidence seems to show that the interstices between atoms in solids and liquids must be small relatively to the size of the atoms themselves, if, indeed, there are any interstices at all. The compressibilities of 35 elements were studied with sufficient care to leave no doubt as to their relative values. It became manifest that the formation of a compound of a compressible element was attended with greater decrease of volume than was the formation of a similar compound of a less compressible element, other things being equal. This is just what the theory leads us to expect, and is inexplicable by any other hypothesis known to me. Then as to cohesion, if the pressure of chemical affinity causes compression of the atom, may not

the pressure of cohesive affinity do the same? The affinity which prevents solids and liquids from vaporising is generally admitted to set up great internal pressure, and must it not tend to compress the molecules? Molecules of high cohesive affinity—those of substances hard to volatilize—should be much compressed and have a small volume, whilst molecules with little cohesive affinity should be larger. Moreover, those molecules already much compressed by their self-affinity would be only slightly affected by additional pressure. Given two otherwise similar substances, the less volatile would be less compressible, denser, and have greater surface tension. These outcomes of the theory correspond with observed facts in most of the cases so far studied. Differences of structure and of chemical nature sometimes hide these relations, but the bulk of the evidence strongly indicates that cohesiveness, as well as chemical affinity exerts pressure, and that each plays a part in determining the volumes occupied by molecules.

Carried through to its logical conclusion, the idea that atoms are compressible gives one quite a new conception of the molecular mechanics of the universe. The influence of atomic compressibility may be perceived everywhere, and in most cases each fact seems to fit easily and without constraint into its place in the hypothesis. Even apparent exceptions, such as the abnormal bulk of ice, may be ascribed in a reasonable fashion to superimposed effects.

The lecture was received with marked appreciation by a full audience.

The Influence of Temperature on Corrosions.

A paper on "The Action of Salt Solution and of Sea-water on Iron at Various Temperatures," by J. Newton Friend and J. Hallam Brown was read at a recent meeting of the Chemical Society. The authors point out that the results obtained by Heyn and Bauer indicated that solutions of chlorides and sulphates of the alkali metals always exerted less corrosive action on iron than did fresh water at the same temperature. As these results did not conform to the observations of other chemists it was thought desirable to investigate the whole question. Kahlbaum's pure iron foil was used, access of dust was prevented while free passage of air was allowed, unequal illumination was guarded against and equality of conditions was maintained. The loss in weight after 14 days was taken as a measure of the corrosion, and the results showed that at temperatures above 13 deg. C. salt solutions of all concentrations exert a less corrosive action than distilled water, but below this temperature the more dilute solutions are much more corrosive than fresh water. At 13 deg. dilute solutions of salts were practically equally corrosive as fresh water. The results are of importance in this country, where natural waters are usually at a lower temperature than 13 deg. C.

The Measurement of High Temperatures.

At a recent meeting of the London section of the Society of Chemical Industry Mr. C. T. Heycock, F.R.S., read a very interesting paper on the modern methods of measuring high temperatures. The discussion was opened by Mr. Darling, who said he had the impression that Siemens had given up his platinum resistance pyrometer, and that nothing further was effected with it until Callendar and Griffiths worked on it; but the difficulty arising from the heating of the stem was overcome by covering the platinum wire with magnesia instead of winding it on mica. The relative merits of resistance pyrometers and thermo-couples depended on the use to which they were put. For exact determinations of boiling points or melting points the platinum resistance pyrometer gave the closer results; but if the two instruments were compared in a furnace at a high temperature for a considerable time experience showed that for workshop purposes the thermo-electric was the better. Prolonged heating of platinum wires at slightly over 1000 deg. C. materially altered their resistance, and the calibration was then wrong. Taking a reading even with such indicators as the Whipple was a troublesome matter, involving balancing with the Wheatstone bridge, and, even in skilled hands, by the time a balance was obtained the temperature might have varied considerably.

With the thermo-couple a direct reading was got at the instant, so that it had a decided practical superiority. The deteriorations in thermo-junctions occurred equally with platinum, and consequently the thermo-electric instrument was not inferior in this respect. As to accuracy, it was not possible with a large furnace—gas or coal-fired—under workshop conditions to maintain a constant temperature within ten degrees, and it was useless to employ a method giving readings to a fraction of a degree. There were many instances—notably the Royal Arsenal at Woolwich—where after thorough trial resistance pyrometers had been given up and replaced with thermo-couples, mainly because an installation of the latter could be worked from a central control if all the wires were identical in composition.

It was only fair to say that resistance pyrometers had recently been made quite automatic, but it was not possible to adapt even such an instrument as the new Paul indicator to an installation of 50 resistance pyrometers. Another important advantage of the thermo-couple was the facility of repair, while if the resistance instrument got out of order it was best to return it to the maker at once. For laboratory use in getting precise results no doubt the resistance pyrometer was the better.

He wished to refer to a curious effect observed with the Féry pyrometer in which a spiral was employed. When heat was concentrated on that spiral the pointer moved to a certain point on the scale, remained stationary for a moment or two, and then moved further. Which reading should be taken? They recommended taking the first, but that was not always correct, and there was something about it which required investigation. The form with the spiral was not so nearly accurate as that with the thermo-junction and galvanometer.

As a practical example of the accuracy now attainable at high temperatures he would state that in taking temperatures at about 1500 deg. C. some time ago with a Féry pyrometer and an Holborn-Kurlbaum optical instrument, by Siemens, as a check, the two agreed perfectly and responded equally to fluctuations of about 10 deg. either way. They need not fear that pyrometers could only be used in the laboratory, for they could be used with confidence in the workshop.

Dr. R. Lessing asked how readings on the Féry pyrometer were affected by glass or mica windows. He found it best to put the glass on for adjusting the distance and remove it for the actual reading, which was, of course, higher than the reading through the window. He wished that the author had touched on the subject of testing by Seger cones. It was not a very exact method, but was used largely in ceramic industries and had been brought to some degree of perfection; moreover, it could be employed where the use of pyrometers was inconvenient or even impossible.

Prof. W. R. Hodgkinson thought Mr. Heycock had rather neglected the thermo-couple. He considered that it was the pyrometer of the day on account of its simplicity and permitting the attachment of a recorder. In metallurgical works where pyrometers were in constant use, night and day, a recorder was wanted to show what had been going on at any time. True, there was the fact that Rhodium was attacked by carbon compounds, carbon monoxide, etc., and therefore must be protected. No doubt some vapor—probably a carbon compound—came from the iron, but when the wires were enclosed in a silica tube difficulty from that source was overcome.

Mr. W. Macnab said he had no experience of resistance pyrometers, bue he had found the thermo-couple a most convenient instrument for the practical determination of high temperatures.

Mr. Gardner asked if it were quite certain that iridium volatilized.

Professor Hodgkinson: There is not the slightest doubt about that.

Mr. M. J. Butterfield remarked that Mr. Heycock had stated that the range of nitrogen-filled glass thermometers was below 400 deg. C., but they were now made of "boro-silicate" glass with scales extended to 550 deg. and 600 deg. C. They were very convenient, and he found them in fair agreement with thermo-couples.

Mr. Heycock, replying, said his object had been to point out the value of the resistance pyrometer for exact work, and he quite agreed that for practical workshop use it was not so convenient as the thermo-couple. He should hesitate to use a glass or mica window, but would employ a plate of rock salt. He was interested by what had been said about Seger cones, and confirmed Dr. Lessing's observations. As to the volatilization of iridium, the resistance of an alloy of iridium and platinum at high temperatures underwent a much greater change when kept hot for some hours than that of ordinary platinum.

Heat Treatment of Steel.

A. Jung has published some interesting details of his researches on the influence of heat treatment on the tenacity and microstructure of hyper-eutectoid steels contained from 0.99 to 1.56 per cent of carbon, 0.24 to 0.46 per cent of manganese, 0.019 to 0.032 per cent of silicon, 0.020 to 0.031 per cent of phosphorus and no sulphur. These were heated in an appropriate carbon resistance furnace, and the changes in the values obtained by mechanical tests were noted as well as the microstructure after the following variations of treatment: (a) Heating for equal times at different temperatures and hardening in water; (b) tempering at the temperature found to give the best results and noting the results obtained with variation of time; (c) quenching in baths of oil and lead-tin alloy at the same temperature as the tempering was effected at; (d) tempering of the steels hardened in water both at varying temperatures for equal times and for varying times at the same temperature; (e) annealing and subsequently noting the results obtained on mechanical tests, contraction of area, nature of fracture, quality of grain and hardness.

The investigator has arrived at the following conclusions: Such steels are best hardened at temperatures confined to a narrow range, which is as the carbon content; for any given carbon content the ultimate strength is inversely as the temperature at which quenching is effected; at constant quenching temperature the ultimate strength is as the carbon content; the quenching temperature should be the same for all baths; quenching in water and tempering at 350° C. produces the greatest degree of strength; by quenching in water at a low temperature and tempering a somewhat brittle but highly tenacious metal is obtained, but when quenching is done at the same temperature as the tempering the tenacity becomes less while the toughness increases; identical results cannot be obtained from varying kinds of heat treatment, and can only ensue with any one property of the steel; the mechanical properties are dependent on the conditions in which the carbon exists and on the metallic structure; structures containing martensite give the highest degree of hardness, tenacity is increased by troostite and sorbite as elongation is by pearlite; finally no consistent influence of the carbon content on the mechanical properties of the steels was detected.

The Cementation of Nickel Steel.

An investigation by F. Carnevali and F. Giolitti on steels containing from 2.03 per cent to 29.8 per cent of nickel, when cementation was effected with pure ethylene and carbon monoxide, shows that the maximum carbon content in the zone of cementation diminishes as the percentage of nickel increases, and becomes very marked when there is more than 5 per cent of nickel. The variation of concentration of carbon in the layers of the zone of cementation is more regular in nickel steel than in carbon steel. When nickel steels are so cemented as to show a hyper-eutectic zone, the phenomena occurring during slow cooling are similar to those exhibited by similarly treated carbon steel, but differ quantitatively from the latter in that the entity of the liquation phenomena is not so marked in the nickel steels, and the transition from the hyper-eutectic to the hypo-eutectic zone corresponds with that of a carbon steel having a lower carbon value, viz., 0.6 to 0.65 per cent as against 0.9 per cent.

Electrolysis of Sodium Chloride Solution.

R. Sacerdoti has investigated the effect of rise of temperature on the potentials of the electrodes in the electrolysis of sodium chloride solution, with platinum and with iron cathode and platinum and magnetite anodes. In the cathode curve the effect of temperature is but slight, but in the anode curves it is apparent that as the result of a rise of temperature from 20° C. to 100° C. the anode potential corresponding to a given current density falls 0.4 to 0.8 volt.

A diagram shows the relation between electric potential and temperature for different current densities at both electrodes, and demonstrates that the reduction in voltage due to rise of temperature is never more than 0.75 volt, and that when high densities are used the figure is always remote from the potential of reversible polarization. With a decidedly alkaline solution the reversible anode potential is 1.3 volts and the reversible cathode potential 0.8 volt.

Copper, Nickel, and Cobalt Ores.

An investigation by H. Pedersen of a mixture of magnetic pyrites, nickel ore and slag consisted in digesting the mixture with concentrated nitric acid and treating with sulphuric acid until SO_3 was evolved; when the solution was cold it was treated with water and again evaporated until fuming occurred. The residue was treated with water, and after filtration from the slag the filtrate was precipitated with ammonia, and the ferric hydrate dissolved in dilute sulphuric acid, and after reprecipitation was estimated by the usual titration. The solution containing the copper and cobalt was acidified with sulphuric acid, evaporated to a convenient bulk, and after addition of a small quantity of strong sulphuric acid the copper was estimated electrolytically. The solution containing the nickel and cobalt was neutralized with ammonia in distinct excess and the solution submitted to electrolysis. The nickel and cobalt on the cathode were dissolved in excess of nitric acid, the solution evaporated to dryness on the water bath. The nitrates were eliminated by a small addition of hydrochloric acid and repeated evaporation, then redissolved in dilute hydrochloric acid and suitably diluted; the nickel was then precipitated by an alcholic solution of dimethylgloxime and ammonia; the precipitate was collected in a dried and weighed Gooch crucible, and after drying for about two hours at about 110° C. the precipitate contains 20.31 per cent of nickel.

Engineering Imports and Exports.

According to the Board of Trade returns for the six months ended with June, the imports of iron and steel, including manufactured articles, had a value of £5,685,566, an increase of £1,343,165 on the value for the corresponding period of 1910; the exports amounted to £22,160,641, and showed an increase of £1,212,451. For other metals the imports were £13,446,938, an increase of £1,854,921, and exports were £5,485,763, an augmentation of £443,020. In electrical goods there is a decrease of £32,307 in imports and also a decrease of £338,361 in exports. The value of imported machinery is £3,148,648, an improvement of £867,086; while exports amounted to £15,729,408, showing an increase of £1,648,922. The value of imported ships is £47,040 and of exported ships £2,532,246, and there are respectively an increase of £45,950 and a decrease of £1,768,181.

Market Prices.

July, 1911.

Copper has been fairly steady throughout the month, with

downward tendency, dropping more sharply after the 24th. Opened at £57-5-0 and closes at £50-7-6.

Tin rose over the first fortnight, though not steadily, opening at £194-10-0 and reaching £196-15-0 by the 14th. It then dropped sharply away to £188-10-0, recovered to £193-10-0 by the 19th, and closes £189.

Lead was steady at £13-15-0 to the 18th, when it commenced to rise, reaching £14-3-9 by the 20th. Closes at £14-5-0.

Hæmatite dropped after opening at 62/- to 60/10, recovered by the 10th, and has since been from 61/3 to 61/4½.

Scotch Pig rose from 52/3 smartly to 53/-, but has since eased to 52/10.

Cleveland rose from 46/3 to 47/- and remained fairly steady, closing at 46/10½.

Rubber rose but has not exhibited very extensive fluctuations, being from 4/1 to 4/7 (19th) and closing at 4/8.

	£ s. d.
Alum, lump, loose, per ton	£ 5 12 6
Antimony, black sulphide powder, per ton	22 0 0
Borax, British refined crystal, per ton	16 0 0
Copper ore, 10 to 25 per cent, per unit	9s. to 10 0
Copper sulphate, per ton	19 13 0
Carbolic acid, liquid 97/99 per cent. per gal	1 4
Creosote, ordinary good liquid, per gal	2¼
Camphor, 1-oz. tablets	1 9½
Caustic soda, ash 48 per cent, ordinary, per ton	5 10 0
Litharge, flake, per ton	15 15 0
Mica, small slab, original cases, per lb	6d. to 2 0

Hæmatite	4½
Scotch pig	7
Cleveland	7½
Rubber	7
Litharge	5 0
Petroleum	1⅛
Sulphate of ammonia	12 6
Quicksilver	12 6
Zinc V. M.	17 6

The following show a falling off in price:

Copper	£ 7 6
Tin	5 10 0
Copper sulphate	3 7 0
Carbolic acid	1
Tin ore	3 0 0

The stamp-tube mill combination for fine grinding, so common in South Africa, is being assailed as inefficient from a mechanical standpoint. Many engineers are inclining to the belief that other machines, particularly rolls and Chilean mills, will do the work with greater mechanical efficiency.

The principal use of fuller's earth in this country is in bleaching, clarifying or filtering fats, greases and oils. The common practice with mineral oils is to dry the earth carefully after it has been ground, and run it into long cylinders through which the crude black mineral oils are allowed to percolate very slowly. As a result the oil which comes out first is perfectly water white and much thinner than that which follows. The oil is allowed to continue percolating until maximum shade is reached. The earth is then purified.

SYNOPSIS.

Gold and Silver.

Cyaniding Antimonial Gold Ore.—An interesting experience in the treatment of a gold ore carrying some stibnite is detailed in the July, 1911, issue of the *Mining Magazine* (London), by Mr. H. T. Brett.

The Globe and Phoenix mine in Rhodesia produces a hard white quartz ore almost free from base minerals except for the presence of antimony as sulphide. This mineral occurs in average quantities of about 1 per cent, but in some places as much as 3 per cent is found. An analysis shows: SiO_2, 76.32 per cent; Sb, 0.73 per cent; Fe, 2.58; S, 0.91; CaO, 1.21; MgO, 6.44; As, Trace; Cu, Trace; Au, 1.6 oz. per ton; Ag. 6 oz. per ton.

More or less difficulty has been experienced in the treatment of this ore on account of the effect of the antimony. For example, in cynaiding sand and slime, with everything favorable for good extraction, the presence of only 1 per cent of stibnite makes an extraction of more than 20 per cent of the gold practically hopeless. Concentration is difficult on account of the friability of the antimony mineral.

The original plant erected for the treatment of the Globe and Phoenix ore consisted of 40 stamps, a sand-leaching plant and a slime decantation plant. When the antimony appeared in the ore, the extraction dropped to 30 per cent on slime and 40 per cent on sand. It was then discovered that by allowing the slime to weather for six months it was more amenable to cyanidation, and this course was then adopted. But the sand did not yield to such treatment and, moreover, rusty gold began to appear in the ore, thus complicating matters. Various attempts were made to overcome difficulties by regrinding the sand in pans, and by sorting out as much antimony as possible on sorting belts and jigs. The latter proved disappointing. All roasting of the ore gave satisfactory results, but the installation of a plant for this process would disturb existing conditions too seriously. Finally after much experimenting on a large scale a method of treatment was adopted which includes various features which were found valuable.

The ore is now crushed and washed in a trommel 10 ft. 6 in. long by 5 ft. 6 in. diameter at the large and 2 ft. 9 in. at the small end, perforated with 1½-in. holes for the first 4 ft. of its length and ¼-in. holes for the remainder. The trommel oversize is delivered onto a sorting belt from which massive stibnite is sorted in quantities ranging from ½ ton to 1 ton per day. After sorting, the oversize of the trommel is combined with the undersize and delivered to the mill bins.

Forty stamps of 1250 lb. weight crush the ore through 25-mesh screen. It then flows over amalgamated plates, the lower 3 ft. of which are covered with blankets to catch coarse rusty gold. This product is afterward amalgamated in a barrel. The tailing leaving the plates is classified into sand and slime. The sand is concentrated on vanners to remove as much pyrite and stibnite as possible. The concentrate is sent to the roasting plant while the sand tailing is reground in grinding and amalgamating pans and combined with the classifier slime. This fine pulp is then run over blankets where a fine concentrate is recovered, which is later treated in the roasting plant together with the coarse concentrate from the vanners. The fine tailing then flows to the sump of the tailing dump, whence it is pumped to a large spitzkasten for the separation of fine sand and slime.

The fine sand is collected for leaching in tanks which are filled to a depth of 6 ft. Each charge is subjected to from six to eight days actual treatment, but even then the extraction is unsatisfactory, and on ore carrying 1.5 oz. gold the tailings are too rich to throw away. It has been found that as soon as antimony on the sand charge exceeds 0.2 per cent the extraction drops rapidly.

The fine slime from the last spitzkasten is dewatered and

pumped to the storage dams. The clear water recovered from the slime is returned to the stamp mill. As soon as a dam accumulation has reached a depth of 6 ft. and contains about 10,000 tons dry slime, the stream is turned to another dam, and so on. After two months' time the dry accumulation is plowed and harrowed, and finally when the surface appears to be dry and thoroughly oxidized it is taken to the plant, mixed with cyanide solution in proportions of about 1½ parts solution to 1 of slime. This treatment of the surface of the dam is repeated until all the accumulated slime has been removed. Cyanidation of the slime is carried on in the decantation plant originally erected for this purpose, but a vacuum filter plant is under consideration. The extraction of the weathered slime is 75 to 80 per cent. The same material unweathered gives an extraction of only 30 per cent.

The pyrite and stibnite concentrates mentioned above are roasted in a Merton roaster, ground and amalgamated in pans, in which cyanide solution is used. It then flows over blankets where rusty gold is caught. Finally the pulp is agitated for 24 hours and filtered in a Dehne press. The residue is taken to the dump for oxidation and future treatment if required. The raw concentrate contains about 5 per cent Sb and 9 per cent S, while the roasted material carries about 3 per cent Sb and 0.72 per cent S, thus showing the difficulty of eliminating the Sb. The extraction varies from 85 to 90 per cent on a head value of from 2 to 15 oz. per ton. The following table shows the percentage recovery from the various materials treated:

Source.	Value per ton milled.	Per cent per ton milled.
Stamps and pans	$28.04	70.86
Concentrate	2.41	6.65
Sand	0.39	1.08
Slime	2.15	5.91
	$33.89	93.50

Slime Settlement.—Metallurgically speaking, the term slime applies to the finest portion of crushed ore, while sand is the coarsest. Various definitions have been proposed, but the foregoing statement is believed to cover the essentials as far as mill practice is concerned. The settling of slime is an important matter in the present practice of cyanidation, and various means have been adopted for accomplishing this end. In the *Monthly Journal* of the Chamber of Mines of Western Australia for May, 1911, Mr. B. L. GARDINER writes regarding the method adopted at the Sons of Gwalia mine.

The plant was originally equipped with nests of spitzkasten, but the settlement was inefficient and some means was sought of improving the efficiency by materially altering the apparatus then in use. The expedient hit upon resulted in practically increasing the settling area, and in delivering a thicker pulp than before. It consists simply of suspending in the pulp in an inclined position a number of sheets of corrugated iron. The idea is not altogether new, as it has been adopted in the United States and is one of the features embodied in the thickener of John E. Rothwell, made by the Colorado Iron Works Company.

The idea may be illustrated by filling a glass cylinder with slime and then noting the different rates of settlement when the cylinder is placed in a vertical position and at an angle of 45 degrees from the vertical. In experiments made by the author the rate in the vertical cylinder was 40 mm. per minute, while the rate in the cylinder set at an angle was 180 mm. per minute, or four and one-half times as great. The reason for this is obvious on close examination, for, on the upper side of the inclined cylinder a stream of clear water can be seen rising, while the particles of slime settle in a vertical direction from the inclined side of the cylinder.

The effect of the inclined sheets of corrugated iron in the spitzkasten is to reproduce many times the effect noted in the inclined glass cylinder. Wherever there is a surface facing downward the pulp must settle away from it, leaving the water to be forced up. The increased settling area obtained by this arrangement is stated by the author to be the total area of the sheets by the cosine of the angle they make with the vertical, or the projection of their area to the horizontal plane.

To test the efficiency of the inclined sheets, one section of spitzkasten was fitted with them, while three sections were allowed to remain in their original condition. The section fitted with the accelerating sheets showed a fall of slime at the rate of 0.168 in. per minute, while the three unaltered sections gave a fall of 0.107 in. per minute. The altered section gave a thickened pulp containing 41.1 per cent dry slime, while the three unaltered sections showed only 26.1 per cent.

The principle has its limitations, but a simple test with the glass cylinder will show what may be expected from any given pulp. The advantage of the device lies in the fact that it can be applied to existing spitzkasten.

Assay of Silver-Bearing Ores.—To test the effect of varying quantities of different reagents on the assay of silver ores CHARLES R. KEYES and D. F. RIDDELL made many experiments which are recorded in a paper published in the July, 1911, *Bulletin* of the A. I. M. E.

The ore analyzed as follows: Fe, 8.7 per cent; Pb, trace; Cu, 25.6; Zn, 6.2; Mn, 1.0; CaO, 15.0; S, 10. Assays were made to determine (1) how acidic a charge could be run; (2) how basic a charge could be run; (3) how large an amount of borax could be used in a charge; (4) how the normal charge for the kind of ore would behave, and (5) how the use of an excess of litharge would affect the results.

The conclusions deduced from the data given are: 1. A dead roast is not so satisfactory nor so accurate as a run with a large excess of niter or a scorification on a charge of 0.1 A. T. or more. 2. An excess of borax glass gives low silver results, especially in the presence of large amounts of sulphur, copper, iron or other matte-forming substances. The use of amounts approaching 1 A. T. must give low results. 3. An excessively acid flux fuses with great difficulty and yields poor buttons. In the presence of matte-forming substances the silver determination is low. 4. A very basic flux is open to all the objections that are raised to a very acid flux. Both give variant results most of the time. 5. Ores high in copper cannot be run by any crucible method without scorifying the lead buttons. 6. Direct scorification on high-grade copper ores does not check as well as the combination of crucible and scorification. 7. The normal or usual charge for coppery ores gives as high results as any method on this type of ore, but the checking is not as good as when an excess of litharge is used. 8. For ores high in copper, or carrying some zinc, a large excess of litharge in the flux improves the buttons and renders them easily handled. Furthermore, the time and temperature of fusion are decreased, and the buttons check well, with very close to actual valuations for the silver in the ore.

Cyanidation in Korea.—That improvement is the order of the day in all parts of the metallurgical world will be seen from the following description of present and proposed practice at the Unsan mines, Korea. The notes are abstracted from an article by G. C. EVANS in the June, 1911, issue of the *Mining & Engineering Review* (Australia).

The company has five mills, in all of which the same practice is followed. The ore is crushed by stamps, roughly classified in V-boxes for the purpose of getting some coarse sand to mix with the concentrate prior to cyaniding. The entire pulp with the exception of the sand mentioned is then concentrated on vanners. The vanner tailings run over canvas tables and then to waste. The concentrate is given an 18-day treatment in leaching tanks. Under this system the recovery is about 85 per cent. The vanner tailings average about 70 cents per ton and the recovery is 86 per cent; the concentrates are valued at about $22.30 per ton and the recovery is 84 per cent. The milling costs, exclusive of cyaniding, are 54 cents per ton, and the cyaniding costs $1.35.

A modern cyaniding plant is to be installed to treat the con-

centrate, together with an accumulation of old tailings amounting to 195,507 tons. The old tailings are valued at about $4.75 per ton. The new system will include concentration on Wilfley tables, grinding of the table concentrate in tube mills, agitation in Brown tanks, filtration in Dehne presses, and precipitation of the gold bearing solution in Merrill presses with zinc dust. This plan, it will be seen, embodies most of the latest ideas in cyanidation, and is expected to prove profitable to the company.

Mercury.

Wet Process for Cinnabar.—Little work has been done in improving methods of treatment of mercury ores, except in the line of furnaces for volatiling the metal. Low-grade ores have hitherto been without a suitable method of treatment. Mr. C. A. Mulholland has devised a wet process which he believes is practicable in view of the improvements made in the handling of large quantities of wet material. The details of the process are given in the *Aust. Min. Standard* for June 8, 1911.

The process consists in dissolving from the ore the very finely divided cinnabar, and reprecipitating it in a concentrated form ready for distillation in a comparatively small apparatus, in which efficient condensation can be carried out, and the escape of fumes prevented. It has long been known that cinnabar is soluble in alkaline sulphides containing free alkaline hydrates, and may be reprecipitated by the addition of suitable chemicals or electrolized for the recovery of the metal.

According to the author's experiments, the ore could be crushed to ¼ in., and then slimed with the solvent in a tube mill, or other convenient machine. Agitators could be used following the tube, if found necessary to complete solution, and these agitators should be heated by a steam jet. The solvent solution should contain at least one molecule each of alkaline sulphide and hydrate to each molecule of mercuric sulphide, but in practice an excess would be used. When solution is complete the pulp is settled and the clear solution decanted for precipitation. The residue is washed with weak solution and the washings used for extracting fresh ore.

The pregnant solution is now precipitated with zinc hydrate, when zinc and mercury sulphides will fall out of solution and are separated by filter pressing. The mixed precipitate is treated with dilute sulphuric acid and steam which will dissolve the zinc as sulphate, leaving a mixture of mercury sulphide and mercury. This is mixed with lime and iron and retorted in the usual way.

In treating the mixed zinc and mercury precipitate with acid, sulphuretted hydrogen is evolved, which is passed into the filter press effluent to regenerate alkaline sulphide for further use.

From small scale experiments the author has calculated the probable cost of operation on the basis of treating 100-ton lots of ore of varying grades, from 0.05 per cent to 1.0 per cent mercury. For example, on ore of 0.3 per cent grade, worth about $4 per ton, he believes that an efficiency of 80 per cent could be obtained, or a value of $3.20 per ton, at a cost of about $1.85.

Lead and Copper.

Concentrating Table.—In the July, 1911, *Bulletin* of the A. I. M. E. Mr. S. A. Krom presents some considerations on the proper form of table best adapted to the separation of minerals from gangue by methods depending on difference of specific gravity. He rather deprecates the use of riffles, and even states that in the near future they may be entirely eliminated from tables. He believes that riffles rather upset and retard the process of stratification which they are supposed to promote. He argues further that no concentrate can be delivered from a riffled table until the deck has become bedded, and that this bed must be maintained by very carefully adjusted feed of pulp and rate of discharge, or else the efficiency of the table is lowered. Perhaps Mr. Krom is too severe on the riffled table, and as he is engaged mainly in making out a case for an unriffled table, his criticisms will be taken properly modified by that fact.

The author describes a table invented by U. S. James, in which certain radical departures have been taken from the ordinary table. Stratification is obtained in a settling basin into which the table feed runs, and which is formed by two planes of different inclinations to each other, meeting in a line diagonal to the motion of the table. From this basin the concentrate is discharged over the deck of the table by reason of the table motion, and the tailings flow to the discharge. It is claimed that the settling basin does not require bedding and that it is difficult to overfeed." Adjustments in the eccentric motion of the table are made by an adjustable pin, which gives a wide range of different movements.

Copper Smelting in Michigan.—The simplicity of operations in smelting concentrates of native copper in Michigan has given rise to the idea that there is no metallurgy in Lake Superior smelting. In the School of Mines *Quarterly* of Columbia University for July, 1911, Mr. Henry D. Conant gives a descriptive statement of smelting operations in Michigan in which he shows that despite the simplicity of the operation there is opportunity for the engineer to show his ability in the effective use of fuel, the efficiency of labor, the production of clean slags, and the proper refining of the impure metal.

Lake Superior copper is obtained by concentrating the conglomerate or amygdaloid rock, which contains from 1 to 3 per cent copper, and obtaining what is locally called "mineral," containing 60 to 80 per cent copper. This concentrate is smelted in reverberatory furnaces without any fluxes, the slag skimmed off and further treated in cupola furnaces, and the reverberatory copper refined in either the same furnace or a second reverberatory into which it is tapped. In the first smelting operation the impurities are largely oxidized and slagged off. Some of the copper is at the same time oxidized, forming copper suboxide, which must be reduced again. This is accomplished by poling with green wood, after which the copper is cast into forms suitable for the various needs of commerce. Both the oxidizing and reducing operations are governed by the experience of skilled workmen, who take samples from time to time, and determine the end of the reaction by the appearance of the sample.

The reverberatory slags are either acid or basic, according to whether they are produced from amygdaloid or conglomerate mineral respectively. These are properly fluxed with lime, iron and silica, and reduced in cupolas, under a blast of from 3 to 4 oz.

The author describes in a general way the four plants now operating in Michigan, and gives some interesting historical data on the changes that have occurred in practice in later years.

Electrochemistry.

Fixation of Atmospheric Nitrogen with Intermittent Load.—The problem of utilizing the electrical energy of central stations at times of low load has always been attractive for electrochemists on account of low power costs, while electrochemical processes have been attractive for central station engineers to equalize their load curve. The question whether electrochemical processes can be operated intermittently with a financial profit has therefore often been discussed, but there is very little exact information available from commercial working. A note in a recent number of the London *Times* Engineering Supplement is therefore of considerable interest. As abstracted in London *Electrician* of August 4, it states that "for some time past experiments have been in progress at Legnano, Italy, with the object of utilizing the excess power generated during the night and certain hours of the day by a large hydro-electric station. The aim was to produce nitric acid and nitrates from the nitrogen of the air, and it is considered that the problem has now been satisfactorily solved. Some months ago the employment of 4000 kw. for the production of nitric acid was initiated, and now preparations are being made for the use of 9000 kw. more, energy being supplied by the Societa Lom-

barda per Distribuzione dell' Energia Elettrica at a pressure of 50,000 volts."

Electrolysis Destruction of Water and Gas Pipes Due to the Stray Currents from the Rails of Tramway Systems.—Considerable trouble was experienced at Pittsburg, Pa., with stray currents from the rails of the tramway system attacking underground structures of the water system. A very full discussion of these troubles is given in a paper by E. E. Lanpher and L. B. Smith before the Engineers' Society of Western Pennsylvania and published in the *Proceedings* of the Society for July. The authors conclude that the only certain method of preventing electrolysis is the installation of the double-trolley system and the most successful method of mitigating electrolysis is the installation of the "return pipe feeder system." The latter system was introduced in Pittsburg, but this solution was criticised in the discussion by various speakers especially by Prof. A. F. Ganz who favors the radial insulated return feeder system; the return feeders being designed to drain the rails of current at many selected points, leaving these points at the same potential, thus greatly reducing the rail drops and minimizing stray currents on underground structures. In the reply of the authors the unusual conditions prevailing in Pittsburg are pointed out but they do not claim that under different conditions the results would have been equally satisfactory, in fact the conditions as they existed in Pittsburg were almost ideal for the installation of the return pipe feeder system.

With respect to **local electrolysis** brought about by impurities in steel pipes some interesting remarks were made in the discussion by Mr. F. N. Speller of the National Tube Company. To correct a misapprehension that is very widespread as to corrosion being often due to irregularity in the composition, he said that they made a great many experiments along that line which indicated that steel or iron has to be much below the average before the irregularity incident to commercial material became an important influence in corrosion. As a matter of fact, the difference in potential between the greatest irregularity which is ordinarily found due to segregation does not begin to compare with the differences due to the accidental presence of foreign material such as mill scale on the surface of the metal itself. If all the scale could be removed from the pipe, one would probably have much less trouble with the corrosion of underground piping.

Primary Battery.—In our August issue, page 401, a paper by Mr. W. R. COOPER on the Benkö cell was given. In connection with this it is interesting to note a recent exhibition by Mr. Cooper of the Benkö cell at a meeting of the Physical Society in London. Several types of this cell were exhibited. The battery depends essentially upon the use of a porous carbon electrode in the form of a pot (open at the top) which is surrounded by a closed lead shell. The elecrolyte (a bichromate solution) is fed into this shell under a suitable head to give a flow of ½ liter or more per hour per cell. It passes through the carbon to the zinc, where it is removed by an overflow pipe. Polarization is thus reduced to a minimum and remains constant for a given current, provided the cell is not overloaded. The size of cell referred to is 9 ¼ in. high overall, 6 ¼ in. long and 1 ¾ in. wide; it weighs about 10 lb., excluding the tank for electrolyte, and will give a steady current (depending upon the strength of the electrolyte and rate of flow) up to, say, 25 amps. at 1.5 volts. The internal resistance is below 0.01 ohm. There is no "mess" and no difficulty in keeping the apparatus in order. The cell is therefore very suitable for laboratory use or work where the cost is not of prime importance. Various types are being made according to the work required, and these include cells which depend for their action upon diffusion as distinct from a steady flow.

In the discussion, which followed, G. L. Addenbrooke asked whether the contact between the lead and the carbon remained satisfactory over a long time. The author replied in the affirmative so far as his experience (extending over 15 months) had gone. Prof. Callendar inquired as to the maximum number of watts that could be taken from the battery continuously, and whether, weight for weight, more power could be taken from it than from a lead storage battery. The author replying to the first part of the question said about 25 to 40 watts, depending on the solution, and stated that, excluding the reservoir, 2.4 to 4 watts per pound could be taken from the battery as compared with ½ watt (8-hour rate) up to 2½ watts (automobile cells at 5-hour rate) for lead cells.

Mr. W. Duddell asked how the battery would compare with lead cells for giving a steady current of the order of 5 amperes to 1 part in 5,000 or so. Lead cells could only be relied on to keep steady to about one part in 1,000. The author said he could not reply definitely, but he would expect a battery result from the Benkö battery bulk for bulk. Replying to other speakers the author stated that the emf. of a diffusion cell began to fall after 10 hours' use, and that the electrochemical efficiency of the zinc in a Benkö cell was about the same as in an ordinary primary cell.

General Physics and Chemistry.

Chemical Effects of Canal Rays.—It has been the source of a long series of discussions as to whether chemical elements in the form of canal rays will react with other substances with a greater amount of kinetic energy than is possible if brought to reaction otherwise at highest attainable temperatures. V. KOHLSCHUETTER publishes another interesting contribution in the May 15 number of the *Zeitschrift fuer Elektrochemie*. Canal rays were permitted to act upon various substances, the tubes being filled at the start with small amounts (0.01 to 0.04 mm) of either hydrogen, nitrogen, oxygen, argon, carbon dioxide, sulphur dioxide, or hydrogen sulphide. The author found that the products of reaction were identical with those obtained whenever the substance, which had been acted upon by the canal rays, was used as cathode instead. It was impossible to show absolutely that singular chemical reactions could be brought about by the action of canal rays. The chemical reaction observed seemed to be secondary to a primary effect of the rays, possibly a bombardment or a sudden increase in temperature. At all events this primary effect, whatever it may be, is altogether independent of the chemical nature of the gas in the tube. The effect was stronger in the presence of the heavier gases. Compounds such as oxide of copper and sulphide of silver were reduced more readily in nitrogen than in hydrogen. Chloride of mercury was reduced to the metal even though the gas in the tube was oxygen. Many other examples are cited.

Electrical Resistance of Pure Metals at Very Low Temperatures.—For several years Prof. H. KAMERLINGH ONNES, of Holland, has carried out exceedingly interesting experiments on the enormous decrease of electrical resistivity which pure metals undergo at very low temperatures. He has now perfected his experimental facilities for the use of liquid helium (which by the way was found to be an excellent insulator) and the results of his determinations of the resistivity of pure gold and pure mercury at liquid helium temperatures are given in a recent issue of the *Proceedings* of the Koninklijke Akademie van Wetenschappen, Amsterdam, of which a translation in abstract appears in the London *Electrician* of August 4. The author's recent experiments with gold have greatly strengthened his former conclusion that the resistance of pure gold vanishes at helium temperatures. Even more interesting are the experiments with mercury. The measurements were made with the differential galvanometer by the method of overlapping shunts (Kohlrausch) and also by the method of the measurement

of current strength and of potential difference. The value of the mercury resistance used was 172.7 ohms in the liquid condition at 0°c; extrapolation from the melting point to 0 C by means of the temperature coefficient of solid mercury gives a resistance corresponding to this of 39.7 ohms in the solid state. At 43°K (4.3 degrees on the krypton themometer) this had sunk to 0.084 ohms, that is, 0.0021 times the resistance which the solid mercury would have at 0°C. At 3 K. the resistance was found to have fallen below 3 v 10^{-7} ohm, that is, to one-ten-millionth of the value which it would have at 0°C. As the temperature sank further to 1.5°K, this value remained the upper limit of the resistance. The next step was to look for the point at which the resistance first becomes measurable as the temperature is raised. The temperature of this point was found to be slightly more than 4.2°K, at which the resistance was found to be 230 microhms or one-hundred-thousandth of the resistance (solid) at 0°C.

Recent Metallurgical Patents.

Lead and Copper.

Hydrocarbon Blast Furnace.—The use of oil as fuel for producing the necessary heat in a blast furnace was the subject of considerable experimenting by the late John W. Nesmith, of the Colorado Iron Works Company, of Denver. Recently two patents have been issued, assigned to the company mentioned, based on the experimental work inaugurated by the original inventor.

In Fig. 1 is shown a vertical section of a furnace adapted to carry out the invention. The vertical stack *A* is connected

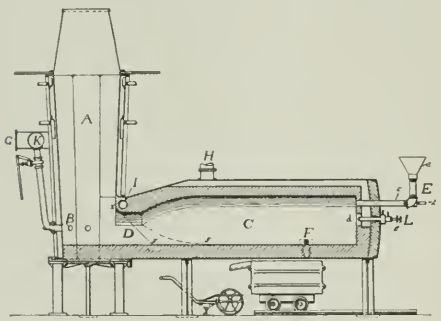

FIG. 1.—HYDROCARBON BLAST FURNACE.

by a passage *D* with a combustion chamber *C*. Tuyeres are located at *B*, and a bustle pipe *K* is connected with an air supply *G*. Air for the combustion chamber is admitted at *H* and passes along the top of the combustion chamber to the inlet shown at *D*. *L* represents an oil burner, *e* being the controlling valve. Provision is made to tap slag and matte at *F*. In order to prevent the burning out of the arch at the connection between stack and combustion chamber a water pipe *I* is located at this point. A hopper with device for forcing fine ore or concentrate into the combustion chamber is located at *E*.

In operation, the regular charge of coarse ore is fed to the stack in the usual manner, and the base of the column fills the opening *D*, the ore taking the natural slope of such material, say 45 degrees. Combustion is maintained in the combustion chamber by means of oil and air admitted at *d*, and the charge gradually smelts to a fluid condition, running onto the hearth of the chamber. The tuyeres are located below the top line of the combustion chamber, as it was found in practice that when located higher on the shaft there was tendency to form a secondary smelting zone in the shaft, causing some of the metals to liquate and flow to the hearth, leaving a skeleton hanging in the shaft. The hot gases from the combustion chamber pass upward through the charge in the shaft and escape.

The combustion chamber is relatively large, as it was found in actual operation that when using petroleum as fuel the volume of space in the chamber should be not less than 35 cu. ft. for each pound of combustible burned per minute.

The provision for introducing fine ore, concentrates or flue dust directly into the combustion chamber offers advantages in smelting such materials, which are always difficult to handle economically. Such fine material is introduced into this furnace from the hopper *E* and accessory devices, by means of a blast of air. Being introduced directly into the combustion chamber they are immediately melted or burned and combined with the molten mass on the hearth. If any part of them is not so smelted it is readily caught in the fusing and semi-fused mass in the stack.

The furnace is thus adapted to the continuous treatment of coarse ore in the usual manner, and the continuous or intermittent treatment of fine material. By this method it is possible to smelt current productions of flue dust, as well as moderate quantities of fine ore and concentrates. Furthermore, in the case of sulphide concentrates, the sulphur contained is utilized as fuel and reduces the quantity of fuel oil required. (905,365-6, June 13, 1911.)

Ore Roasting Furnace.

An annular mechanical roasting furnace adapted for the treatment of pyrite or blende is the basis of a patent of Curt Pfaul, of Blasewitz, Dresden, Germany. A representation of the furnace is given in vertical section in Fig. 2. It has a helical bed with rabbles *b* traveling parallel to it, they being

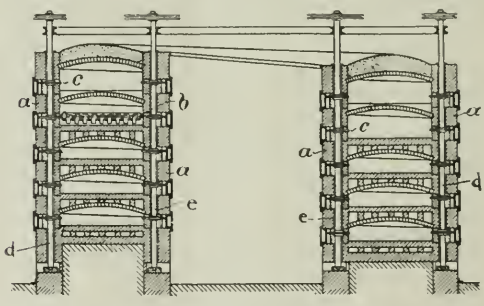

FIG. 2.—ROASTING FURNACE.

carried on rollers *c* bedded in the walls of the furnace. The vertical shafts *d* and *e* upon which the rollers are mounted are arranged at intervals in the circular walls of the furnace. The frame *b* is simultaneously supported by three rollers *c*, and by turning the shafts in either direction the frame carrying the rabbles may be made to move upward or downward in the furnace. The scheme avoids the production of the large quantities of dust formed in the multiple hearth furnaces where the rabbled material falls from one hearth to the other. In this furnace the rabbling is accomplished as the frame moves downward through the furnace. It is then returned to the top by reversing the movement of the shafts, and the operation is repeated (989,868, April 18, 1911).

Fume Condensing Apparatus.

The condensation of the solid and soluble parts of furnace gas by means of water and steam sprays continues to attract the attention of inventors despite the fact that apparatus of this kind has not been usefully applied on a large scale. Paul Kestner, of Lille, France, has patented apparatus for this purpose. He recognizes the fact that dry dust has characteristic repulsion for water, but that if it be preliminarily

dampened it may be readily absorbed in water. He therefore bases his process on first spraying the gas with steam and then cooling it, causing the steam to condense on the solid particles in the fume and dampen them. By subsequently spraying the gas with water he claims that the solids are easily removed. The apparatus is represented in Fig. 3, in which *A* is

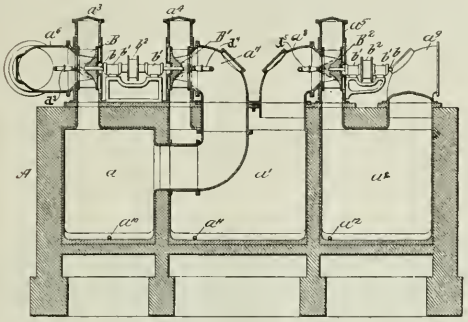

FIG. 3.—KESTNER FUME CONDENSING APPARATUS.

a chamber divided into three compartments a, a^1 and a^2. Above these are casings a^5 a^4, a^5 which are connected with their corresponding compartments and in which are located fans, B, B^1, B^2 operated by means of pulleys b^2. Spray pipes are arranged to discharge into the face of the fans. As the furnace gases flow into the receptacle at a^6 they are thoroughly mingled

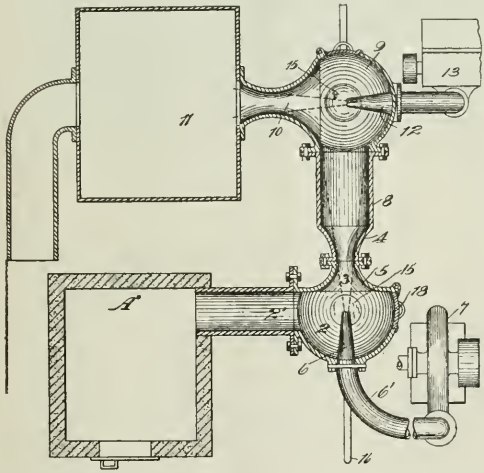

FIG. 4.—FUME CONDENSING APPARATUS.

with steam flowing from the jet against the fan B. They then flow into the compartment a, where they cool and become wetted with the condensed steam. They then flow successfully through the other compartments and fans, being sprayed with water in the latter. The cleaned gases pass out by way of a^5, and the water with the collected fume is accumulated in the chambers a, a^1, a^2, from which it flows to other receptacles by way of pipes a^{10}, a^{11}, a^{12} (991,157, May 2, 1911).

Another apparatus for condensing fume in furnace gas from smelters, garbage crematories, etc., is patented by GEORGE C. RICHARDS, of Berkeley, Cal. He first subjects the gases to a jet of water and later to a blast of air. The first jet wets the solid particles and the air blast cools the gases and aids condensation.

The apparatus is shown in plan in Fig. 4. The source of gas is represented by A, from which it passes through the passage $2'$ to a globular head 2, having a contracted discharge at 3. The water jet is delivered from the nozzle 6. The wetted gas then flows to another globular head 9 where it receives a blast of air from the nozzle 12, which discharges through a contracted orifice 10 into a chamber 11, where the fume is collected. The effect of the angular flow of gas is to break it up and avoid the formation of strata. The accumulations of tarry or other matter in the globular heads may be removed by suitable gates placed in the bottom of each head. The vacuum creating effect of the air blast assists in the force of the induced draft through the apparatus, but its main effect is its cooling action which insures precipitation and condensation (990,009, April 18, 1911).

Electrolytic Production of Oxygen and Hydrogen and Welding and Cutting by the Oxyhydrogen Flame.

The simplest and cheapest way of producing oxygen and hydrogen in equivalent quantities is by electrolysis of water. The process is used in numerous plants in Europe, and the oxygen and hydrogen gases thus produced are widely employed there for welding and cutting by the oxyhydrogen flame and for other purposes. The reason why this country has been behind Europe in this development is probably the fact that the oxy-acetylene flame was early introduced here and was believed, on account of its high temperature, to be superior to the oxyhydrogen flame. It has been since found, however, that both have their distinct fields of applications, and with the increasing demand for hydrogen alone (for instance, in connection with aeronautics) it is but natural that the electrolytic production of hydrogen and oxygen on a large scale has finally found its way to this country.

The International Oxygen Company, of 68 Nassau Street, New York City, has erected a plant at Waverly Park, Newark, N. J., which is one of the most completely equipped of its kind in the world, producing some 10,000 cu. ft. of oxygen daily. This company either furnishes to its customers hydrogen and oxygen gases in cylinders or instals their electrolytic apparatus at the consumers' premises to suit their requirements, so that they produce their own hydrogen and oxygen whenever needed.

The electrolytic cell used is very simple, an outside view being given in Fig. 1 and a diagram in Fig. 2. The iron tank A of Fig. 2 serves as the cathode, being connected to the negative pole of the electric supply circuit. From the cover B of this tank are suspended the hydraulic joint C and a perforated tank D which serves as the anode, being connected to the position pole of the supply circuit. It is made of a specially selected low-carbon steel, to prevent the formation of spongey rust.

By means of an asbestos sack E suspended from the hydraulic joint C two separate compartments are formed, one being the anode compartment and the other the cathode compartment. The cell is thus a true diaphragm cell.

Through the opening F in the cover a solution of caustic alkali in distilled water is poured into the hydraulic joint C and distributed in the two compartments.

The whole cell is placed on insulating supports H of porcelain.

When current is turned on, electrolysis results and the total reaction is the decomposition of water into oxygen gas and hydrogen gas. The oxygen gas is set free at the anode D and the hydrogen gas at the cathode A. The two gases, thus produced separately from each other, are prevented from mixing by the asbestos sack diaphragm.

The hydraulic joint C is a special feature of the cell, as it adjusts its inner working. Another feature is that the oxygen

and hydrogen gases evolved do not pass directly from their compartments to the off-take pipes, but first bubble through water contained in the two lanterns on top of the cell, as shown in Figs. 1 and 2. They enable the operator to see at a glance how the cell is working.

The purity of the gases produced is very high. A sample of hydrogen, produced by this electrolyzer analyzed by the Conservatoire National des Arts et Metier in Paris, showed 99.70 per cent hydrogen, the fraction of the impurities being so small that they were not looked for.

All that is required for the operation of the cell is the daily addition of some distilled water to make up for the quantity decomposed into hydrogen and oxygen. About 1 gal. of water is required to produce 100 cu. ft. of oxygen and 200 cu. ft. of hydrogen. Otherwise the operation of the cells needs no further attention, manipulation or supervision by an expert. As to the electrical energy requirements a joint test made in November, 1910, by the Laboratoire Centrale de l'Electricite and the Conservatoire National des Arts et Metiers with two unit cells of this type of electrolytic cell showed that the production of 1 cu. ft. of oxygen and 2 cu. ft. of hydrogen requires 0.2797

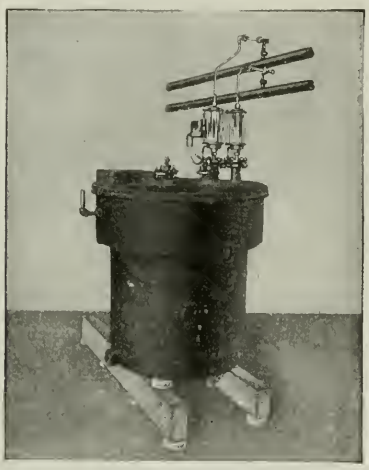

FIG. 1.—VIEW OF CELL FOR ELECTROLYTIC PRODUCTION OF OXYGEN AND HYDROGEN.

kw-hours. Reversely 1 kw-hour produces, 3.54 cu. ft. of oxygen and 7 cu. ft. of hydrogen.

Each unit cell requires a little above 2 volts and from 300 to 400 amp. A current of 350 amp produces about 65 cu. ft. of oxygen and 130 cu. ft. of hydrogen per day.

A plant made up of such unit cells is very flexible, since the units can be arranged in single file and double file, also in many rows and tiers, or in any way to suit the given conditions. Fig. 3 shows three double rows of cells, as installed at the Waverly Park plant of the International Oxygen Company.

The main item of the cost of operation is the cost for the electric current. In New York City the wholesale rates vary from 5 to 3 cents per kw-hour, according to the size of the plant; since 1 kw-hour produces about 3 cu. ft. of oxygen and 6 cu. ft. of hydrogen, the electric power cost for producing 1000 cu. ft. of oxygen and at the same time 2000 cu. ft. of hydrogen would be between $16.70 and $10. However, in large manufacturing plants which have their own power houses the cost of energy is much less; thus it is known that at the South Chicago works of the U. S. Steel Corporation the electrical energy supplied to the electric furnace is charged at the rate of half a cent per kw-hour. At this rate the electric power cost for producing 1000 cu. ft. of oxygen and 2000 cu. ft. of hydrogen would be only $1.67.

Besides the electric power cost there are the cost for attendance which is very small as already mentioned, and the cost for the distilled water which must be added to the cells to make up for the decomposed quantities of water. The latter cost may be calculated from the fact that 10 gal. of distilled water are required to produce 1000 cu. ft. of oxygen and 2000 cu. ft. of hydrogen.

As to the relative advantages of the oxyhydrogen and the oxy-acetylene flame for welding, the lower temperature of the oxyhydrogen flame and its easy regulation are of importance. They render the oxyhydrogen flame superior for thin sheets, especially in the form of kitchen materials and liquid containers that are to be enameled, also for welding aluminium, copper, bronze, and like metals. On the other hand, the oxy-acetylene flame is specially suitable for welding heavy pieces. (A most noteworthy example of heavy oxy-acetylene welding may be mentioned here, namely the recent welding of joints on the pipe line of the Central Colorado Power Company. On the part of the pipe line leading from the reservoir at the power house in Boulder Canyon down to the power house the joints were found leaking, and if the pipe line was to be saved it became

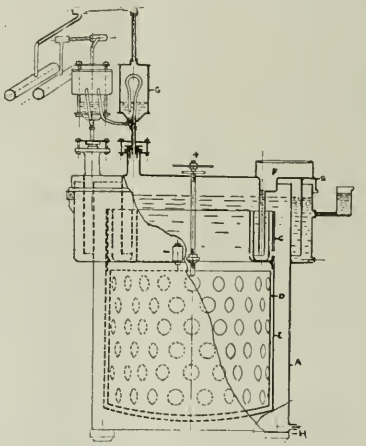

FIG. 2—DIAGRAM OF CELL FOR ELECTROLYTIC PRODUCTION OF OXYGEN AND HYDROGEN.

necessary to weld the joints. This has been carried out by the oxy-acetylene process. It is probably the biggest job of its kind every done and the difficulties were very great, as the pipe line is carried down in a very narrow tunnel and the heat in welding in such a narrow space was intense. Each complete joint took the time of two men for about a day and a half, the method used being quite analogous to that of lead burning. The Central Colorado Power Company must be congratulated on the successful outcome of this exceeding interesting piece of work. The welded pipe line is now giving absolute satisfaction.)

As to oxy-cutting, the following comparison is given by the International Oxygen Company. In oxy-cutting, oxygen and acetylene will cut on the average from 4 to 6 in., whereas with oxygen and hydrogen cuts up to 24 in. have been obtained. The cuts with oxygen and hydrogen are said to be usually smoother and more quickly made than with oxygen and acetylene.

In oxy-cutting the metal is first heated either by the oxyhydrogen or the oxy-acetylene flame, then the current of hydrogen or acetylene is turned off, and a jet of oxygen is blown upon the molten or melting metal. The cut which results is due to the formation of oxide iron by burning the metal in the

jet of oxygen. This oxide remains outside of the molten steel or iron, and as it is very light, it is blown away by the oxygen under pressure, and thus a cut is produced.

Now it is an important fact that if the oxygen used should contain any appreciable portion of inert gases they will prevent the oxygen from thoroughly oxidizing the steel or iron and will thus render good or deep cutting difficult. The International Oxygen Company attributes the difficulties of oxy-acetylene cutting to the fact that when oxygen combines with acetylene much carbon dioxide is formed which as an inert gas hinders the effectiveness of the oxygen.

The great effect which impurities in oxygen have on the results in cutting were well brought out in a recent paper of J. M. Morehead, of Chicago, before the New York Railroad Club. Numerous tests were made on cutting a mild steel plate ¾ in. thick, the total length of cut being in all cases about 67½ in. In the different experiments oxygen of different purity was

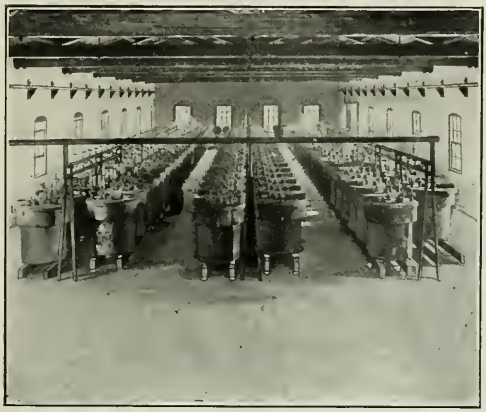

FIG. 3.—CELL ROOM OF INTERNATIONAL OXYGEN COMPANY.

used. We give here only the results of the tests with oxygen of 99.3 per cent, 96.4 per cent and 83.3 per cent purity.

Purity of oxygen, per cent.....	99.3	96.4	83.3
Cutting time in seconds	272	360	855
Oxygen used in cu. ft.	7.5	11.3	18.9

The cut with the 99.3 per cent oxygen was very good, like a hot saw cut. The cut with the 96.4 per cent oxygen was ragged and cindery. The cut with the 88.3 per cent of oxygen was very rough and slaggy, the metal not being properly cut through. The tests show clearly the very appreciable increase in cutting time and quantity of oxygen required, the less the purity of the oxygen. From the tests it would appear that with a percentage of about 80 per cent it is not possible to cut a ¾-in. plate.

An interesting simple application of oxy-cutting is the removal of rivets by the oxy-hydrogen process. An oxy-hydrogen welding torch is used, the rivet is heated until red, the hydrogen is then shut off, and the oxygen burns the rivet away. The meal about the rivet hole remains untouched and the hole is as clean and round as it was before the rivet was put in.

The Super-Calender is the title of a new home organ published monthly by the Pusey & Jones Company, of Wilmington, Delaware. Its circulation is limited to paper mill superintendents. The main part will be devoted to questions and answers relating to problems of paper manufacture of general intrest. The first issue contains an interesting picture of an early Chinese paper maker and a discussion of two interesting problems. The mechanical make-up is of very high class. Editorially it is of decided originality.

Lining Alloys.

The Lumen Bearing Company, brass founders, of Buffalo, N. Y., and of Toronto, Ont., has sent us an interesting little booklet, entitled "Progress in Lining Alloys," the author of which is the manager of their babbitt department, Mr. Alfred H. Greenburg.

It is emphasized that the term "genuine babbitt" has a rather indefinite meaning as to chemical composition. If it ever meant anything it was simply this: That the preponderant constituent was tin, and that its two other constituents were antimony and copper. Until recent years the term generally implied that the composition was free from lead. This, however, is no longer the case, since the low cost of antimonial lead as a by-product for the last fifteen years and the constant increase in the price of tin have weighed so heavily on the manufacturer of "genuine babbitt" that to-day the term no longer positively excludes lead from its composition. (The composition mentioned in Mr. Isaac Babbitt's first patent in 1839 was 50 parts tin, 5 antimony, and 1 copper. His favorite composition which he later sold to Mr. Phillips, was 10 parts tin, 1 antimony and 1 copper.)

There is no universal bearing composition that is best for all requirements. Hence bearing metal should be specified with great care according to requirements.

The heating of bearings is the principal cause of annoyance, and in cases where the metal punishment is so severe that heating cannot be avoided, a metal of high melting point should be selected. The efficiency of the alloy, therefore, depends upon the quality of the wearing surface that can be produced and maintained under service. A properly selected metal carefully applied, both as to design and workmanship, produces a bearing which, with proper lubrication, has no metallic contact while running. That is, the journal and its bearing are separated from each other by a film of oil which is maintained in operation. As soon as the movement of the journal is stopped, the film of oil is gradually squeezed out and the metallic surfaces are brought into contact. Therefore in selecting the metals for a bearing they should be sufficiently dissimilar so that when starting the machine there will be no danger of scoring the shaft until the oil film shall have been restored.

Aside from the chemical composition, even more important is the method of uniting the different constituents. In general, the metals should be melted in an iron vessel and kept covered as much as possible in order to prevent excessive oxidation. They should be heated considerably above their melting point before using, but must not be kept in a molten state at a high temperature longer than necessary. Overheating should be carefully avoided, and a good rule for general practice is to heat the molten babbitt to a point where it chars a pine stick, at which temperature it casts perfectly.

Further, with respect to analysis. Where the service conditions are severe, owing to great pressure, a metal having considerable compressive strength is necessary regardless of what the speed may be, and this condition would require a relatively high percentage of tin. Where there is high speed and the pressure light and moderate, a metal having a fairly high percentage of lead may be used. In the same manner with intermediate conditions between pressure and speed, correspondingly intermediate composition can be selected.

The surroundings of a bearing and the amount of care and attention which can be given to it must also be taken into consideration. A bearing that is lubricated at long intervals or with a poor grade of lubricant requires a higher grade of metal than that which would be required under more favorable conditions.

The gist of the matter is that while there is nothing very difficult in making babbitt suitable to any clearly specified kind of service, yet it requires an experienced metallurgist.

The little booklet of the Lumen Bearing Company is carefully prepared and well worth reading.

Titanium Rails.

The Titanium Alloy Manufacturing Company, of 1225 Oliver Building, Pittsburg, Pa., have just issued a handsomely illustrated pamphlet, entitled "Facts, Figures and Illustrations Proving That Titanium Has Solved the Rail Problem." It gives very interesting figures on the rapid increase of the use of titanium-treated rails in the last few years.

Three years ago titanium-treated rails were merely being tried on two or three roads, while now they are in service on more than fifty steam railways and on the more important trolley traction lines. Over 40,000 tons of titanium rails are now in actual use. The production of titanium rails in 1910 was 195,940 tons.

The beneficial effect of titanium is not that of an alloying element proper, but the titanium acts simply as a purifier. It is a powerful deoxidizer and removes part, if not all, of the nitrides as well. It prevents brittleness, hence the carbon content of the rail may be materially increased and should be increased if the full benefit of the titanium treatment be desired. The extra cost of the titanium is only about $2 per gross ton of finished rails.

The pamphlet contains interesting illustrations of the structure of titanium-treated and untreated rails, and illustrations with descriptions on the use of titanium rails on many roads in this country.

The following is a test of open-hearth 85-pound rail made recently by the Lackawanna Steel Company for the Delaware & Hudson Co. This steel was treated with 0.15 percent titanium alloy and tested by the National Tube Co. The elastic limit was 100,800 lb. per sq. in., the ultimate strength 147,200 lb. per sq. in., the elongation 12.50 percent, the reduction 16.29 percent.

The analysis was 0.86 C, 0.132 Si, 0.022 P, 0.032 S, 0.88 Mn, 0.065 Ti.

Manufacture of Ferro-Alloys in England.

The National Smelting Company, Ltd., has recently been formed with a capital of £200,000, which, when in full working order, will be practically the first of its kind in England. It has been formed chiefly for acquiring as a going concern the business and assets of Electric Furnace & Smelters, Limited, a company which was incorporated as a private company in 1910 for the purpose of making experiments in the smelting of ferro-alloys and various ores, and whose offices are at 110 Cannon Street, London. It will also acquire other electric furnace patents.

It is reported that the experiments made by Electric Furnaces, Limited, in the making of ferro-tungsten and other ferro-alloys were highly successfully, yielding a metal free from obnoxious impurities at a low cost For the purpose of demonstrating the success accomplished and ascertained by the experiments, a small factory, with plant capable of turning out about 12 tons of tungsten metal per month, was erected at Luton, and is in active daily operation. Adjoining the factory are the works of the Luton Iron Foundry, a business carried on for some years past by Mr. Archibald Finlay Maclaren, the managing director of Electric Furnaces. The benefit of a contract between Mr. Maclaren and Electric Furnaces, whereby the latter acquire an option to take over the land, business and plant of the Luton Iron Company, has been transferred to this company.

Large quantities of tungsten and other alloys are required by British steel manufacturers, over 900 tons of ferro-tungsten being used yearly in Sheffield alone, while the consumption of other high-priced alloys, such as ferro-vanadium, is at least as great. In the past these alloys have been imported to England from other countries. It is intended that the company shall, at its works in Luton, produce at least 1000 tons of ferro-tungsten and other ferro-alloys annually. Arrangements have been made whereby the company will be able to obtain a supply of electric power at a very low cost.

During the year 1910 an experimental electric furnace was erected at St. Ives, Cornwall, and about 20 tons of tin were smelted there. The result was highly satisfactory and proved the profitable nature of the process. (See the extensive article by Mr. Harden, published elsewhere in this issue.) It is proposed that this company shall proceed with the carrying on of this process, which is provisionally protected.

The directors have entered into an agreement with Mr. Maclaren whereby he becomes the managing director of this company for a period of ten years, and Mr. Johannes Harden will be the technical manager for the like period of ten years. The Board will consist of Mr. Archibald Finlay Maclaren, managing director of Electric Furnaces, Limited, who has been engaged in the foundry business all his life; Mr. Francis Barkley Henderson, director of The National Minerals Corporation, Limited; and Earl Russell, chairman of Plenty & Son, Limited.

Efficient Drying of Cement Rock.

The effect of the fineness to which Portland cement clinker is ground upon the physical property of the resulting cement is well understood, but it is not always appreciated that the fineness to which the material is to be ultimately ground depends to a large extent upon the drying of the product as it comes from the gyratories. Furthermore unless all the hygroscopic moisture is removed the clogging of screens and the cutting down of the capacity of fine grinding mills will result. It will, therefore, be seen that the dryers have played an important part in the development of the cement industry, which in 1910 in this country alone amounted to 70,000,000 barrels, as they have made it possible for cement plants to run at their maximum capacity.

In every industry the efficiency of machines performing certain operations has been studied with keen interest during the last few years in connection with the development of some scientific management scheme and in the cement industry the dryer has received particular notice as it was clearly seen that a considerable saving could be made by the use of the proper dryer and the utilization of the hot gases from the kilns.

Of course, the simplest form of machine for drying cement rock, clay, etc., is a single revolving shell equipped with lifting plates on the inside and having a furnace at one end and a fan at the other end, but the heavy expense of upkeep and its low efficiency due to radiation and the high temperature of the stack gases make it absolutely impracticable. The excessive fuel consumption of this type is decreased when the shell is protected by brick work and the hot gases pass under and back through it.

One of the most efficient and generally used types of dryers is the Ruggles-Coles, which consists of two concentric shells of steel rigidly connected and resting on eight bearing wheels and driven by a heavy cast gear located between the two tires.

It is of particular interest to note how the high economy is attained in the Ruggles type of dryer. In most dryers the hottest gases meet the cold material first with the result that the flames are suddenly quenched and a large amount of carbon passes off unconsumed which is the cause of one of the largest losses in efficiency. In the Ruggles type the hot air enters the central flue at the feed end, passes through this and then back through the space between the two shells, thus drying further the material which is advancing toward the other end.

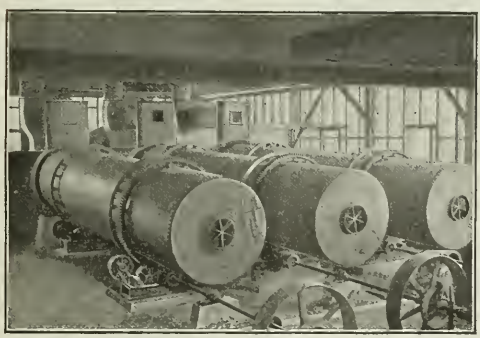
The material to be dryed as it is fed into the space between the concentric shells is picked up by lifting buckets and

dropped onto the inner shell. By revolution of the machine the material is then dropped on the outer shell and this operation continues until it reaches, due to the inclination of the dryer, the discharge end.

It will be seen that the long central flue acts as a large combustion chamber in which space and time are given for the perfect combination of oxygen and monoxide, thereby increasing the efficiency. A resulting exhaust temperature of 100 deg. Fahr. is generally found.

The capacity of any dryer depends directly upon the efficiency and when this is determined the capacity may be figured directly in proportion to the fuel consumed and almost inversely with the moisture contained in the material to be dried With a stack to produce draft the amount of fuel which can be burned is limited and, therefore, the capacity of the dryer cannot be increased without adding additional stack, which is a troublesome and expensive operation to say the least. By furnishing a fan to run at low speed the Ruggles-Coles dryer may be speeded up by changing a pulley and the capacity of the dryer increased in almost direct proportion. This is a very valuable feature when the material varies in moisture at different seasons of the year and in the cement industry sudden increases of output must be met.

As far as durability is concerned the single-shell type of dryer for cement rock, etc., is practically out of the question as the losses by radiation in such a machine are very large.



DRYER PLANT.

It is not unusual to see these machines red hot for one-third of their length. This means not only constant repairs, but that they are difficult to work near and are sometimes positively dangerous on account of fire. In the two-concentric-shell type, the cold material falling on the top of the inner flue at the hot end, it is impossible for this flue to become overheated, while the outer shell is always practically cold.

As to just what may be expected from a good cement dryer may be ascertained from the following data secured by actual test of a Ruggles-Coles dryer at the Pennsylvania Cement Company, Bath, Pa., in the drying of cement rock.

Calorific value of fuel used	14,100.
Fuel consumed per hour in lbs.	360.
Amount of moisture in material	2.3%
Water evaporated per hour in lbs.	1852.
Water evaporated per lb. of fuel in lbs.	5.1
Material dried per hour in lbs.	78,684.
Fuel per ton of dried material in lbs.	9.2
Heat lost in exhaust air	8.5%
Heat lost by radiation	5.0%
Heat used to evaporate water	40.9%
Heat used to raise temperature of material	45.6%

Hence the total efficiency, defined as the ratio of the heat used to raise the temperature of the material and evaporate the water to the total heat is 86.5 per cent.

Non-Corrosive Bronze.

"Tobin Bronze" is the title of a little booklet issued by the Ansonia Brass & Copper Company of 99 John Street, New York, from which the following information is taken. This bronze is the invention of Mr. John A. Tobin of the Engineer Corps of the U. S. Navy and is manufactured by the Ansonia Brass & Copper Company.

Tobin bronze, a "combination of copper with other metals" combines great mechanical strength with non-corrosibility under difficult conditions.

The specific gravity of tobin bronze is 8.379, hence less than that of copper (8.9).

As to the ability of tobin bronze to withstand chemical influences, tests made by Mr. Charles Taylor of the U. S. Assay Office in New York are interesting. Five samples of tobin bronze, each weighing about 5.5 ounces, were immersed in five different solutions for a period of five months each.

In a saturated salt solution the loss of weight in five months was 0.002 ounces (less than 0.04 per cent). In view of this its wide use in marine construction is not surprising. Thus the hulls of the American cup defenders Columbia and Reliance were entirely made of tobin bronze.

In a caustic potash solution the loss in weight of the 5.5 oz. sample in five months was 0.003 ounces. In a solution of sulphuric acid ("about one-third strength") the loss was 0.014 oz. In a U. S. Standard ammonia solution the loss was 0.161 oz.; in a solution consisting of one-half water and one-half U. S. Standard ammonia the loss was 0.081 oz.

Used in the form of bolts, rods, and plates, its resistance to wear and oxidation makes it a useful material for chemical works, dyewood extract works, tanneries, sugar houses, and coal mines.

When rolled hot, tobin bronze is remarkable for its high elastic limit, tensile strength, hardness, and unifom texture. It can be drawn to a very high degree of tensile strength. But in order to insure the best results in uniformity of tensile strength with the maximum degree of elongation, standard practice of the Ansonia Brass & Copper Company, as to ultimate tensile strength and elongation, of rods of different diameters is as follows:

Diameter of rods.	Ultimate tensile strength.
Up to 1 in.	60,000 lb. per sq. in.
1 to 1½ in.	58,000 " "
1½ to 2 in.	56,000 " "
2 to 2½ in.	54,000 " "
2½ to 3 in.	52,000 " "
Above 3 in.	50,000 " "

The elongation is not less than 30 per cent in 2 inches for all rods 1¼ in. diameter and larger. It is not less than 20 per cent. in 2 in., for all rods smaller than 1¼ in. diameter.

As stated before, the tensile strength can be made higher, but if this is done the elongation is decreased. The elastic limit is about one-half the ultimate tensile strength.

Tobin bronze can be welded electrically.

At a cherry red heat, tobin bronze can be forged as readily on steel. Bolts, nuts and rivets may be made from it either by hand or machinery.

Another feature in working it at cherry red heat is that it can be stamped and drop-forged in the same manner as steel.

Improved Method of Securing Battery Posts.

An arrangement for securing battery posts to the concrete foundation block is described by F. W. Sewell, in the *Informes y Memorias* of the Mexican Institute of Mining and Metallurgy, Vol. 2, No. 3. The arrangement is used at the mills of the Guanajuato Cons. M. & M. Company and the Zacatecas M. & M. Company.

A cast-iron shoe is bolted to the concrete block, and the

shoe, in turn, receives the battery post and holds it in place by suitable bolts and brackets. The shoe weighs 860 lb. and has a bearing surface on the concrete of 4 ft. 6 in. by 1 ft. It has a cavity cast in it 2 ft. long by 10 in. wide and 6 in. deep, into which the battery post fits.

The shoe is secured to the concrete block by two 2½-in. rods, each 5 ft. long, threaded at both ends. The threaded portions are of enlarged cross-section, so that the diameter of the base of the thread is not less than that of the remainder of the rod. The lower ends of the rods pass through broad, square, cast-iron washers embedded in the concrete, and are secured thereto by square nuts. Hexagonal nuts or lock nuts are used on the top end to hold down the shoe.

The battery post is held securely in the shoe by means of 1½-in. bolts 2 ft. 7 in. long, connecting brackets on the side of the post with the cast-iron shoe. At each end of the shoe are cast suitable projections which are bored vertically to receive the long bolts mentioned. The two side brackets, which weigh about 100 lb. each, are recessed into the 12-in. faces of the post and held in place by five ⅞-in. rods passing through the post from one bracket to the other. These rods are threaded at both ends, and lock nuts hold the brackets firmly in position. Passing vertically downward from each bracket to its respective end of the shoe are two rods, mentioned above, with square nuts to attach them to the shoe and hexagonal nuts to attach them to the bracket. The lowest part of the bracket is 1 ft. 2 in. above the top of the shoe.

In erecting the battery, the cavity in the shoe is half filled with oil, and the foot of the post is cut slightly larger than the cavity, the point being cut so that it will just enter the cavity. When the post is forced into place by means of tightening the connecting rods, aided by blows from heavy hammers on top, the oil is forced into the end of the post. This insures protection from rotting due to water. The entire post is then oiled occasionally until no more oil is absorbed, when it is painted.

Fibrous structure is one of the most useful properties of matter, and when found in mineral substance adds greatly to its value. The best grade of asbestos is beautiful silky fiber with a high degree of flexibility, elasticity and tensile strength. It can be spun into a thread so as to run 225 yards to the ounce.

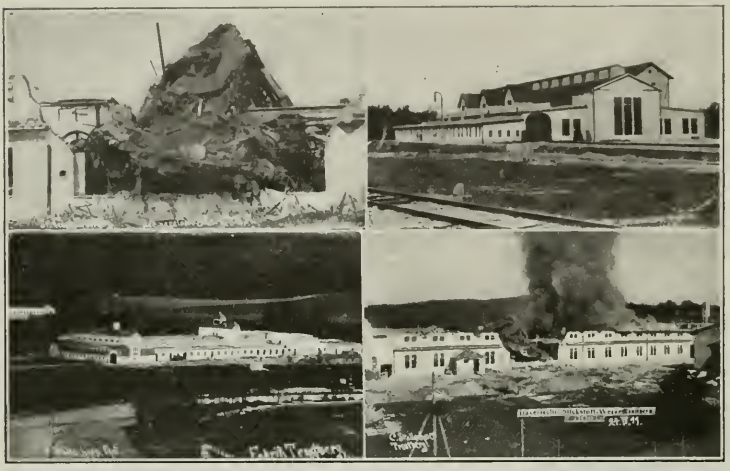
Acetylene Explosion in Cyanamide Plant.

The interesting pictures which are herewith reproduced are taken from some picture postcards sent us from Trostberg in Bavaria, Germany, where the Bayerische Stickstoffwerke have a monster plant, making calcium cyanamide. The factory is located in a valley with the snow-clad Alps surrounding it.

A couple of these pictures are of special interest, showing some details of an acetylene explosion which took place there on the 24th of June this year. Dealing with calcium carbide requires care and precautions, as acetylene is readily formed and even small amounts of acetylene mixed with air will give explosive mixtures. The strength of such an explosion is evident from the pictures.

From time to time reports have come from the European factories concerning similar disasters and it was expected that in this latest constructed plant all precautions had been taken, found in former experience, to make such explosions impossible.

It is only fair to state in this connection that in most older chemical industries where formerly many accidents occurred, these have been very largely reduced in recent years, due to a more careful arrangement and a better construction.



CALCIUM CYANAMIDE PLANT IN BAVARIA.

The lower right-hand picture shows the fire caused by the acetylene explosion; the upper left-hand picture shows a destroyed silo.

Alundum Refractory Exhibit.

The adjoining illustration shows the exhibit of alundum refractories displayed by the manufacturer, the Norton Company, of Worcester, Mass., at the last American Foundrymen's Convention in Pittsburgh.

REFRACTORY EXHIBIT.

As to the properties and manufacture of alundum refractories there is nothing to be added to the exhaustive paper of Mr. L. E. Saunders on page 257 of our May issue.

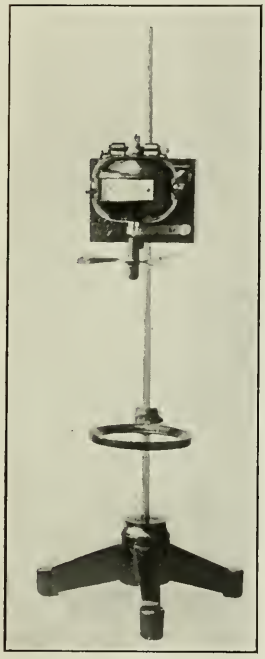
The exhibit brings out the numerous uses to which alundum refractories are now being put, including muffles of various

shapes and sizes, Cooch type filter crucibles, and crucibles for general laboratory work, combustion boats, extraction thimbles, filter tubes, filtering dishes, electric furnace sections and parts, corrugated furnace cores, arc lamp economizers, tubes, etc. It will be remembered that in the new Hering electric furnace, making use of the pinch phenomenon alundum is used for the electrode tubes with good success.

A New Rotating Anode.

The accompanying illustration shows a new design for a rotating anode for electrolytic analysis, made by Queen & Company, Inc., of Philadelphia, Pa.

The motor is of a new type totally enclosed except on the commutator end which is on top. A fan is mounted on the motor shaft immediately below the contact brush which supplies current to the anode, so that the possibility of gases entering the motor parts is eliminated. In this particular the tripod base, upright and the supporting ring for the dish cathode are heavily enameled. The clamp screws for adjusting the height of the motor and supporting ring have been designed so as not to injure the enamel. Current to the anode is supplied by a specially constructed brush, which bears against a suitable copper ring on the motor shaft. Provision is made to prevent excess of oil from the motor bearings finding its way down to the anode.



ROTATING ANODE.

The tripod base is of iron and heavy enough to prevent vibration and is fitted with soft rubber tips. Binding posts are provided for the current terminals and a rheostat not shown in the illustration controls the motor speed. The illustration does not show the electrodes. The anode is held in position by means of a knurled screw and can be quickly removed.

Institute of Metals.

The annual autumn meeting of the (British) Institute of Metals will be held at Newcastle-on-Tyne on September 20, 21, 22.

Sir Charles A. Parsons is acting as chairman of the local committee and Dr. J. T. Dunn as secretary.

Sessions for the reading and discussion of papers will be held on the mornings of September 20 and 21 at the Armstrong College; on the afternoons of these two days visits to plants will be made. In the evening of September 20 a conversazione will be held, and on September 22 a steamer trip down the Tyne River and back will be made.

Sir Gerard A. Muntz is the president and Mr. G. Shaw Scott, Custom House, Westminster S. W., London, is the secretary of the Institute.

The Non-Ferrous Metal Market.

The markets for non-ferrous metals generally showed a firm tone during August. The copper surplus was reduced in July, and the foreign demand coupled with the reduced production caused some expression of fear that a copper shortage was not outside the bounds of possibility. In zinc the situation is equally favorable, and that metal has a good outlook. Foreign consumption of zinc is heavy, and the price has advanced so that it is not impossible that there may develop a foreign demand for American spelter.

Copper.—The market has been firm, but without advances in price. Lake copper is quoted at 12⅝ to 12¾ cents; electrolytic at 12.40 to 12.45 cents.

Lead.—Business in this market has not been heavy, and the quotations are practically unchanged at 4.50 cents, New York, and 4.42½ to 4.45 cents, St. Louis. The St. Louis quotation is relatively high, as there is usually a greater disparity between New York and St. Louis lead markets.

Tin.—It is reported that the Syndicate in London has temporarily suspended operations, but the foreign market remains firm. The domestic market is good, but there is a scarcity of spot tin owing to dock strikes abroad. August tin was quoted at 42⅝ cents, with spot at 43⅛ cents.

Spelter.—The statistical position is strong and prices have advanced. The latest quotations are 5.90 to 6 cents, New York, and 5.75 to 5.85, St. Louis. The foreign market is reported as firm.

Other Metals.—Aluminium has not changed much during the past month. Quotations stand at 20 to 20½ cents for No. 1 ingots. Sales in antimony are small and prices range from 7.25 to 8.5 cents for various brands. Considerable business has been transacted in quicksilver and prices are steady at $48 to $49, New York, for 75 lb. flasks. San Francisco quotations are $48 for domestic and $45.50 for foreign orders.

Notes.

American Electrochemical Society.—The following gentlemen were elected members at the meeting of the Board of Directors on July 21: Albert A. Heimrod, Newark, N. J.; C. R. Corning, New York City; Frederic S. Mason, New York City; Irving R. Valentine, Schenectady, N. Y.; Thomas D. Robertson, Toronto, Canada; Otto Stalmann, Salt Lake City, Utah; John I. Blair, South Bethlehem, Pa.; Archibald W. Diack, Detroit, Mich.; Harrison W. Johnson, Niagara Falls, N. Y.; John M. Tippett, Colorado Springs, Colo.; Charles R. Barton Ellwood City, Pa.

Vanadium Steel for Aeroplanes.—The July issue of "American Vanadium Facts," published by the American Vanadium Company, of Pittsburgh, contains a great many interesting facts on the use of vanadium in steel making. Thus tubular shells of chrome-vanadium steel, not more than ⅛ inch in thickness are now successfully used as shafts for 50-hp motors to transmit the power on aeroplanes with an ample factor of safety. The shafts weigh 18 pounds each and are 2½ in. outside diameter, 40 in. long, with a 2¼ in. hole bored through their entire length. On account of its excellent forging qualities, its great strength and high elastic limit, and its freedom from crystallization, chrome-vanadium steel finds not only increased use for aeroplane, automobile, and marine motor purposes, but in the construction of chisels, rivet sets, punches, gears, etc.

Oildag for Aeroplanes and Automobiles.—Other interesting examples of the way in which the latest advances in aeroplane and automobile construction have been rendered possible by recent progress in chemistry and metallurgy, are given in a little pamphlet, issued by the International Acheson Graphite Company of Niagara Falls, and entitled "Three Little Stories of Three Big Events and Three Winning Lubricants." Lincoln Beachy, in his recent flight over the Falls of

Niagara, used oildag in the lubricating oil in the engine of his Curtiss biplane. Ray Harroun, the winner of the 500-mile automobile race in Indianapolis, used oildag and gredag. Harry F. Grant, the winner of the big sixth Vanderbilt race on Long Island, used oildag and gredag. It is hardly necessary to add here that oildag is deflocculated graphite diffused in oil (in colloidal condition); gredag is a combination of pure Acheson graphite and a high-grade grease, the two being blended in proper proportions.

The Driver-Harris Wire Company, Harrison, N. J., have developed a new high-fusion wire for combustion furnaces and laboratory heating furnaces. This wire which will be placed on the market under the trade name "Nichrome II" will be efficient for services up to 2000° F. and its chief points of advantage are its extremely high melting point and the proportionately greater resistance to oxidation.

The Electric Furnace Company, Alliance, Ohio, has completed its new furnace-testing laboratory. The building is located on a tract of land secured from the Stark Electric R. R. Co. at their Lake Park power house near Alliance and power for testing purposes will be received direct from the R. R. Company's bus bars. The plant will be supplied with a 200-kilovolt-ampere Westinghouse special regulating transformer, a complete set of electrical recording and indicating instruments, pyrometers, a small chemical laboratory, and equipment for microscopic examination of metals. The Electric Furnace Company has developed a line of electric heating furnaces for forge shops and similar plants, and the new testing laboratory is to enable the company to test new types of furnaces, that are being rapidly called for. The standard type of their electric furnace for heating bars and billets was described in detail and illustrated in a paper by Mr. Thaddeus F. Bailey on page 202 of our May issue.

The first by-product coke ovens in the United States were built in 1893 at Syracuse, N. Y. This country is far behind Germany and other European countries in adopting the economies resulting from coking coal in by-product ovens. Figures compiled by the U. S. Geological Survey show that, while beehive ovens in the United States in 1910 produced coke amounting to only 64.54 per cent of the coal burned, retort ovens in the same year gave a production of 74.9 per cent. The value of the by-products recovered from the retort ovens amounted to about one-third the value of the coke. The by-products recovered were 27,692,858 cu. ft. of surplus gas; 66,303,214 gal. of tar; 70,247,543 lb. of ammonium sulphate or its equivalent; 20,229,421 lb. of anhydrous ammonia; 4,654,282 gal. of ammonia liquor. The value of the recoverable but wasted by-products from beehive ovens in 1910 is estimated by the Survey at from $35,000,000 to $40,000,000. If all the coke produced in the United States were made in retort ovens, there would be a yield of gas over and above that required for the regeneration of the ovens, without by-product recovery, approximating 1,000,000 hp per hour for every day in the year. Complete data on the subject may be obtained from the U. S. Geological Survey, Washington, D. C.

The Bureau of Mines, Washington, D. C., has issued several pamphlets of interest. *Bulletin* 12 treats of the apparatus and methods for the sampling and analysis of furnace gases; *Bulletin* 14 on briquetting tests of lignite, with a chapter on sulphite-pitch binder; *Technical Paper* 1 on the sampling of coal in the mine, and *Technical Paper* 2 on the escape of gas from coal.

Personal.

Mr. A. D. Akin recently has accepted a position as managing engineer for the Monarch Mining & Smelting Company, Yavapai County, Ariz.

Mr. N. H. Brown, of Idaho Springs, Colo., has succeeded Mr. S. B. Tyler as superintendent of mines and mill of the Frontenac Consolidated Mines Company at Central City, Colo.

Prof. F. G. Cottrell, of the University of California, recently went to Montana to confer with Dr. J. L. Holmes of the Bureau of Mines in regard to the smelter smoke problem.

Mr. W. S. Ferris, superintendent of the cyanide plant of the San Rafael y Anexas Company, Pachuca, Mexico, was in Denver recently.

Mr. R. L. Hallett, formerly with the Arizona Smelting Company, Humboldt, Ariz., has been appointed superintendent of the Sandoval Zinc Company's smelter at Sandoval, Ill.

Mr. H. W. Hardinge has gone to Montana on professional business and will return to New York by way of Arizona.

Mr. George J. Hough, chemist and metallurgist, has recently established a laboratory and assay office at Salida, Colo.

Dr. L. D. Ricketts, who was appointed one of a committee of three to investigate the smelter fume problem at Anaconda, Mont., recently spent several days at Anaconda and vicinity.

Mr. Lloyd Robey, superintendent of the cyanide plant of the New York and Honduras Rosario Mining Company, San Juancito, Honduras, has spent a leave of absence in this country.

Mr. Sidney B. Tyler has resigned his position as superintendent of the Frontenac Consolidated Mines Company, Central City, Colo., and has accepted a similar position with the Continental Mining Company, Monclova, Coahuila, Mexico.

Mr. Pope Yeatman, consulting engineer for the Braden Copper Company, Chile, has returned to New York from an inspection of the company's mine and new concentrator.

Obituary.

William L. McLaughlin, of Deadwood, S. D., died at Deadwood on July 28, aged 50 years. Mr. McLaughlin had been identified with the mining and metallurgical industry in a managerial capacity for many years. He was at one time manager of the Horseshoe Mining Company and later manager of the Mogul Mining Company and the Wasp No. 2.

William C. Greene, known for his connection with the copper industry in general, and more particularly with the Green-Cananea copper mines and works at Cananea, Mexico, died at Cananea on August 5. The immediate cause of death was acute pneumonia induced by injuries received a few days ago previous in a runaway accident. Mr. Greene had a rather spectacular rise and fall in financial circles, and ultimately his copper interests were absorbed by other parties.

Mr. Alfred J. Bettles, of Salt Lake City, died in that city on August 3, 1911. Mr. Bettles was one of the foremost metallurgists in the West and had been identified with some of the largest projects in ore dressing. He was associated with Samuel Newhouse during that operator's development of the Cactus and Boston Consolidated companies. The immense mill of the latter was at the time of its construction one of the largest mills in existence. It is designed to treat the low grade copper ores of Bingham, Utah, carrying from 1.5 to 2 per cent. copper. Mr. Bettles adopted radically different steps in the treatment of this ore than were adopted in another mill built about the same time to treat the same ore. His judgment in installing stamps as grinding machines instead of Chilean mills and rolls, was seriously questioned at the time, and the departure attracted much attention in milling circles. The metallurgical results obtained in the Boston mill, however, apparently justified his judgment, although later the mill was remodeled to conform with more advanced practice and to obtain greater tonnage.

Mr. Bettles was recognized as a man of high integrity as well as excellent professional attainments. This combination rendered particularly valuable to his employers and associates at a time when so much depended on both qualities. In the last few years he had given attention to his own interests and to consulting practice. He was fifty-five years of age at the time of his death, which was due to uremic poisoning following an operation.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Toronto Meeting of the American Electrochemical Society.

The report, printed elsewhere in this issue, of the Toronto meeting of the American Electrochemical Society held from September 21 to 23, will be found so complete that little could be added to the details of this highly enjoyable and successful convention. But we may use this opportunity to say a few words on some broader aspects of the remarkable development of this Society which is not yet ten years old.

Firstly, the Toronto meeting—the second one held on Canadian soil—confirmed what scrutiny of the membership list and of the papers published in the Transactions has long indicated: that in one respect at least the Society has already outgrown its name. It is no longer a national, it is an international society. In view of the unbounded hospitality which the visitors enjoyed at Toronto and the splendid arrangements which had been made by the local committee with Dr. W. Lash Miller as chairman and Mr. W. P. Cohoe as secretary, it goes without saying that everyone felt very much at home in Canada. And the coincidence of the first convention day being the day of the Canadian anti-reciprocity election only served to emphasize more strongly that in the interchange of ideas there can be no tariff. In the realm of exchange of ideas reciprocity expands freely by God-made laws.

Secondly, the glorious resurrection of Section Q with their clever and funny electric-furnace farce, presented at the smoker, deserves a word of notice. A keen observer who has attended many meetings of societies here and abroad has remarked that it is at the meetings of the American Electrochemical Society that "the most human crowd" is found. Nor is this to be wondered at. The Society is devoted to a borderland of sciences and industries and much of its work is pioneer work in virgin fields of science and engineering. We need only think of Bret Harte's stories to see how pioneer work of any kind brings out the human element, how it makes men respect each other for their accomplishments and love each other for their shortcomings, how it breeds a sense of humor. This was the spirit in which Section Q was born and this is the reason why the Electrochemical Society could not be without it. The fun of the farce presented at Toronto was so clever and good-natured that nobody could be hurt by the hits made in the fanciful play. Goethe's maxim of life of "Tages Arbeit, Abends Gäste, saure Wochen, frohe Feste," was followed in that long to be remembered smoker after the two heavy professional sessions of the first day.

Thirdly, for a Society with such a record as the American Electrochemical Society the danger would generally be great to rest on its laurels. But in this case the spirit of youthful unrest inherent in all electrochemists would not permit a policy of "let well enough alone." This is forcibly brought out in the report of the special committee appointed to consider and report "whether a higher standard of selection of papers read

at the meetings or published in the Transactions should be observed" and in the unanimous adoption of the committee's recommendations by the Board of Directors. These recommendations are now to be worked out to be carried into effect in due course of time. They involve no criticism of the splendid work done in the past, but recognize distinct possibilities of doing better in the future. As long as such a self-conscious and critical spirit is alive in those who are intrusted with the Society's management there can be no doubt that the career of the Society must continue to be one of ever-increasing usefulness.

The Eighth International Congress of Applied Chemistry.

The Eighth International Congress of Applied Chemistry—the first one to be held in this country—is now only one year off. The time has, therefore, come for everyone to start energetically to do his share to make the Congress a success worthy of this country and American chemistry.

The Congress has been organized on the principle of broadest chemical democracy. As the Acting President, Dr. Wm. H. Nichols, remarked in one of his early speeches: "Every chemist in the United States must feel that he is part of the Congress from the very creation of the organizing committee down through all the details of management to the very close of the Congress."

The different sections have been organized and are ready to begin their systematic work. But every single chemist in the United States himself, directly or indirectly through his professional, business or educational affiliations, has a personal share of responsibility in the success of the Congress.

The success of the Congress will depend essentially on the contents of its printed Transactions. Thus the securing of the papers becomes the most important task of the near future. Tentative rules and regulations for the papers have been formulated. They are printed in full on pages 510 and 511 of this issue. Since they will be adopted in their final form in December, it is necessary that any criticisms or suggestions should be made to the Secretary of the Congress before December.

But aside from this more formal matter, the all-important point must be kept continually in mind that everything be done to secure for the Congress any worthy paper and thus to make the Transactions a truly representative document

Transfer of the Ray Smelter.

The Ray Consolidated Copper Company, Arizona, was planned as a complete copper mining, concentrating and smelting concern, with full equipment for carrying on these several operations. Recently, however, the smelting end of the project has been abandoned before its completion, and the plant has been sold to the American Smelting & Refining Company. Apparently the Ray company intends to stick close to mining and concentration, in which fields its promoters have gained signal success; while the Smelting company takes advantage of an excellent opportunity to extend its smelting operations and gain a foothold in Arizona.

The arrangement should be advantageous to both companies, each of which will operate in its chosen and successful field. The Ray company has assurance that its concentrates will be treated by a friendly company practically as cheaply as in its own plant, and at the same time it is relieved of the arduous work of conducting a large smelting industry. The smelting company, on the other hand, enters into competition in one of the largest copper-producing States in the Union, and in a district where almost 150,000,000 tons of low grade copper ore are developed.

The promoters of the Ray began their immense operations in the Utah Copper Company, later developing the Ray in Arizona and the Chino in New Mexico. They also have been interested in Nevada Consolidated. Almost from the beginning they have had close working relations with the Guggenheims, and the recent transfer of the Ray smelter to the latter is a logical if unexpected move.

Some Recent Crushing and Grinding Tests.

Evidence is accumulating on the subject of crushing and grinding which forces a modification of some views formerly held, and the results obtained in some recent tests must be accepted regardless of stubborn prejudice or nice theory. In the Synopsis of Current Literature in another part of this issue reference is made to the work of ball mills in Australia and the excellent performance of these machines in dry crushing. Three-inch ore is crushed to pass approximately 30-mesh screen, with a power consumption of about 0.5 hp per ton. The quantity of minus 150-mesh material produced is not as great as with other pulverizers and the product is sharp and granular even in the finer sizes.

This reference to the ball mill recalls the belief which is finding acceptance among many engineers that the ball mill and tube mill in tandem will be found a most efficient system of wet grinding. This belief is substantiated in a large measure by the recent tests of the so-called Giesecke ball-tube mill in South Africa. This machine is a ball mill and tube mill combined, with compartments for coarse crushing and fine grinding, and a suitable connection for passing the product of the former to the latter. It has a total length of 24 ft., of which 5¾ ft. at the feed end is the ball mill compartment with a diameter of 7 ft. 6½ in., and the balance is the tube mill with a diameter of 5 ft. 10 in. Steel balls of various sizes ranging from 1¼ in. to 4 in. are used as the crushing medium. The larger sizes are used in the ball end and the small in the tube. Their total weight is 23 tons. The liners are 2-in. iron plates with one end bolted to the shell and the other projecting inward about 9 in. The entire mill weighs 68 tons without load, runs at 24 r.p.m. and requires about 235 hp when running. Its capacity is 360 tons per day of 7-in. material, which is reduced so that 80 per cent will pass a 200-mesh screen.

Here is a departure in grinding machines, with preliminary results that are very attractive. If the cost of operation and maintenance should prove to be no greater than that of stamps and tubes a marked saving is possible in cost of installation as compared with the latter combination. And even if the Giesecke mill in the form described should, for various reasons, prove an unwieldy combination, there still exists the probability that separate ball and tube mills may prove an efficient combination.

One feature in particular which contributes to the capacity

of the Giesecke mill is the small quantity of water used in grinding—just sufficient to make the pulp flow. This insures an efficient grinding action of the balls approaching that of the dry ball mill, where no fluid other than air can tend to wash the particles of ore out of the path of the rolling and tumbling balls.

The Giesecke mill or the separate ball and tube mill combination gives stage crushing in a compact apparatus. Judging from the success attained by the ball mill and the tube mill when used separately for specific purposes, their combination should be more thoroughly investigated, and the tests made in South Africa will serve to draw more attention to their possibilities.

Of a different nature, but relating to the subject of crushing, were the tests on rolls and Chilean mills as grinders of disseminated copper ore at the Miami mill in Arizona. In the construction of this plant one section was equipped with rolls and the others with Chilean mills. The tests have been completed to the marked advantage of the Chilean mills, which, although noted as producers of slime, did more efficient work in liberating the copper mineral from gangue than the rolls, which gave a more granular product. This test adds to the prestige of the Chilean mill in copper concentration in the West and gives it a position which it holds apparently through merit alone.

Wages in the Steel Industry.

In the past four years the steel industry has come to occupy a very unfortunate economical position. Its selling prices were admittedly not inordinately high in 1907, although they were entirely satisfactory. From the average prices of that year to the present time the decline has been fully $10 a gross ton as the average of all products outside of standard sections of steel rails, which are unchanged in price but are subject to much more rigid specifications and to a higher manufacturing cost. The general average level of commodity prices in the United States has not declined materially, if at all, since 1907, so that the steel industry stands at a very great disadvantage, in having suffered a reduction of $10 a ton in its selling prices, equal to between 20 and 25 per cent, computed upon material in the finished rolled form.

The average wage rate in the steel industry is higher than in 1907, through the general advance which was made in the spring of last year. The average increase is not large, but the fact that the change in wage rates has been in this direction places strong emphasis upon the peculiar economic position resulting from the great reduction in selling prices.

The last vestige of artificial control of prices in the steel industry appears to have vanished, if the maintenance of the $28 price on standard section rails be disregarded. It may be due to a survival of the co-operative idea or may be due to a refusal of the railroads to entertain lower prices. The railroads realize fully that the price is not high for the quality of rail they desire, and that a period of open competition in rail prices would make it much more difficult to secure the improvements in quality which they desire. Thus we may say that there is no longer any artificial control in steel prices through joint action or tacit understanding among the steel producers. The course of the markets in the past three months has clearly betokened conditions of open competition. Declines have not been clear cut, as have been those which occurred during the long period of a controlled market, but have been of the nature of a gradual sagging, with resistance on the part of sellers yielding to the necessity of making concessions in order to obtain individual orders. The downward trend in prices continues at this time and no indication is found in the markets that it will be arrested other than by prices reaching the cost level. Below that level they may possibly go, for most of the producers have large reserves and may become willing to make sacrifices in order to retain their trade. The "battle of the giants" which the daily newspaper paragraphers have delighted at times to predict is not among the possibilities, however, unless the total tonnage of demand should fall much below the present level, for the "giants" have not sufficient capacity to supply the existing demand. There are enough producers in a relatively poor position to be eliminated to leave a comfortable tonnage for those in better position.

In the circumstances outlined a general reduction in wages in the steel industry seems to be a certain prospect, and that not at a distant date but in the relatively near future. There is reason to believe that the subject has been thoughtfully discussed in the inner circles for several weeks past. In any circumstance a wage reduction is to be deplored, and would be a serious matter, but there seems to be no easy means of avoiding one.

The decline in steel prices has been so great that the average level of prices, outside of standard rails, is computed to be not more than about $4 a ton higher than the lowest level ever recorded, the average prices in the years 1897 and 1898, when individual commodities fluctuated but little, being about $4 a ton lower than the present level. Since then costs have increased in some respects and decreased in others. The wage rates in the iron and steel industry proper have greatly increased; the cost of ore mining has greatly increased, due to the necessity of seeking ore farther underground. Freight rates paid upon raw materials have materially increased, and practically all the commodities the industry buys are much higher. To offset these increases, which amount to very much more than $4 per ton of finished product, the industry has introduced many economies in practice. Its wage rates have not, we may assume, increased materially more than rates in other industries, and not as much, probably, as in the building industry, and it is particularly unfortunate that no means seems to be afforded whereby savings can be effected in other directions.

The situation is simply this: The steel industry finds itself with much lower selling prices than formerly, and naturally turns to the wage rates it pays. If the general level of wages should come down, then it would be fairer that the industries which the steel industry patronizes, like railroading and the manufacture of its various supplies, should themselves reduce wages, seeing that the steel industry must pay them higher rates than formerly. The steel industry has effected many economies in its processes, and it is unfortunate that if it cannot keep the results as return upon its capital investment it cannot at least use them to avoid a reduction in wages. A fair adjustment based upon theory would call for economy to be practised at these outside points.

American Institute of Chemical Engineers.

The fourth annual meeting of the American Institute of Chemical Engineers will be held in Washington, D. C., from Dec. 20 to 22 (Wednesday to Friday).

A number of papers will be presented on the general subject of patents and on the manufacture and testing of explosives as well as on other chemical engineering subjects.

One day will probably be devoted to visits to chemical engineering plants in Baltimore and vicinity. Visits to laboratories and other points of interest in Washington will also be arranged for.

Latest Results in Electric Furnace-Smelting of Iron Ore.

The Trollhättan furnace is now working with round electrodes 550 mm. diameter, screwed into each other and thus entirely consumed. These screw-joints hold well, not giving any trouble by heating at the joints. While the electrode consumption of this furnace using square unjointed electrodes, from Nov. 15, 1910 to April 9, 1911, was 10.28 kilos per ton of pig iron, counting the lost butts, the consumption from Aug. 4 to Sept. 4, 1911 was 6.2 kilos, and it has now (middle of September), reached 5.5 kilos.

The furnace has now been running steadily since Aug. 4. The gas pipes have been made stronger, so that pressures of 0.3 to 0.4 atmosphere are now used under the vault. The ore is charged more towards the middle of the furnace shaft, and the percentage of carbon dioxide in the escaping gas has been increased to over 30 per cent.

The output of pig iron has been increased, the consumption of charcoal has decreased, and the output per horsepower year has reached the figure of 5.05 tons per kw year, or 3.7 tons per hp year, this being the figure reached in the week Sept. 3-9. The detailed figures for that week are as follows:

Ore	192.5 metric tons
Limestone	7.7 metric tons
Charcoal	44.2 metric tons
Electric energy used	228,000 kw-hours
Average power	1357 kw
Pig iron produced	131.4 tons
Slag	22.1 tons
Charcoal per ton pig iron	336 kg
Pig iron per kw-year	5.05 tons
Pig iron per hp-year	3.70 tons
Kw-hours per ton of pig iron	1736
Hp-hours per ton of pig iron	2315

The builders and operators of this furnace feel every reason to be satisfied with these splendid results, which fulfill all expectations.

At about the end of 1911, four similar large electric pig iron furnaces will be in commercial operation in Scandinavia, viz.:

1—2500 hp at Domnarfet, Sweden.
1—3500 hp at Tyssaa, Norway.
2—3000 hp at Hagfors, Sweden.

The Western Metallurgical Field.

San Juan District, Colorado.

The production of vanadium and uranium from this district is assuming the proportions of a considerable industry, and the prospect is that within the next year a great deal of attention will be given to mining and milling these ores. A great deal of unfounded and irresponsible talk is current regarding this district, especially regarding the alleged fabulous value of the ores and the probability of supporting a thriving radium industry. The facts seem to be that in San Miguel County there are commercial deposits of uranium and vanadium ores some of which are treated locally and others shipped abroad.

The only local treatment of vanadium ore in operation now is carried on at Newmire by the Primos Chemical Company. This company is operating under lease and bond, the mines and mill owned by the Vanadium Alloys Company. The latter concern worked its properties for some time, but met with difficulties in the mill work. These were in a measure due to the fact that the work was new and there were no guides to successful operation. In addition to this some of the equipment installed was unsuited to the work. The Primos Chemical Company has now been operating the mill for about two years and is in a fair way to make a success.

The ore treated is an impregnated sandstone the nature of which will be found more fully described in Mr. Bleecker's article elsewhere in this issue. The average grade of ore milled is not known exactly, but is not in excess of 1.5 per cent vanadium and probably lower. The details of treatment are not given out by the company, but the method probably does not differ greatly from that used by the Vanadium Alloys Company, the principal improvements being in the mechanical operation. The former company roasted its ore with salt in a McDougal roaster. This roaster as installed proved very unsatisfactory and gave rise to constant trouble. Difficulty was experienced in getting the heat evenly distributed to the various hearths and on one occasion a rabble arm broke by sticking in the fused mass and caused a serious explosion when the cooling water was injected onto the hot material. Although the same roaster is now in use, it is understood that the Primos company has remodeled it to use oil and that it gives fair satisfaction, although plainly not adapted to this kind of work.

The roasted ore is leached with water, getting a solution of sodium vanadate, and this is precipitated with ferrous sulphate. Various means of leaching have been tried at this mill, both with and without agitators, and the latter have been discarded. The vanadate of iron obtained by the precipitation with ferrous sulphate is shipped to Primos, Pa., where it is reduced to ferrovanadium.

The ores shipped abroad are rather higher in vanadium content, containing probably 5 per cent to 6 per cent. It has been a matter of surprise to some that this ore could stand the charge of transportation abroad, but one shipper is authority for the statement that the rate from Placerville, Col., to Liverpool is 5 cents per ton less than from Placerville to Pittsburgh or common eastern points. The rate from Placerville to Pueblo, Col., is $6 per ton; from Pueblo to Galveston, $5, and from Galveston to Liverpool, $2.50. Total, $13.50. The rate to Pittsburgh is $13.55.

Silverton District.

The mining and milling industry in the vicinity of Silverton is in a quiescent state, due to a number of causes. Briefly these are the complexity and low grade of the ores, and the fact that the processes of milling installed some years ago are not applicable to present conditions. Recently there has been a commendable tendency to investigate new and accessory processes and the prospect is fair for renewed activity in the near future.

One of the greatest difficulties is the separation of the complex ores into concentrated products of shipping grade. Iron, lead, copper and zinc occur together in many of the ores, and ordinary wet processes of concentration are not profitable. Recently there has been renewed interest in the possibilities of electrostatic separation as a means of reviving many dormant properties. Inquiry brought out the fact that many mills already built but not in operation would be benefited by adding electrostatic separation to their present process, enabling them to separate the copper and iron from the zinc and make the latter a profitable metal instead of a stumbling block. Probably a score of these mills could be so benefited immediately. Two solutions of the problem are in sight, viz., the installation of electrostatic machines in the individual mills or the establishment of a separate electrostatic separation plant to be supplied with zinc-iron-copper middlings from the various mills.

Undoubtedly the former plan would be more satisfactory to all concerned if the individual companies could raise the necessary money. The latter offers the advantages and disadvantages which any custom plant gives to a community, but mainly its success depends on the assurance of a constant and adequate supply of material.

Still another possibility for the improvement of the industry in the Silverton district lies in cyanidation. There are silicious gold and silver ores which have proved amenable to this treatment, giving extractions of 90 odd per cent of the gold and 65 per cent to 75 per cent of the silver. An effort is now being made to secure a guaranteed tonnage of these ores to supply a custom cyanide mill and some progress has been made in this direction.

Idaho.

The Lost Packer smelter, which is situated about 100 miles from Mackay, Idaho, the nearest railroad point, was blown in for the summer campaign early in August. This is the first time in three years that this plant has operated, and it is not hard to see that the work is carried on under difficulties. Operations must cease with the advent of winter on account of the impossibility of getting fuel and other supplies. Coke has to be hauled to the smelter and matte has to be hauled out to the railroad, and considering the shortness of the campaign it is rather remarkable that the plant can be operated at all. Since the last operation of the plant a great deal of mining development has been carried on and the prospect is fair for a good campaign this summer.

In the Silver City district of Idaho the Rich Gulch Mining Company is preparing to erect a modern amalgamation and cyanidation plant. For the past six years this company has been opening a large body of low-grade gold and silver ore, averaging about $11 per ton, and sufficient ore has been blocked out to warrant the erection of the milling plant. The estimated cost for mining and milling is about $3 per ton, and with reasonably good extraction of the metals there should be a good profit.

Gold, Silver, Copper and Lead in California.

The mine output of gold, silver, copper and lead in California in 1910 had a value of $27,020,405, according to figures compiled by Charles G. Yale and just made public by the United States Geological Survey. The production of gold was $19,715,440; that of silver 1,840,085 fine ounces, valued at $993,646; that of copper 48,700,756 lb., valued at $6,184,996; and that of lead 2,870,977 lb., valued at $126,323.

These figures show a decrease in the output of gold, silver and copper as compared with the figures for 1909, but a large increase in lead. The 1909 figures are as follows: Gold, $20,237,870; silver, 2,098,253 oz., valued at $1,091,092; copper, 57,288,281 lb., valued at $7,447,476; lead, 1,502,597 lb., valued at $64,612.

There were 1079 mines producing gold, silver, copper or lead in California in 1910, of which 564 were gold placer mines. Of the deep mines 485 were gold mines, 9 were silver mines, 10 were silver-lead mines and 11 were copper mines. Of the placer producers 168 were hydraulic mines, 72 were dredges operated by 41 companies, 139 were drift mines in ancient river gravels and 185 were sluicing mines. Measured by the number of producers as well as by tonnage and metal output, deep mining decreased somewhat in California in 1910. Among the placers sluicing decreased also, but dredge and drift mining increased.

In 1910 there were 2,697,885 short tons of ore from deep mines sold or treated in California, with an average total recoverable value of $6.71 per ton, against 3,041,688 tons in 1909, with an average recoverable value of $6.41. Of the total recovered value in ores in 1910, milling ores yielded $10,005,190 in gold and silver; and smelting ores, $1,669,008 in gold and silver, $6,184,996 in copper and $126,323 in lead. Placers produced $8,888,795 in gold, of which $635,498 was from hydraulic mines, $516,929 from drift mines, $7,550,254 from dredges and $186,114 from sluicing mines, the yield from dredges alone being over 38 per cent of the total gold output from all sources in California in 1910.

Gold dredging has been of constantly increasing importance in California since 1899, when the yield from this source was $206,302. In 1910 it was $7,550,254. The total gold output by dredges in California to the end of 1910 was $40,318,775. The three great dredging fields are those of Yuba, Sacramento and Butte Counties, of which the Yuba County field showed an increased output of $730,557 in 1910, while the production from Butte County decreased $501,038 and that of Sacramento County decreased $164,542.

Of the total gold placers furnished $2,468,505 from Butte County, of which $2,389,235 was from dredges; $1,394,537 from Sacramento County, of which $1,369,594 was from dredges; and $3,199,952 from Yuba County, of which $3,172,476 was from dredges. Dredges also produced $191,900 in Calaveras County, $213,980 in Merced and Stanislaus Counties combined, and $109,182 in Siskiyou County.

Hydraulic placers produced $179,105 in gold from Siskiyou County and $328,154 from Trinity County.

Drift mines produced $147,599 in placer gold in Nevada County and $151,743 in Placer County.

Surface or sluice placers produced $29,700 in Plumas County, $22,339 in Siskiyou County and $27,476 in Yuba County, and smaller amounts of gold in most of the other producing counties of the State.

The largest increases in gold production by counties in California were $347,461 in Amador, $80,815 in Mono, $122,363 in Sierra, and $734,408 in Yuba. The largest decreases were $499,288 in Butte, $292,866 in Calaveras, $78,885 in Mariposa, $126,752 in Nevada, $272,940 in Sacramento, and $310,077 in Tuolumne. The Mother Lode in Amador, Calaveras, Eldorado, Mariposa and Tuolumne Counties produced 1,170,497 short tons of ore in 1910, with a total recovery in gold and silver valued at $4,435,802, or an average of $3.78 per ton, against 1,338,160 short tons yielding $4,854,355, an average of $3.60 per ton, in 1909.

Arizona and New Mexico.

The porphyry coppers continue to make an excellent record in ore development and milling. It is claimed that the work at the Ray Consolidated is resulting in 70 per cent recovery. Four of the eight sections of the concentrator are now in operation treating about 800 tons each per day, or slightly below their capacity of 1000 tons each. It is probable that no more sections will be placed in commission until after October.

During the past seven months the Inspiration Copper Company has added over 7,000,000 tons of developed ore to its supply. This gives a grand total of over 25,000,000 tons of developed and partly developed ore, averaging 2 per cent copper. Based on a milling capacity of 5000 tons per day, this amounts to about 14 years' supply. Plans for the mill are now being prepared and although a definite site has not been selected the Inspiration will shortly have to be counted among the producers.

The first section of the Chino mill was to have gone into commission before the end of September, treating 1000 tons of ore per day. A good record has been made in bringing this property to the producing state, only two years and three months having elapsed since its acquisition by the present owners. The entire original milling plant of three sections should be in operation before the end of this year and the two additional sections recently decided upon will be ready for operation next year. Over 50,000,000 tons of ore have been developed by means of churn drills. Two years' supply of ore is already stripped and three steam shovels are constantly at work on further stripping operations.

American Mining Congress.

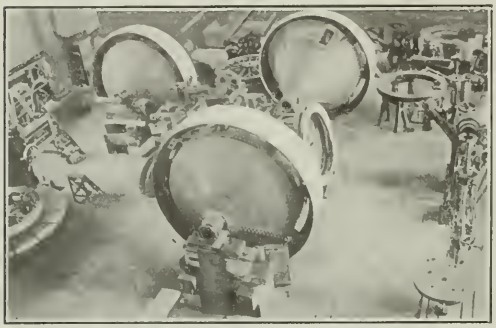
The annual convention of the American Mining Congress will be held in Chicago, October 24 to 28 inclusive. This is

the second change of date that has been made since the first announcement of the meeting, and corresponds with the date originally set. It is expected that President Taft, Secretary Fisher and Director Holmes will be present, and the change in date is for their accommodation. Matters of considerable interest to the metalliferous mining industry will come before this session of the congress, and it is expected that steps will be taken which will result in the national government taking a more direct interest in metallurgical problems, particularly those of the Western states.

Driving of Large Pebble Mills.

A certain innovation has recently been made in the driving of large-diameter pebble mills. The ordinary and common practice has always been gear drive owing to the unusual moment of high power necessary to start a mill from the state of rest.

An innovation was made by the Calumet & Hecla Mining



DRIVING OF LARGE PEBBLE MILLS.

Company, who, after testing out a gear-driven Hardinge 8-ft. conical pebble mill, equipped the 8-ft. mill with an improvised pulley around its largest diameter, extending the pulley diameter to 10 ft. The testing out of this mill under this improvised condition appeared to show that it would take about three to four horsepower in excess of the gear-driven mill. The results of this experiment, however, did not deter the Calumet & Hecla Company from instituting this method of driving this class of mills, which they were then building, as is shown by the enclosed photograph of the Calumet & Hecla shops.

This enormous pulley on a direct-driven mill was obtained with a 26-in. belt. It finally worked out that instead of taking an excess of power there was a decrease in power nearly to the amount as had been expected would be an increase. In other words, while a 35-hp to 36-hp mill under the gear-driven system was expected to require 40 hp, it was found that two of these mills were started from a state of rest with a full load when driven by a 70-hp motor without the motor showing any effect of an excessive load.

It is estimated that these mills are taking in fact from 30 hp to 32 hp.

The point of interest in a mechanical way is the elimination of gears at a sacrifice of a larger belt. It is stated that a belt of about 20 in. in width would give the necessary power. So successful was the operation of the four mills so constructed that the Calumet & Hecla Company are completing the balance of the first installation of about eight to ten more mills under the same conditions.

Arizona Copper Company.

It has been definitely decided to proceed with the erection of the new works which the Board of Directors have had under advisement for some time. Dr. L. D. Ricketts, of the Cananea Consolidated Copper Company, has been retained as consulting engineer for a period of three years. He will have charge of the preparation of plans and erection of the works, and will be assisted by the company's general manager, Mr. Norman Carmichael. It is expected that plans will be ready to submit to the board this fall.

New Mill for Inspiration.

For some time past there have been reports of a consolidation of the Inspiration and Miami properties, or at least of joint operation of a large milling plant. It appears now, however, that no agreement has bee nreached and that the Inspiration company will proceed with the construction of its own concentrator. The overtures for joint operation of a mill are said to have emanated from the Miami company, and the suggestion for consolidation from the Inspiration, but the various propositions did not meet with the favor of the two interests.

The capacity of the new Inspiration mill will be 5000 tons per day. The present developed tonnage of ore is 24,000,000 tons and new drill work is adding to this amount monthly

The Iron and Steel Market.

The steel market has again gone contrary to expectations. July and August proved to be months of fair activity, when extreme dullness had been expected, while September has shown a decline in prices and in activity when improvment was confidently expected. There have been no disorderly breaks in prices, but instead a constant though very gradual sagging, somewhat more rapid in September than in July and August, which was quite natural in view of the reduced demand.

The decrease in activity has been most marked in respect to new buying. Specifications on contracts have been fairly satisfactory, though hardly at as good a rate at the close of September as during August. Buyers are pursuing an extremely conservative course, keeping their stocks down to the lowest possible notch.

A very unfavorable feature of the situation from the standpoint of mill operations is the fact that buyers are ordering and specifying in very small quantities, and the mills themselves have no accumulation of specifications. As a result rolling schedules must be made up almost from day to day, roll changes are frequent and tonnage outputs at the mills are disappointing while the production cost of course is increased. Buyers cannot be induced to place larger specifications, for as it is specifications are obtained only with difficulty, and mills cannot accumulate so as to arrange specifications to advantageous rolling because when material is once specified the buyer insists on the earliest possible delivery.

A rough estimate would indicate that during September the independent steel interests operated at an average of 65 per cent. of their capacity and the United States Steel Corporation at an average of 75 per cent. of its capacity, which means that the domestic business was divided approximately according to the respective capacities, while in addition the steel corporation produced its usual large tonnage of export material.

Finished steel products, with the exception of rails, have receded since July 1 by $1 to $2 a ton, plates, bars, sheets and tin plates having declined $2 a ton and structural shapes, wire and merchant pipe $1 a ton. These recessions have not been by definite drops but by slight gradations. A trifle more than one-third of the total decline occurred in September. During these three months open market conditions have prevailed, practically for the first time in a decade or more.

The steel industry has lost practically all its optimism. There is little if any expectation of an improvement in demand this year. Conditions are regarded as although unsatisfactory, but the blame is attached more to excess of capacity than insufficiency of demand. The country has been making and consuming pig iron at the rate of about 23,000,000 tons a year, ca-

pacity being slightly in excess of 33,000,000 tons. The best output in 12 consecutive months has been about 30,000,000 tons, from August 1, 1909, to August 1, 1910, but that output was not all consumed. The best previous record was 27,000,000 tons in the 12 months ended October 31, 1907. These are now recognized to have been exceptional periods. The recent rate of output represents the maximum capacity in so recent a year as 1905, when this was the production with all capacity employed and conditions generally satisfactory.

While the continued decline in prices has not brought the average level of finished steel products down to the historic low level, the present average is not more than $4 a ton above that level, made in 1897 and 1898, at a time when wage and commodity rates were very much lower than at present. The advances in these items amount to much more than $4 a ton, so that as the steel industry was making very little money in 1897 and 1898 it would be losing heavily at this time were it not that various economies have been introduced. It is recognized that with prices as low as they are now, and showing prospects of further declines, a general reduction in wages can hardly be averted, and reductions averaging 10 to 15 per cent. are likely to be ordered before the close of the year.

PIG IRON.

Southern iron has again become easily obtainable at $10, Birmingham, a price which almost disappeared in August. Sales are light, consumers having bought more heavily than necessary considering the rate of consumption in the past two months. Foundry iron in other districts is practically unchanged. In the central west deliveries of merchant basic iron have decreased somewhat. A new low price on basic iron at valley furnaces has been made, 1000 tons being sold for prompt delivery at $13,50, delivered Pittsburgh or $12.60 f.o.b. valley. Prices are quotable as follows: Birmingham, $10 for No. 2 foundry; delivered Philadelphia, $15 for No. 2X foundry, $14.75 for basic; f.o.b. Chicago district furnaces, $14.50 for No. 2; f.o.b. valley furnaces, 90c higher delivered Pittsburgh; Bessemer, $15; basic, $12.60 to $13; malleable, $13; forge, $13; No. 2 foundry, $13.50.

STEEL.

The smaller open-hearth steel mills are offering billets and sheets bars at substantial concessions, $2 a ton below prices prevailing early in August. The large mills making Bessemer steel have important contracts based upon arrangements for monthly adjustment of price, and can not afford to disturb such adjustments by selling at prices the limited amount of steel which could thus be absorbed. The result, due to this peculiar market alignment and in no respect to difference in cost of manufacture or availability for finishing operations, is that open-hearth material is quotable at $2 less than Bessemer. We quote open-hearth steel f.o.b. Pittsburgh district mills at $19 for billets and $20 for sheet bars and Bessemer steel f.o.b. mills Pittsburgh or Youngstown districts, $21 for billets and $22 for sheet bars. Rods are nominally quoted at $27, Pittsburgh, but could probably be bought at $26.

FINISHED MATERIAL.

Due to open market conditions a considerable range of prices exists on several of the products, according to tonnage and specifications involved in the given order. Prices quoted below are the ordinary minima for desirable orders, but in exceptional cases the prices on bars, plates and shapes are slightly shaded. Small orders and orders for forward delivery generally command slightly higher prices than here quoted. Prices are f. o. b. Pittsburgh, except where otherwise stated:

Rails standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, 1.25 cents for tank quality.

Shapes, 1.30 cents for beams and channels, 3 to 15-in., inclusive, zees, and angles 3 x 3 and larger.

Steel bars, 1.15 cents, base; iron bars, 1.25 cents, Pittsburgh; 1.22 cents, delivered Philadelphia; 1.20 to 1.25 cents, Chicago.

Wire nails, $1.65, base: plain wire, 1.45 cents, base.

Black sheets, 28-gage, 1.90 cents; galvanized, 2.90 cents; blue annealed, 10-gage, 1.40 cents; painted corrugated roofing, $1.35 per square; galvanized, $2.50.

Tin plates, $3.60 per base box.

The Non-Ferrous Metal Market.

The September market was not characterized by anything unusual either in prices or sales. The foreign situation in zinc continues to indicate a shortage there and an advance in price. The domestic lead market at St. Louis has resumed almost normal relation to the New York market. Spelter and copper have been without feature and prices have been about stationary.

Copper.—There has been a disposition on the part of producers to make concessions in order to get business, and the largest transactions have been at receding prices. The market has been almost stationary at 12½ to 12⅝ cents for Lake, and 12.30 to 12.35 cents for electrolytic.

Lead.—The New York market has held steadily to 4.50 cents since our last report. The St. Louis market has declined somewhat on account of unusually large offerings of Missouri lead, and the latest quotations are 4.35 to 4.40 cents, which is more nearly in accord with the New York price.

Tin.—Prices for spot tin have fluctuated widely in the past month. At one time a premium as high as 4 cents per pound was paid for spot tin in New York, but later this receded to ¾ cents. In general, however, the market has been dull and September tin was quoted at about 41¾ cents.

Spelter.—The stocks of this metal seem to be low and consumers are apparently well supplied. Efforts have been made to create an interest in future business, but the only result has been a tendency toward lower prices. The New York market has stood at about 5.83 to 5.90 cents, and St. Louis at 5.70 to 5.75.

CORRESPONDENCE.

Fixation of Atmospheric Nitrogen.

To the Editor of Metallurgical and Chemical Engineering:

Sir—Referring to my letter concerning the Notodden and Rjukan plants for the production of nitrates from air (published in the September issue, page 436), I have just noticed a mistake in the fourth paragraph. This paragraph should read as follows:

"With reference to the chemical part of the Rjukan plant it had been decided some time ago to use the absorption towers of the Badische Company. It has been decided recently, however, that absorption towers of the Birkeland and Edye type will be used at the Rjukan plant" (instead of Notodden plant, as said in the former letter).

Paris, France. A. S. Garfield.

Aluminium in Ferrotitanium.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In reply to Dr. G. B. Waterhouse's criticisms of the content of aluminium in carbonless ferrotitanium made by the aluminothermic process, I would like to make the following remarks:

The addition of aluminium to carbon-free ferro-titanium, containing 24 per cent of titanium, is intentional and decidedly useful. Titanic acid is well known to be very difficult of fusion, and for this reason the titanic acid which is being formed from the ferrotitanium separates out only with great difficulty, if alone present. If, however, alumina is produced together and simultaneously with titanic acid, the two react together at once, forming aluminium titanate, which is much more easily fusible than titanic acid and also more easily fusible than alumina.

Aluminium, used to such a large extent in the steel industry,

has also the disadvantage that its oxide alone is fusible only with great difficulty and does not separate out easily. By microphotographic methods it is easy to show the small particles of alumina enclosed in steel.

A simple experiment shows that aluminium titanate gives a much more fusible slag than either titanic acid alone or alumina alone. Let us try to melt pure alumina alone and pure titanic acid alone in a piece of clay pot or in a small shallow crucible by means of the oxy-acetylene flame. Either oxide alone will refuse to melt, except if the flame is applied for a very long time and concentrated directly on the oxide, but even then we will succeed only in melting together small globules.

But if we now mix the two oxides together, say in the ratio of three to four parts of titanic acid to one part of alumina (that is, in same proportion in which the two oxides are formed in the oxidation of the carbon-free ferrotitanium, containing aluminium and made by the aluminothermic method), the two oxides together will melt in a very short time. This simple experiment shows clearly the advantages of the aluminium content in titanium.

But there is another important point. Aluminium is a more strongly deoxidizing reagent than titanium. It is wrong to say that titanium is a better deoxidizer than aluminium. This is proven by the fact that aluminium reduces titanic oxide and titanium does not reduce alumina.

The use of the titanium has other objects than the aluminium. While the titanium is a strong deoxidizer, it also reacts with the nitrogen and is effective in small quantity as titanium itself.

When, however, the steel contains quantities of oxides which could be deoxidized by means of aluminium, if this was present, the titanium acts as a deoxidizer, and is consumed uselessly as such wholly or partly. In order to avoid this useless consumption of the titanium aluminium is added simultaneously with titanium, so that all the impurities and oxides are first reduced by the aluminium. When this is done the titanium can manifest its own effect more strongly, and *experience* has shown that to produce the same results *smaller quantities* of ferrotitanium containing aluminium are required than of ferrotitanium containing carbon.

The above-mentioned difficulties with alumina alone in steel have not escaped other experimenters who have tried to avoid and overcome them. I call attention to English patent 6323 of the year 1895, relating to the use of an alloy of manganese, silicon and aluminium, instead of pure aluminium. It is emphasized there that this alloy in statu nascendi yields an easily fusible slag. This alloy is made by the world-renowned firm of Friedr. Krupp in Essen, who are the owners of the above patent.

HANS GOLDSCHMIDT.

Essen-Ruhr, Germany.

Ferrotitanium for Rails and Rolls.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The article in your July issue, page 342, by Dr. Hans Goldschmidt is as usual of interest to all who have undertaken to use titanium as a purifier in iron or steel, but I take exception to that part in which the author attributes the success of titanium in rails and rolls to a carbonless alloy.

Statistics compiled by the American Iron and Steel Institute show that 195,940 tons of ferrotitanium rails were rolled during the year 1910. The records of the Titanium Alloy Manufacturing Company show that we shipped a quantity of titanium alloy with carbon to the great steel mills of this country for a considerably greater tonnage than has reached the attention of the Institute.

There are in use in this country to-day very nearly 500,000 tons of titanium rails for which this company has furnished the alloy. Orders on our files indicate that every rail mill in the United States but one purchases the titanium with carbon alloy made by this company and the one exception is a company which assures us that they have not yet used any ferrotitanium beyond the samples furnished by this company.

Orders for titanium alloy made by us have run as high as 900,000 lb. in a single instance with dozens of orders varying from a carload up to 14 carloads as a maximum, the 900,000-lb. order having required 18 cars of 50,000 lb. capacity.

Under these circumstances it seems evident that a free-from-carbon alloy with its necessarily higher price and its greater tendency to cause brittleness, both due to the very considerable aluminium content cannot possibly have been an important factor in the manufacture of steel rails.

We have proportionately strong evidence on the subject of chilled rolls, but there are more manufacturers, so that of this line we cannot speak quite as positively.

CHARLES V. SLOCUM.

Titanium Alloy Mmanufacturing Company, Pittsburgh, Pa.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir: With reference to the letter from Mr. Charles V. Slocum on the subject of ferrotitanium for rails and rolls, I would like to state on behalf of Dr. Hans Goldschmidt, who is at present in Germany and therefore not in a position to write a prompt reply on the subject, that I am quite sure that he had no idea of attributing the success of titanium in rails and rolls only to the carbonless alloy.

What he desired to convey was the fact that for this class of work the carbonless alloy possesses very many advantages over a ferrotitanium containing carbon. As he has brought these advantages out in a reply which he has written to Dr. Waterhouse, it is hardly necessary for me to repeat them.

I would like to say further that in Dr. Hans Goldschmidt's article entitled "Melting Point and Its Relation to Alloying Capacity," published in METALLURGICAL AND CHEMICAL ENGINEERING July, 1911, his remarks were entirely general and scientific and related to his personal experience with the carbonless alloy. No one would be more ready than Dr. Hans Goldschmidt to accord Mr. Slocum credit for his energy in introducing his alloy to the steel trade, but his apparent intention to draw the conclusion that the carbonless alloy has found no field of usefulness in the lines he mentions is hardly correct.

WILLIAM C. CUNTZ.

Goldschmidt Thermit Company, New York City.

The Oil Engine for Electrochemical Plants.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In your August editorial on "the power problem for electrochemical plants" you have not spoken of the cheapest one of all, namely the oil engine. I have long ago abandoned steam wherever practicable: and the gas engine I have also laid aside after thirty-five years' use, for I find the new F H oil engine built by the De La Vergne Company beats even the gas engine, for with oil at 2.25 cents per gallon, a kw-hour can be obtained for $0.005 and less, and with less labor and trouble than gas.

How dreadfully slow people are to take up new ideas even when based on scientific principles, to wit: in 1876 when the late Sir W. Siemens first melted steel electrically he said to me, "like everything else it will take a generation before this is brought into practical use"; and this is generally true, for I can point out numerous great ideas which took over thirty years to come into use.

In this western country there are natural conditions which would not lie undeveloped a day in Germany, but I have tried in vain to interest Eastern capital. The answer always comes back: "We know nothing of that kind of business." Oh! for a firm out here like Siemens & Halske. There would be something doing.

WALTER E. KOCH.

El Paso, Tex.

Recent Ore Dressing Practise at Silverton, Col.

Editorial Correspondence.

The rugged mountainous district of southwestern Colorado is generally spoken of as the San Juan region, or simply "the San Juan." It is divided naturally by the mountain ranges into districts which are tributary to the important towns of the region, of which Silverton is one of the most prominent. The winning of gold and silver from the mountains in the immediate vicinity of Silverton dates back to 1860, when gulch mining was first attempted by a party of miners headed by John Baker. But it was not until the early eighties that the deposits of rich silver ore in the vicinity of Red Mountain were discovered and successfully worked. At that time ore worth less than $100 per ton could not be marketed at a profit on account of the difficulties of transportation. With the extension of the Denver & Rio Grande Railroad into Silverton in 1882 an impetus was given to the mining and smelting of lower grade ores, but with the waning price of silver the precious metal content of the ores still had to be comparatively high in order to yield a profit.

Crude ore only was shipped from this district up to 1890, when pioneer attempts at concentrating the lower grade ores were made at the Silver Lake and Sunnyside mines. Prior to this time lixiviation plants had in a few instances been successful in extracting silver by a process of chloridizing, roasting and leaching with strong brine.

At the present time, however, attention is being directed to the concentration of the low grade milling ores, which are abundant in the district. These are mixed sulphides of lead (galena), zinc (sphalerite), copper (tetrahedrite and chalcopyrite) and iron (pyrite). Silver occurs mainly with the copper ores and sometimes with the finely crystalline galena. Gold accompanies the pyrite and sphalerite in small quantities. Zinc minerals almost always accompany galena, and in the past have given much trouble in concentrating. In brief, operations in the Silverton district are at present confined almost wholly to the separation of these low grade mixed sulphides into marketable products of lead and zinc, and the future of the mining industry there practically depends on the use of the most modern and improved methods of ore dressing.

The presence of considerable quantities of copper and iron minerals with the lead and zinc complicates wet dressing and calls for accessory treatment such as electrostatic separation. The latter process is not now in use in the district and as a consequence many mines and mills are closed, and only those are operating which can produce marketable lead and zinc concentrates by straight water concentration. At present these are the Silver Lake, Vermillion, Ledge, Iowa and Sunnyside. The Vermillion and Ledge mills may be taken as typical of the best ore dressing in the district.

The Vermillion Mill.

The concentrating mill of the Vermillion Mining Company is situated about 1½ miles west of Animas Forks in California Gulch, near the head waters of the West Fork of the Animas River. The crude ore is a mixture of galena, sphalerite and pyrite finely disseminated in a gangue of rhodonite. An average assay will show about 5 to 6 per cent lead, 10 per cent zinc and 3 to 4 per cent iron. The ratio of concentration is about 5½ to 1, and for the month of July, 1911, the saving was 81 per cent. At present the mill is running below capacity and treating only 75 tons per day. Water is obtained partly from the mine, about one-third the total quantity used being taken just as it flows from the tunnel. The balance is pumped from the creek 146 ft. below by a 7x8 Gould triplex pump operated by a 15-hp motor. Pumping is apparently a necessary expense, as the mill is situated so near the head waters of the creek that a pipe line or flume run at the proper level would not collect a sufficient volume of water. From 12 to 13 tons of water are used per ton of ore treated.

The method of treatment follows: Ore is trammed from the tunnel to the head of the mill and dumped into crude ore bins, first passing over a ⅞ inch grizzly. The coarse ore is reduced to ⅞-inch size in a Blake crusher, 11x18 in., and added to the grizzly undersize. The bin capacity is sufficient for the storage of 200 tons of crushed and an equal tonnage of uncrushed ore. From the second bin the ore is drawn by a plunger feeder and belt conveyer to the roughing rolls. These are 14x27 in., running at 60 r.p.m. and set ½ in. apart. The main elevator, which delivers the roll discharge to the trommel screen line, has 55-ft. centers and 14-in. buckets on a 16-in. belt.

A single line of trommels covered with Tyler double crimped screen prepares the feed for jigging. The first screen is 2-mesh, the oversize of which is reground in a set of 14x27 in. rolls running at 125 r.p.m. and set ⅛ in. apart. This roll product is again elevated to the screens. The second and third screens are 6 and 14-mesh, respectively, and their oversizes are treated in 3-compartment Harz jigs. Owing to the abrasive action of the gangue, screens are rather short lived in this mill. Trommel screens last about three weeks, and it is probable that punched steel screens will be used in place of wire, as local experience indicates that the life of the latter will be about three months. With punched screens the pitch of the trommels will be changed from 1 in. per foot to ¾ in.

Jigging practise varies with the physical condition of the ore. At times the mineral does not occur coarse enough to warrant the use of the coarse jig. With both jigs running, however, the first receives a feed ranging from —2 to +6 mesh, and the second from —6 to +14 mesh. The coarse jig has 5-mesh screen in the first compartment, and 6-mesh in the second and third. It runs at 210 r.p.m. and has a stroke of ⅝ in. The fine jig has 8-mesh screen in all compartments, runs at 235 r.p.m. with a ⅜ in. stroke.

Both jigs make a clean lead concentrate in the hutch and side gate of the first compartment. A shipping grade of zinc concentrate is made in the third compartment of the fine jig only. The middlings and tailings of the coarse and the tailings of the fine jig are reground in a Chile mill, while the middlings of the fine jig are returned to its first compartment for retreatment.

One 6-ft. Chile mill is used for regrinding jig tailings and middlings. This machine is grinding about 40 tons per day through ton-cap screen corresponding to 14 mesh. The life of the screen is but 10 days due to the excessive abrasion of the rhodonite. The die ring is 4½ in. thick, while the roll tires are made 3½ in. thick on the outside and 3¼ in. on the inside. These dimensions are calculated to give about equal life to die and tires. Under the light feed at present given to the mill it is run at only 24 r.p.m.

The Chile mill product is elevated and combined with the undersize of the last, or 14-mesh trommel, and thickened in a 3 x 3 ft. dewatering box preliminary to classification in a Richards 4-in., 6-compartment pulsator classifier. The overflow of the dewatering box flows successively to two Callow tanks, each of which gives a thickened feed to one Card table. The overflow of the second Callow tank runs to waste.

Each of the six products from the classifier is treated on a separate Wifley table. The first three tables make high grade lead and zinc concentrates, a two-inch streak of mixed lead and zinc mineral being returned to the tables by raff wheels. The fourth, fifth and sixth tables give a finished lead product, but the zinc mineral from these is combined with the zinc from the Cards treating the Callow product and retreated on another Wilfley. The coarse middling from the first Wilfley is reground in the Chile mill and the middlings from the succeeding five Wilfleys are combined and treated as a mixed feed on a separate table. This last table also has a raff wheel for the return of its middling product. The slime water from all tables except the zinc retreating table is thickened in three Callow tanks and retreated on a Card table.

Table Speeds and Strokes.

	Speed r.p.m.	Stroke in.
No. 1 Wilfley	245	⅞
Nos. 2 and 3 Wilfley	250	¾
Nos. 4, 5 and 6 Wilfley	255	⅝
Midd. Wilfley	250	¾
Cards	260	9/16

An interesting feature of the table work at this mill is the manner of running the Wilfley tables adopted by Louis D. Bastian, mill superintendent. When the tables were run flat enough to bring all mineral—galena and sphalerite—to the head of the table in the usual manner more or less of the rhodonite gangue appeared scattered throughout the concentrates and the zinc separation especially was poor. Mr. Bastian found that by increasing the pitch of the table so as to bring the zinc mineral over the side, and only the lead over the head of the table, he could increase the grade of zinc concentrate from 37% to 43%, and at the same time throw the rhodonite out of the mineral. Additional wash water is used near the head of the table to assist in washing the rhodonite out of the concentrates, and under present conditions this coarse gangue appears as a narrow streak below the zinc.

Ultimately all concentrates of like character from jigs and tables are mixed for shipment. The average grade of these products is indicated in the following figures:

	Pb %	Zn %	Fe %	SiO_2 %
Lead Conc.	57-62	7	7	2
Zinc Conc.	8	43	7	6-7

Of the iron in the zinc concentrate a little over half is combined in a manner which precludes separation, but the iron in the lead concentrate represents practically free pyrite. Electrostatic separation, therefore, would be of little benefit to this ore, as the added cost of further cleaning the zinc mineral would hardly be repaid.

The Vermillion mill is operated by electric power supplied by the San Juan Water and Power Company. The distribution of motors in the mill follows: 25 hp for crusher; 75 hp for rolls, trommels and elevator; 30 hp for Chile mill; 20 hp for 10 tables, classifier, two centrifugal pumps and middlings elevator; 15 hp for pump. The total power requirement under running load is 90 hp.

Acknowledgment is made to Mr. L. D. Bastian, mill superintendent, for assistance in collecting the data given and to Mr. R. W. Hollis, manager, for permission to publish the same.

The Ledge Mill.

The ore of the Ledge Consolidated Mining Company at Chattanooge, near Silverton, differs decidedly from that of the Vermillion as to the nature of the gangue, although the mineral content is not much different. Instead of the hard rhodonite gangue noted in the Vermillion ore, that of the Ledge is kaolinite, soft enough to be scratched by the finger nail and making an excessive quantity of slime in the milling process. The minerals are galena, sphalerite and pyrite, the percentage of lead being about 10 and of zinc 12. The ore also carries about 3 oz. silver and 0.02 to 0.03 oz. gold per ton. About 150 tons are treated daily. The ratio of concentration is 5 to 1.

The ore as mined is delivered to the mill by an aerial tramway one-half mile long. The buckets have a capacity of about ⅓ ton each, and the daily tonnage can generally be delivered on one shift. The ore breaks easily and preliminary crushing is rather coarse to avoid the production of slime. The first break is made to about 1½ in. size in a Blake 10x20 in. crusher. This product is further reduced in rolls, 16x36 in., running at 60 r.p.m. and set ¾ in. apart. Water is added at the rolls and the pulp is elevated to the trommel screen line. The elevator has 64 ft. centers and 14 in. buckets on a 16-in. belt. Ample screening capacity is one of the features of the mill, there being a double line of four trommels, each 9 ft. long and 42 in. in diameter, fitted with ton-cap screens corresponding to 4, 6, 8 and 16 mesh respectively. The oversize of the 4-mesh screen is reground in a set of 14x27 in. rolls, running at 100 r.p.m. and set ¼ in. apart and returned to the elevator and screen line. The oversizes of the second, third and fourth trommels comprise the feed for three 3-compartment Harz jigs, and the undersize of the last screen is thickened and classified for table concentration.

The following tabulation gives data regarding the operation of jigs:

	Size of feed Mesh	Screen Mesh	Speed r.p.m.	Stroke in.
Jig No. 1	−4+6	5	180	1¼
Jig No. 2	−6+8	8	220	⅞
Jig No. 3	−8+14	10	240	⅝

Galena concentrate is drawn from the first compartment in all jigs and from the second compartment also of the third jig. No zinc concentrate is made in the jigs. All jig middlings and tailings are dewatered in a trommel and collected in a bin, from which they are fed to a Chile mill. The water recovered from this pulp is stored in a tank and used in the Chile mill as needed. This procedure is preferable to allowing the pulp to flow from the jigs to the mill without dewatering, as a better ratio of water to pulp can be maintained.

The Chile mill runs at 32 r.p.m. and grinds about 75 tons per day through 16-mesh ton-cap screen. These screens last about three weeks. The die ring is cast thicker than the roll tires, so that all have about the same life, viz., three months.

The performance of the Chile mill at this plant emphasizes the difference in the physical properties of the Ledge and Vermillion ores. The quantity reground at the Ledge through 16-mesh screen is almost twice that reground at the Vermillion through 14-mesh, and yet the screens at the Ledge have about twice the life of those at the Vermillion, where the gangue is rhodonite.

The Chile mill product is elevated and combined with the undersize of the 16-mesh trommel, flowing to a spitzkasten, where it is thickened before classification. On account of the large quantity of slime in the pulp which tends mechanically to carry fine mineral to waste, extra large settling capacity is provided so that all slime is ultimately thickened and concentrated. To this end the overflow of the spitzkasten flows successively to Callow tanks, sufficient in number so that the overflow of the last will be practically clear. The underflow of these Callows is combined and classified in a Richards 4-compartment pulsator classifier and treated on four tables. The thick pulp from the spitzkasten is classified in a Richards 6-compartment pulsator classifier, running under a 16-ft. head of hydraulic water and making 160 pulsations per minute. A hutch product of clean galena is made in this machine, amounting to one ton per day.

The Wilfley tables in this mill are arranged on two floors, ten on each floor. Of those on the upper floor four treat the classified fine material from the Callow tanks and six receive the different grades of coarse pulp. All tables on this floor make a finished lead product only. The zinc-iron middling from each of these tables is retreated on a complementary table on the floor below, where zinc concentrates are separated from the iron and small amount of lead remaining with it. By way of further recovering fine mineral now going to waste it is planned to collect the slime water from the tables on the upper floor, thicken it and reconcentrate on additional tables. It is planned also to regrind the coarser middlings from some of the upper tables. When this plan is in operation the only material going to waste will be the tailings from the lower tables and the overflow from Callow tanks.

All concentrates are laundered to boxes at the foot of the mill and dewatered by a screw conveyer working in an inclined launder at one end of the box. The overflow from the

box passes through a series of settling launders before leaving the mill. The lead concentrates as mixed for shipment assay from 55 to 60 per cent. lead, and the zinc concentrates carry from 40 to 45 per cent. zinc.

During the summer season the mill is operated by water power. Two Pelton wheels running under a head of over 800 feet of water furnish all the power required. One 36-in. wheel, with 3/8-in. nozzle, provides power for the concentrating tables only, thus assuring steady operation. The balance of the mill is run by a 56-in. wheel, 3/4-in. nozzle. About 150 hp. is required for the whole plant under running load, or one hp. per ton of ore treated per day. Electric power is available when water is scarce, and only a short time is required to make the change.

For the data and information given herewith acknowledgment is made to Mr. W. Z. Kinney, manager, and Mr. D. C. McNaughton, mill superintendent.

Cost of Alkali Chloride Electrolysis.*

By Victor Engelhardt.

Aside from the electrolytic production of chlorates, there are two main groups of commercial processes for chloride electrolysis:

(a) Direct Production of Hypochlorite Solutions.—For this purpose the products of the electrolysis, chlorine and caustic alkali, are directly combined in the electrolytic cell itself to form bleaching liquor (hypochlorite). There is, therefore, only one final product. Such installations are suitable only in works in which hypochlorite solutions are directly needed.

Since in this case no saturated solutions are employed and the temperature is kept relatively low (as otherwise chlorate would be formed), the power consumption is comparatively high. Further as the ampere-hour efficiency decreases with increasing amount of active chlorine in the hypochlorite solution, it is impractical to decompose the whole chloride so that part of it is wasted.

On the other hand, these installations have the advantage that they need hardly any attendance and that any number of cells can be connected in series so as to suit any given supply voltage. For this reason the cells may be connected to dynamos which are also used for other purposes; for instance, direct-current dynamos which supply the lighting current during the night, may be connected to the bleaching liquor cells during the day.

This last-named practice is especially suitable for the cotton industry and for laundries, where the amount of hypochlorite solution required is relatively small. The electrolytic cells, when operated only during the day, will therefore furnish sufficient chlorine for the requirements of the works, especially as for cotton there is a relatively large saving of active chlorine, if electrolytic hypochlorite solutions are used, as compared with bleaching powder.

On the other hand, in the linen industry and in paper and pulp mills much greater quantities of hypochlorite solution are required, so that in this case it pays in general to install a special dynamo for the electrolytic plant, especially as the latter may then be made of 50 per cent less capacity, being operated continuously day and night. Moreover, in this case there is not such a large saving of active chlorine for hypochlorite solutions as compared with bleaching powder, so that for this reason alone the quantity of hypochlorite solution needed is relatively large.

(b) Production of Chlorine and Caustic Alkali Separately.—To keep the chlorine and caustic alkali separate from each other cells of three different types may be used: (1) Diaphragm cells, yielding chlorine gas and a caustic solution containing some undecomposed chloride, which can be removed completely only with some difficulty during the further treatment; (2) gravity cells (Glockenverfahren) yielding also chlorine gas and generally a caustic solution containing chloride; (3) mercury cathode cells, yielding chlorine gas and a caustic solution free from chloride.

In all processes for the separate production of chlorine and caustic alkali a hot concentrated electrolyte is employed. From the caustic solution produced it is possible in diaphragm and gravity processes to recover the undecomposed chloride during the further treatment; this is unnecessary in mercury-cathode processes. The power consumption is, therefore, lower and the utilization of the chloride is more complete than in the direct electroytic production of hypochlorite.

For the purposes of this article, which compares the different processes from the standpoint of commercial efficiency, the diaphragm and gravity processes may be grouped together, while the situation may be somewhat different, according to the conditions, for mercury-cathode processes. The latter produce a purer caustic alkali, free from chloride, such as needed for some purposes like the manufacture of metallic sodium or potassium, and which may be sold sometimes at a higher market price. As an offset there are higher capital investment and also mostly higher power consumption, due to the use of higher voltages.

On a large commercial scale processes of all three groups are employed for the production of chlorine and caustic alkali. For industrial works which need chlorine and caustic alkali for their own purposes, diaphragm cells are probably most suitable, since they are simpler and of less delicate construction. Such industrial works may proceed further by either of the following two methods:

(1) If the producer has no use for caustic alkali and no facilities for marketing it, he can combine the chlorine and the caustic outside of the electrolytic cell and produce alkali hypochlorite.* From a commercial standpoint, this method has the advantages of better utilization of the sodium chloride and smaller power consumption (due to both higher ampere-hour efficiency and smaller voltages) over the direct production of hypochlorite in an electrolytic cell.

(2) If the producer can use himself the caustic alkali or if he can market it readily, it is preferable from a commercial standpoint to combine the chlorine gas not with the valuable caustic soda or potash, but with milk of lime (calcium hydroxide) and form a chloride of lime solution.

Installations for the separate production of caustic soda and chlorine in industrial works are suitable only for relatively large capacities, since in order to reduce the relative cost, the apparatus must be built for high current strengths and a sufficient number must be connected in series. Moreover they must be operated continuously day and night, they require their own dynamo, attendance, etc., and would, therefore, be uneconomical for small capacities.

The power cost is of fundamental importance in chloride electrolysis since it is the most important item in the cost sheet. We will assume two limiting values: a minimum value of 0.5 cent per kw-hour for waterpower plants and by-product gas plants, and a value of 1.25 per kw-hour for steam plants.

On the basis of the above discussion the different cases to

*Translated from *Chemiker Zeitung*, Vol. 35, No. 64 and 65, p. 573 and 582 (1911). Slightly abstracted.

*This method is, of course, possible only if what the producer needs in his works, is bleaching liquor. If he needs chlorine gas, this method cannot be used. At the plant of the U. S. R. & R. Co. at Colorado Springs, Colo., where chlorination of gold ores with cyanidation of the tailings is in very successful operation, the chlorine is produced by a diaphragm-cell process and the caustic soda solution is wasted, since there is not such a ready market for caustic soda in the neighborhood as to justify the erection of expensive and troublesome evaporation apparatus. While the waste of the caustic soda seems peculiar from the standpoint of the Eastern producer of caustic soda and chlorine, it is undoubtedly the logical thing to do under the existing conditions. That the chlorine gas can be produced at very much less cost by electrolysis than from bleaching powder, bought in the market, and sulphuric acid, was proven by extensive tests at this plant, using both methods side by side over a considerable period of time.—Editor.

be treated and compared with each other, may be grouped as follows:

I. Direct production of hypochlorite solution at the consumers works.

IA. Smaller installations (cotton industry), operated only during the day. A saving of 30 per cent of active chlorine, as compared with the use of bleaching powder, is assumed.

IB. Larger installations (linen and paper industry), operated continuously during day and night. A saving of 10 per cent of active chlorine, as compared with the use of bleaching powder, is assumed.

II. Separate production of chlorine and caustic alkali.

II. 1. At the consumer's works.

II. 1A. With recombination of chlorine and alkali, to form alkali hypochlorite. Continuous operation day and night.

II. 1B. With production of chloride of lime solution and separate utilization of the caustic alkali. Continuous operation day and night.

II. 2. Separate production of chlorine and caustic alkali on a large scale for selling both products.

II. 2A. Diaphragm processes with production of a caustic alkali containing undecomposed chloride. Continuous operation day and night.

II. 2B. Mercury-cathode process with production of a caustic alkali free from chloride. Continuous operation day and night.

In order to arrive at a fairly satisfactory comparison between the different processes of alkali chloride electrolysis, attention must be paid to the fact that in the separate production of caustic and chlorine these two products are obtained simultaneously from the same raw material so that it is not possible to charge a definite proportion of the cost of operation against the manufacture of either product. On the other hand in hypochlorite manufacture the bleaching liquor solution only is produced.

For this reason, in considering processes for the separate production of chlorine and caustic alkali it will be more correct to deduct the value of the caustic alkali produced from the total cost of operation and to consider the difference as the cost of the bleaching material produced.

Since in industrial plants sodium chloride will probably always be used, it will be sufficient to give the comparative calculations for sodium chloride only. Further it would be wrong to assume always the same values for cost and selling price of sodium chloride, calcium chloride, and caustic soda, since smaller consumers cannot get as favorable prices as large consumers.

I.—Direct Production of Hypochlorite at the Consumer's Works.

In the main the following three electrolytic hypochlorite cells are now in commercial use, differing from each other by the material used for the electrodes: *a*, Siemens & Halske and Kellner, both electrodes being platinum. *b*, Schuckert, one electrode being of carbon, the other of platinum. *c*, Haas and Stahl, both electrodes being of carbon.

The following calculations are based on the system of Siemens & Halske and Dr. Kellner, with which the author is most familiar.

IA: Hypochlorite production at the consumer's works in small installations of the cotton industry, electrolysis being carried out during the day only.

Assumptions: The electrolytic cell is operated with 120 amp. at 110 volts (the power being, therefore, 13.2 kw), for 10 hours a day. 22.2 kilograms of active chlorine daily, 300 days of operation during the year. $28.75 per 1000 kilograms of chloride of lime at the plant, $3.75 per 1000 kilograms of sodium chloride at the plant. A saving of 30 per cent active chlorine compared with chloride of lime with 35 per cent Cl. (Therefore, about 25 kg of active chlorine in a NaOCl solution correspond to about 100 kg of chloride of lime.)

First Cost:	
Platinum electrodes	$1,350
Accessories (cells, pump, etc.)	1,150
Total	$2,500

	Cost of kw-hour. 0.5 cent.	1.25 cent.
Yearly Cost of Operation:		
13.2×10×300 = 39,600 kw-hours	$198.00	$495.00
170×300 = 51,000 kg Na Cl at $0.38 per 100 kg	191.25	191.25
4% amortisation and maintenance of platinum	54.00	54.00
10% amortisation and maintenance of accessories	115.00	115.00
5% interest on accessories	57.50	57.50
	$615.75	$912.75
Under the assumption of 30% saving of active chlorine, as stated above, the amount of bleaching liquor produced per year is equivalent to 26,700 kg of chloride of lime; hence the cost of the ton of equivalent chloride of lime	$23.05	$34.18

If for small quantities of chloride of lime the ton is bought at the consumer's works at $28.75 as assumed above, the production of the bleaching liquor by electrolysis at the works results, therefore, in a saving of $5.70 per ton of equivalent chloride of lime, if the kw-hour costs 0.5 cent, and in a loss of $5.43, if the kw-hour costs 1.25 cent. Under the above assumptions there will be neither a saving nor a loss if the kw-hour costs about 0.875 cent. In other words, if the power costs less than 0.875 cent per kw-hour, the electrolytic production of bleaching liquor at the works will be less expensive than buying bleaching powder.

It should be emphasized, however, that in this comparison the well-known technical advantages of electrolytic hypochlorite solutions could not be considered, because they cannot be given in figures. Further the present very high market price of platinum must be taken into consideration.

The wages are not considered in calculating the cost of operation since they would represent at least the same amount in bleaching with bleaching powder for the preparation of the bleaching solution, etc.

IB: Hypochlorite production at the consumer's works in larger installations in the paper and pulp industry, with continuous operation day and night.

Assumptions: Electrolytic cells operated at 110 volts, 600 amp (66 kw), for 23 hours a day, 254 kg of active chlorine daily, 300 days of operation during the year, $26.25 per 1000 kg of chloride of lime at the plant, $3.75 per 1000 kg of sodium chloride at the plant. A saving of 10 per cent of active chlorine as compared with the use of chloride of lime with 35 per cent Cl. (About 30 kg of active chlorine in NaOCl solution are therefore equivalent to 100 kg of commercial bleaching powder).

First Cost:	
Platinum electrodes	$6,750
Accessories (as in I A)	5,000
Total	$11,750

	Cost of kw-hour. 0.5 cent.	1.25 cent.
Cost of Operation:		
66×23×300 = 455,400 kw-hours	$2,277	$5,692.50
1900×300 = 570,000 kg sodium chloride at $3.75 per 1000 kg	2,137.50	2,137.50
6% amortisation and maintenance of platinum	405	405
10% amortisation and maintenance of accessories	500	500
5% interest on accessories	250	250
Total	$5,569.50	$8,985
Under the assumption of 10 per cent. saving of active chlorine, as stated above, the yearly amount of bleaching liquor produced is equivalent to 255 tons of chloride of lime; hence the cost of the ton of equivalent chloride of lime	$21.83	$35.23

Larger installations of this kind can buy the chloride of lime at less cost than assumed before, say at about $26.25 per ton at the works. Then the production of bleaching liquor at the works by electrolysis results in a saving of $4.42 per ton of equivalent chloride of lime if the kw-hour costs 0.5 cent, and in a loss of $8.08 per ton if the kw-hour costs 1.25 cents. Under the above assumptions there will be neither a saving nor a loss if the kw-hour cost 0.75 cent. For power costs be-

low this rate the electrolytic manufacture of bleaching liquor will be less expensive than buying bleaching powder.

With respect to the technical advantages of electrolytic bleaching liquor and wages the same remarks may be made here as were made in IA.

II.—Separate Production of Caustic and Chlorine at the Consumer's Works.

Only diaphragm cell processes are here considered. The cell should be of compact construction and it should be possible to build and operate it economically in relatively small capacities. A cell which has proven successful on a large scale in the chemical manufacturing industry as well as in plants of smaller capacity is the Billiter cell* which has been developed by the Siemens & Halske Company, together with the Kaliwerke Aschersleben. It is probably the latest diaphragm cell which has proven successful in practice. The following figures relate to this cell.

II.—1A: Separate production of chlorine and caustic with subsequent recombination to hypochlorite, with continuous operation in paper and pulp mills.

Assumptions: Electrolytic cells operated with 500 amp at 120 volts (60 kw), 8 kw for other purposes (hence total power 68 kw), 24 hours per day, 337 kg of active chlorine in the hypochlorite (figuring a loss of 10 per cent in absorption, etc.). Eight thousand hours of operation per year, $26.25 per 1000 kg of chloride of lime at works, $3.75 per 1000 kg of sodium chloride. A saving of 70 per cent of active chlorine as compared with the use of bleaching powder of 34 to 35 per cent Cl. (About 337 kg of active chlorine in NaOCl solution, are, therefore, equivalent to 1100 kg of chloride of lime).

First cost:	
Electrolytic cells	$7,000.
Conductors and switchboard	525.
Absorption plant and pipe system	1,562.50
Miscellaneous	912.50
Building, foundations	$10,000.
Concrete tanks	7,500.
Total	$17,500.

	Cost of kw-hour	
Cost of operation:	0.5 cent.	1.25 cent.
68x8000 = 544,000 kw-hours	$2,720.	$6,800.
350,000 kg. sodium chloride	1,312.50	1,312.50
Wages 5 men at $300	1,500.	1,500.
10% amortization and maintenance on $10,000 (electrodes, diaphragms, etc.)	1,000.	1,000.
3% amortization of $7,500	225.	225.
5% interest on $17,500	875.	875
Total	$7,632.50	$11,712.50
Under the assumption of 10% saving of active chlorine, the hypochlorite produced is equivalent to 366 tons of chloride of lime per year; hence the cost of the ton of equivalent chloride of lime is	$20.85	$32.

As in IB, the price at which chloride of lime can be bought may be assumed here as $26.25 per ton at the works, so that the production of bleaching liquor at the works by electrolysis results in a saving of $5.40 per ton of equivalent chloride of lime, if the kw-hour costs 0.5 cent, and in a loss of $5.75 per ton, if the kw-hour costs 1.25 cents. There will be neither a saving nor a loss if the kw-hour costs 0.85 cent. For power costs below this rate the electrolytic manufacture at the works will be less expensive than buying bleaching powder.

The use of hypochlorite solutions produced in this way also involves technical advantages. The expense for license for using the patented process is not included in the operating cost in this and in the following cases, since it is not possible to give for this a generally valid figure.

II.—1B: Separate production of chlorine and caustic with subsequent production of chloride of lime solution and use of the caustic soda, with continuous operation in paper and pulp mills.

Assumptions: Electrolytic cells operated with 500 amp at 120 volts (60 kw), 12 kw for other purposes (hence total power 72 kw). Twenty-four hours' operation per day, 337 kg of active chlorine in the bleaching solution (figuring a loss of 10 per cent in absorption, etc.). Eight thousand hours of operation per year, $26.25 per 1000 kg of chloride of lime at works; $3.75 per 1000 kg of sodium chloride at works; $5 per 1000 kg of burned lime, $4.50 per 1000 kg coal (evaporating seven times its weight of water), if bought in relatively small quantities.

The caustic soda is figured at only $3.50 per 100 kg NaOH in form of a solution of 35° Be. on account of the higher selling expenses with such comparatively small plants. There is no saving of active chlorine in bleaching. (Hence 337 kg of active chlorine in CaO_2Cl_2 solution are equivalent to 1000 kg of chloride of lime.) Partial recovery of the undecomposed sodium chloride during evaporation.

First cost:	
Electrolytic cells	$7,000.
Conductors and switchboard	525.
Absorption plant and pipe system	1,562.50
Evaporation plant and tanks	2,000.
Miscellaneous	912.50
	$12,000.
Buildings, foundations and concrete tanks	8,000.
	$20,000.

	Cost of kw-hour	
Cost of operation:	0.5 cent.	1.25 cent.
72x800 = 576,000 kw-hours	$2,880.	$7,200.
250,000 kg. sodium chloride	937.50	937.50
200,000 kg. lime	1,000.	1,000.
166,00 kg. coal	750.	750.
Wages, 6 men at $300	1,800.	1,800.
10% amortization and maintenance on $12,000	1,200.	1,200.
3% amortization on $8,000	240.	240.
5% interest on $20,000	1,000.	1,000.
	$9,807.50	$14,127.50
Less selling price of 140,700 kg. of caustic soda	4,925.	4,925.
Cost of 333 tons of equivalent chloride of lime	$4,882.50	$9,202.50
Cost of 1 ton of chloride of lime	14.68	27.65

The price at which chloride of lime can be bought may again be taken as $26.25 per ton, so that the electrolytic operation at the works in the present case results in a saving of $11.57 per ton of equivalent chloride of lime, if the kw-hour costs 0.5 cents, and in a loss $1.40, if the kw-hour costs 1.25 cents. There will be neither a saving nor a loss if the kw-hour costs 1.175 cents. For power costs below this rate the electrolytic manufacture at the works will be less expensive than buying bleaching powder.

Compared with the former examples, the power may cost considerably more if electrolytic manufacture at the works is to be profitable. This is due to the utilization or sale of the caustic soda.

II.—2. Large-scale separate production of chlorine and caustic soda for sale of the products.

Since in this case we have to do with large plants, relatively low prices may be assumed for the purchase of the raw materials. On the other hand a somewhat smaller selling price must be assumed for chloride of lime. The following figures relate to the Billiter cell for diaphragm-cell processes, while platinum anodes are assumed for the mercury-cathode processes, since figures from experience with the mercury-cathode process with carbon anodes are not yet available.

II.—2A: Diaphragm process with chloride of lime and solid caustic soda (containing some sodium chloride) as final products with continuous operation in large-scale plants of the chemical industry.

Assumptions: Power consumption: 1200 kw for electrolysis, 30 kw for chloride of lime apparatus, 30 kw for evaporating plant, 20 kw for the pumps, ventilators, etc., 70 kw for lighting and miscellaneous, hence total power consumption 1350 kw. Voltage 3.75, amp-hour efficiency 90 per cent, 24 hours of operation during the day, 8000 hours per year. Selling price of chloride of lime in large quantities $20 per ton. Selling price of solid caustic soda (95 per cent), $47.50 per ton, including packing. Purchase price of sodium chloride $3, lime $4.50, coal $4.50 per ton.

*See this journal, Vol. VIII., p. 704 (1910).

First cost.	
Electrolytic cells	$125,000
Copper conductors	13,500
Pipes	13,500
Chloride of lime apparatus	62,500
Evaporating plant	20,000
Melting pots	5,000
Screening and lime burning plant	3,000
Plant for purification of water, solution of salt and lye transport	5,750
Cranes and other transportation facilities	1,250
Packing material factory	4,000
Workshop, motors and gears	7,750
Sum A	$261,250
Lighting and heating plant	$4,500
Equipment of office and laboratory	4,000
Sum B	8,500
Buildings, C	87,500
Building erection, superintendence and miscellaneous, D	30,250
Working capital, E	37,500
Total	$425,000

(Without cost of land and railroad track connections.)

Cost of operation:		Cost of kw-hour 0.5 cent.	1.25 cent.
(a) Power:			
1350x800 = 10,800,000 kw-hours		$54,000	$135,000
(b) Raw materials:			
5505 tons of salt	$16,515		
6086 tons of lime	27,387		
6000 tons of coal	27,000		
	$70,902	71,000	71,000
(c) Renewal and maintenance:			
Electrodes	$14,000		
Diaphragms	2,000		
Electrolytic cells	1,250		
Chloride of lime plant	4,375		
Evaporating plant	2,000		
Melting pots	5,000		
Buildings	1,750		
Balance of equipment	4,375		
	$34,750	35,000	35,000
(d) Wages:			
58 men at $375	$21,750		
3 foremen at $750	2,250		
	$24,000	25,000	25,000
(e) Auxiliary materials:			
Oil, lubrication, belts		6,000	6,000
(f) Packing, excl., wages:			
Caustic soda	$7,000		
Chloride of lime	20,000		
	$27,000	27,000	27,000
(g) General:			
Wages	$6,250		
Office and laboratory	3,000		
Insurance	2,500		
	$11,750	11,750	11,750
(h) Capital amortization: Average, 7%, since all amortization has already been taken into account.		28,500	28,500
(i) Interest: 5% on $425,000		21,250	21,250
Total (not including patent license)		$279,500	$360,500
The yearly production of caustic soda is 3,560 tons (95%)		$169,100	$169,100
Balance for the yearly production of 8,690 tons of chloride of lime		$110,400	$191,400
Or per ton of chloride of lime		12.70	22.33

If, as assumed, the selling price of the ton of chloride of lime is $20, there is a profit of $7.30 per ton of chloride of lime for a power cost of 0.5 cent per kw-hour, and a loss of $2.33 per ton for a power cost of 1.25 cents per kw-hour, assuming an interest of 5 per cent only on the capital. For a power cost of 1.075 cents per kw-hour there will be neither profit nor loss, that is, just the 5 per cent of interest on the capital will be realized.

II.—2B: Mercury-cathode process, with chloride of lime and solid caustic soda (free from sodium chloride) as final products with continuous operation in large-scale plants of the chemical industry.

Assumptions: Power consumption 1600 kw for electrolysis, 150 kw for other purposes, together 1,750 kw. Voltage (at least) 5 volts. Ampere-hour efficiency, 90 per cent; continuous operation for 24 hours per day and 8000 hours per year. Selling price of chloride of lime in large quantities $20 per ton. Selling price of solid 95 per cent caustic is to be assumed higher than in II 2A, namely $50 per ton, including packing. Purchase price of sodium chloride $3, lime $4.50, coal $4.50 per ton.

(f) Packing (as in II. 2 A)	.....	27,000	27,000
(g) General (as in II. 2 A)	.....	11,750	11,750
(h) Capital amortization in the average 7%, with the exception of platinum and mercury which keep their value, hence on about $375,000	.....	26,250	26,250
(i) Interest of 5% on $500,000	.....	25,000	25,000
Total (not including patent license)	.....	$284,750	$389,750
Sales price of 3,560 tons of 95% caustic soda at $50 per ton	.....	178,000	178,000
Balance for yearly production of 8,690 tons of chloride of lime	.....	$106,750	$211,750
Or per ton of chloride of lime	.....	$12.28	$24.38

With a selling price of $20 per ton of chloride of lime and $50 per ton of caustic soda and an earning of only 5 per cent of interest on the capital investment, there is a profit of $7.72 per ton of chloride of lime for a power cost of 0.5 cent per kw-hour and a loss of $4.38 per ton for a power cost of 1.075 cents per kw-hour. For a power cost of 0.075 cent there will be neither profit nor loss, that is, just the 5 per cent interest on the capital investment will be realized.

II.—2. B[1]: If, however, with several large plants of this kind the caustic soda cannot be sold at $50 per ton, but only at $47.50 (as in II 2A), then the results are changed as follows:

	Cost of kw-hour. 0.5 cent.	1.25 cent.
Cost of operation, yearly	$284,750	$389,750
Selling price of 3,560 tons of 95% caustic soda at $47.50 per ton	169,100	169,100
Balance for yearly production of 8,690 tons of chloride of lime	$115,650	$220,650
Or per ton of chloride of lime	$13.33	$25.40

With a selling price of $20 per ton of chloride of lime and an earning of 5 per cent interest on the capital investment, there is a profit of $6.67 per ton of chloride of lime for a power cost of 0.5 cent per kw-hour, and a loss of $5.40 for a power cost of 1.075 cents per kw-hour. For a power cost of 0.925 cent per kw-hour there will be neither profit nor loss, that is, just the 5 per cent interest on the capital investment will be realized. It appears, therefore, that the mercury-cathode processes can complete with diaphragm processes only at very low power cost, say about 0.25 cent per kw-hour.

The results of the preceding seven cost calculations are summarized in form of the adjoining diagram. This diagram gives the cost of the production of the ton of chloride of lime

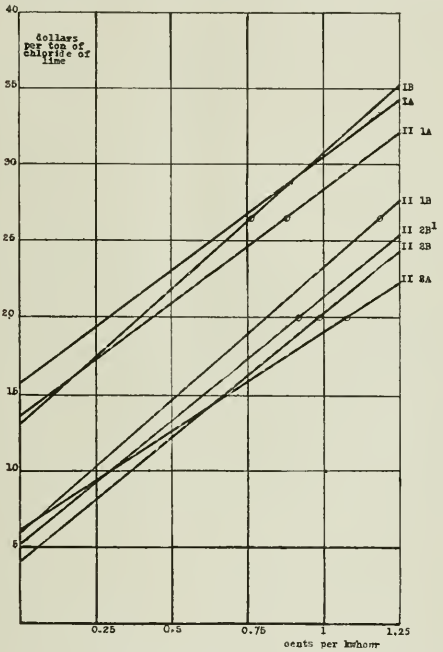
(or in cases IA, IB, and II 1A, of the equivalent ton of chloride of lime) as function of the power cost.

The ordinates give the cost of the ton of chloride of lime in dollars, the abscissas the cost of the kw-hour in cents.

The curves have been plotted by using the following figures which give the end results of the preceding calculations.

	0.5 cent.	1.25 cents per kw-hour.
I A	$23.05	$34.18 per ton of chloride of lime.
I B	21.83	35.23 " "
II 1 A	20.85	32.00 " "
II 1 B	14.68	27.65 " "
II 2 A	12.70	22.33 " "
II 2 B	12.28	24.38 " "
II 2 B	13.33	25.40 " "

The points in the different curves for which under the assumptions made in the different cases we break even financially with alkali chloride electrolysis, are indicated by little circles.



COST OF ALKALI CHLORIDE ELECTROLYSIS PROCESSES AS FUNCTION OF POWER COST.

The parts of the curves at the left of these circles, therefore, represent the conditions under which alkali chloride electrolysis is financially profitable.

If it is desired to use other values than those assumed for the cost of the raw materials or the selling price of caustic soda, the above calculations can be easily changed accordingly.

As the market conditions are at present [in Germany] for the raw materials and final products, we can sum up our results in the following conclusions:

1. According to the different processes, the maximum power cost for which alkali chloride electrolysis is profitable, varies between 0.75 and 1.125 cent per kw-hour.

2. In the smaller installations of the textile industry the direct electrolytic production of hypochlorite (electric bleaching) is in general financially profitable only if a certain saving of active chlorine is figured on. But even if the cost of producing the bleaching liquor by electrolysis is somewhat higher than with the use of bleaching powder, the other technical advantages of electrolytic hypochlorite (less wear and tear of the fibres, smaller acid consumption, etc.) still justify the use of the electrolytic hypochlorite process.

3. In paper and pulp mills as well as in larger installations of the textile (especially linen) industry, it will in general be more profitable not to produce directly a hypochlorite solution, but to produce separately chlorine and caustic soda and make use of or sell the caustic soda. With satisfactory power prices, the erection of such plants is justified *per se*, as against the purchase of chloride of lime.

4. In the large-scale chemical industry and under average conditions the diaphragm processes are superior to the mercury-cathode processes with respect to both first cost and cost of operation. In the case of erection of a new plant, the use of a mercury-cathode cell will be justified only if there is a sure market for the caustic soda, free from sodium chloride, at a higher selling price, and if very cheap power is available.

My thanks are due to Mr. Ebert and Dr. Carl for their help in collecting the data and in checking the numerical calculations.

Electrochemical Department, Siemens & Halske Company, Charlottenburg, Berlin, Germany.

Gold Milling in California.

By William H. Storms.

At the time of the discovery of gold in California the methods and means of milling gold ores were of the crudest possible description. In fact, aside from the operations of Mexicans, with arrastras, and South Americans, with their Chile mills, about all that was known of the science of recovering gold from its ores by wet processes was the extremely inefficient methods that had been in vogue in the region about Dahlonega, Georgia and at a few other places in the South, where mining had been attempted in a most primitive way.

Whatever extremely limited ideas the early California miners may have applied to the conduct of their business were patterned after either the practice of the Southerners or that of the Mexicans or Chilenos. Among the first mills built and operated in California in 1850-51 was one at, or near, what is now Nashville, in El Dorado County. This affair consisted of a battery of five stamps. The stems were square and were made of wood. These were lifted by nearly straight cams which operated in vertical slots cut in the stems, the involute cam having not yet been discovered by the mill men. The lower ends of the stems were fitted with iron-shod square shoes. The mortar consisted of a plate of iron laid in the bottom of a wooden box, iron-bound and secured with bolts. This was placed on a foundation of timbers laid at right angles, forming a solid crib. The power was supplied by a small steam engine.

No copper plates were used, the gold being caught in riffles and on heavy blankets, which latter were washed frequently. It is almost needless to say that this crude affair was a most unsatisfactory gold-saving contrivance, nor that for the greater part of the time it was hung up for repairs.

About the time that this mill began operations a party of prospectors discovered a rich vein outcropping a few miles up the canyon from the mine at Nashville. The owners of the mill above described had a duplicate of it at their place but had not set it up, and when the discoverers of the new mine heard of this they at once opened negotiations for the purchase of the outfit, which it appears the owners were glad enough to sell. The mill was moved up to the new discovery and there set up, but not without sundry improvements over that down the canyon.

The purchasers of this mill, who were the owners of what has since been known as the Union mine, took no pains to deny that they were proud of their new acquisition. This mill, although set up with all the skill, care and knowledge that their limited experience suggested, proved to be but little, if any, better than that down the gulch at Nashville.

Soon after starting up all sorts of unsatisfactory conditions

developed. A set of square iron shoes were made for it at Sacramento, but were found to be no better than the others. One of the men suggested an iron stem and shoe, which idea was favored by the other members of the company, but the departure was too radical from the established practice to take the risk of fitting up the entire battery in this new fashion, so they compromised by arranging for one stamp to be placed in the center between the wooden ones.

This iron stamp was made from a piece of shafting and was so evidently superior to the wooden affairs that it was promptly decided to replace all of the wooden stamps with those of iron, but no suitable bars of round iron could be obtained in either Sacramento or San Francisco at the time, and it was several months later before the necessary iron arrived around the Horn at San Francisco.

When the new battery of iron stamps, with round bosses, shoes and dies was finished and set to work, it proved to be such a marked improvement over any of the cumbersome wooden affairs that all mill builders promptly adopted the innovation. In this new mill the wear and tear of cams and tappets was excessive, as the stamp was prevented from turning by a device arranged for the purpose.

It was then suggested by one of the owners, a Mr. Sanford, I think, that it would be an improvement if the stamp were allowed to turn as it was raised by the cam. Some thought not, but the experiment was tried and of course worked to perfection. The cam "dope" was pine tar, which was smeared on with a stick and quickly spread evenly over the under face of the tappet.

Thus one detail after another in the primitive mill was improved as the necessity for improvement appeared. Each detail was worked out by experiment, there being no other school in which to learn than that of hard and expensive experience. An innovation in any mill that proved a success was promptly copied in every mill along the lode, until, in the course of a few years, the California stamp-mill, as we know it to-day, was evolved by these indefatigable pioneers in the business.

After a time copper plates were tried and proved a great success, but it was not until after 1860 that silver-plating of the copper plates was introduced, the first of these, I think, being on the Comstock Lode. Self-feeders were first attempted about 1858, and although they were a great improvement over hand feeding, it was many years before they reached anything like their present perfection.

The mechanism of the stamp-mill has undergone a great change since those early days—far more than the mill practice in California, at any rate, for, with few exceptions, the mill arrangement and daily routine is much the same to-day as it was 30 or more years ago. One would naturally suppose that after all these years of experimentation and varied practice we would have tried out now about every device and that we should have long since been able to plan the ideal gold mill, a mill that all would be willing to agree was superior to any other, yet such is not the case.

The ideal mill is rarely seen, for the ideas of mill builders—not so much the mill founders as those who buy mills and have them built after their own plans and specifications—are almost as widely different as they ever were.

Even to this day can be seen mills where the rock-breaker sets above the level of the floor, so that every pound of ore that goes through the machine must be lifted on a shovel by the attendant. Still more rarely, fortunately, may be seen the spectacle of a man feeding the battery with a shovel. It is but fair to say of this, however, that it nearly always is due to lack of means to purchase an automatic feeder, rather than to the old-fashioned notion that the work could be done better by hand.

It is generally acknowledged that the rock-breaker should be placed outside the mill building and on a separate foundation, but if the situation be such that the breaker must be placed at the mill it is considered good practice to at least provide it with an independent foundation and separate framework of timbers entirely detached from the mill structure. This I have seen done at no small expense, and the independent timber frame then solidly connected with the mill structure by means of timbers and bolts, thus undoing all the advantage that might have been derived from the separate breaker-foundation arrangement.

Ore bins have come in for their share of discussion, some contending that the bin with a flat floor is the best, as it admits the storage of a greater or less amount of ore and also tends to give steadiness to the mill structure. Others maintain that the bin with the sloping floor is best because it supplies the feeders with ore by gravity, still others take the middle course and favor a bin having a bottom which is flat at the front and sloping at the back.

It is my opinion that the proper place to store broken ore is either in the mine or in a bin outside the mill and that the ore bin in the mill should have a sloping bottom from the front backward at an angle of at least 45 deg. to the back of the bin, from which level it may very properly be vertical. In a bin of this shape all the ore delivered to it will run by gravity to the chute doors, excepting, possibly, a very small amount that may lodge in the angle at the bottom between the chutes.

Flat bins permit the storage of ore, it is true, but when this stored ore has to be drawn upon, whenever the natural slope-angle down which the ore will run by gravity has been reached, men must be put into the bin to pick and shovel the ore to the chute doors, and this can rarely be done under an average cost of 20 cents per ton, and it is generally more. Flat bins may have some advantage for the purpose of storage where the ore is high grade, but where the matter of 20 cents per ton is a serious thing for the manager of a low-grade mine to consider, as it is at most low-grade mines, the flat ore bin has no place in arrangements looking toward economy.

On the other hand, few managers of high-grade mines care to keep a lot of rich ore tied up any longer than necessary, so there seems to be no legitimate place for flat ore bins. I can see no advantage of the bin built with a narrow flat section longitudinally of the bin just back of the chute doors. It looks like a compromise between two extremes with nothing whatever to recommend it.

Mortars vary greatly in shape. Some are wide, some are narrow and there is considerable difference in the slope-angle of the interior of mortars near the bottom. All of these variations have a greater or less effect on the rate of discharge, and also to a great extent they determine the condition in which the pulp is discharged from the mortar. A narrow mortar will discharge more rapidly than a wide one, and so, also, will a flaring one. The wide, deep mortar, with high discharge, will slime successfully if this is what is desired, but if a more granular pulp is wanted then the narrow mortar of what is commonly known as the Homestake pattern is the thing.

All ores do not amalgamate with equal facility, and when the type of mortar to be placed in the new mill is to be decided upon this important matter should receive due consideration. If the ore amalgamates readily and most of the gold present is free, then a mortar that will discharge rapidly is necessary and amalgamation may be carried on both inside the mortar and on the outside plates. In some mills large capacity is the main object and no inside amalgamation is attempted. With some exceptionally free-milling ores this is entirely satisfactory, but with other ores is less so.

Ores which are to be amalgamated and the sulphides concentrated after amalgamation should be crushed only sufficiently fine to free the particles of gold and the sulphides from the gangue, further crushing results in the creation of an undesirable quantity of slimes, which will interfere with both amalgamation and subsequent concentration.

All of these peculiarities of ores should be thoroughly in-

vestigated before the type of mortar is decided upon, but in many cases the old-time mill man argues: "A mortar is a mortar, and so long as it is heavy enough to stand the blows of the falling stamps, what more can you ask?" I should say very much more, as I have endeavored to show above. I once had a millman say to me, after an argument over his method of working, "I have been here thirty-five years, and I guess I know what I am doing." This was an unanswerable argument, so I could only venture that he had been at it long enough, and that it was time for him to retire and give some other poor fellow a chance.

Among the numerous other subjects that have been up for controversy is that of battery foundations, and even now, after sixty years of wrangling, and no end of practical experience at home and abroad, not only the old-time millman, but even the engineers, are warmly discussing the various kinds of battery foundations, their shape and size. I think it may be safely said that, except perhaps with the ultra-conservative, concrete foundations are admitted to be superior to those of any form of wood construction.

But at the present moment it is the manner of placing the anchor bolts in these foundations that is being threshed out. I think anchor bolts should be of ample size, say, at least 1½ in. diameter, and supplied with heavy threads that will not strip, these to be so placed in the foundation as to be always easily accessible for tightening, and so arranged as to direction that a broken or worn bolt may be withdrawn at any time and replaced by a new one. To accomplish this its direction in the foundation must be such that it is not obstructed by any portion of the mortar nor by the woodwork of the battery frame. If this be done there appears to be little left to dispute about, as far as I am able to see.

The arrangement of battery posts and their braces is sometimes influenced by the topographical situation, which in some measure may determine the position of the engine, or other motive power. What is known as the "back-knee" construction is the most generally in use, and is the most satisfactory, under usual conditions, but occasionally it is more convenient to place the line shaft on a level with the cam-shaft floor and in front of the line of battery. Here the "front-knee" frame is employed. It should be avoided wherever possible, in favor of the back-knee frame, which is more stable and gives greater rigidity to the battery frame throughout. The front-knee frame is seldom seen in new mills, its undesirable features having been recognized by mill builders generally.

The manner of distributing power from the engine, waterwheel or motor varies, but is of less importance than some of the foregoing considerations. Line shafts are found below the mortars, both behind and in front of the batteries, and at various elevations within certain limitations. Occasionally it is seen on the cam floor, as previously stated, in front of the battery. The best arrangement I have seen was where the line shaft was back of the battery foundations and below the mortars, being supported on a line of independent concrete piers, at a height of about 20 in. above the floor.

Where concrete foundations are to be used I can see no objection to providing a buttress-like projection at the back of these foundations, and at a proper height, to carry the line shaft of the mill. This will render the shaft always easily accessible and will also permit the desirable downpull on the cam shaft pulley, and should prove an altogether satisfactory arrangement.

I know of but one mill in California where the line shaft has been placed higher than the cam shafts, and this is in the North Star mill, near Grass Valley. There the shaft has been placed at the top of the front side of the concrete ore bin. I fail to see that this presents any advantage over that of placing the shaft below the battery at the back, if, indeed, the North Star idea is as good as the latter.

There is little material difference in the arrangement of the amalgamated copper plates in front of the batteries these days. Formerly plates divided by a central strip, thus making two sluices each about 22 in. wide, were much in vogue, but these have given place to wider plates, which are far more satisfactory. Even now in many mills the plate area is too limited for the best economic results.

It may safely be said that as long as gold can be collected at the foot of a run of plates it is good business to supply additional plate surface. Where tailings are as low as 25 or 30 cents per ton, additional plate area may reduce the loss sufficiently to justify the expense of their installation, and the extra work of caring for them, but no amount of additional plates will be of service unless they be kept in proper condition.

Every square foot of plate in the mill should be kept as bright and clean as industrious rubbing will make them. Some millmen have a stated time for doing all millwork. This is a mistake. The time to dress plates is when they need it, no matter whether it be twelve hours after the last dressing or in half an hour after. This will make extra work for the millman, but that is what he is there for.

Any portion of a mill plate covered with sand, or that is discolored by mineral stain of any sort, is not catching a particle of gold, and the mill may as well be without that plate surface thus affected.

A 5-stamp battery, crushing 5 tons daily per stamp, will in a year crush 9000 tons of ore. If an additional saving of 5 cents per ton can be effected by the provision of more plate area, it should be done, as it would mean a net saving of $450 per year for each 5-stamp battery.

In nearly all California gold mines the gold occurs only partly free, the balance of it being associated with the sulphides of the base metals, iron and copper pyrite, and to a less extent with arsenopyrite, galena and blende, and still more rarely with tellurium. This usually necessitates the concentration of the auriferous sulphides.

Occasionally mines are found where the amount of sulphides present is either too small, or of too low a grade to justify their concentration. At the Yellow Aster Mine, in Kern County, for instance, the quantity of sulphides is both too small and of too low grade to warrant their being concentrated; the Sheep Ranch Mine, which at one time was also a large producer, is another example where the sulphides were too poor to concentrate, although the ore averaged $15 per ton in gold.

The ore of the Golden Gate Mine, near Sonora, in Tuolumne County, on the other hand, carried nearly all the value in the sulphides, amalgamation in the mill yielding only about 50 cents per ton on an ore worth from $5 to $20 per ton. The sulphides from this ore were concentrated on vanners and canvas tables and the gold extracted by the Plattner chlorination process.

It is in the process of concentration after amalgamation that the California millman is, generally speaking, behind the times. There are a few exceptions, but they are lamentably few, indeed. However, there appears to be a disposition to investigate other methods, with a view to improvement. This may be, and probably is, due to the entry of younger men into the profession. These younger men are not yet in the rut, and their schooling is very likely to keep them out of it. As a class they are ambitious, energetic, and seeking methods to bring about needed reforms in an antiquated practice, which all who are unbiased will admit are needed.

Ordinarily, from the mill plates the pulp flows by launder to mercury traps, and from these again by launder to the concentrating machines, which are of many makes, but mostly either vanners or tables of the Wilfley type. Some mills have both. In nearly every mill the practice is to split the stream of pulp from the trap below each 5 stamps, into two equal streams, each of these two streams going to a separate vanner or table. No classification of any kind is attempted, and the result is that there is invariable loss.

This loss may be low, it is true, perhaps not more than 30 to 60 cents per ton, but on ore as easily treated as the most of that on the Mother Lode of California this loss is too high, and it can, in probably every case, be lowered if the pulp be classified before going to the concentrating machines.

Two or even three classes of material should be made by the classifying cones, spitzkasten, or whatever device is employed, and each class sent to a separate belt machine, or table, that is carefully adjusted as to vibration, grade, speed of travel, and volume of pulp to water, so as to save the highest possible amount from each class of material under treatment.

This is a physical impossibility in the present practice, where no classification whatever is even attempted. The additional expense would be in the first cost and in maintenance, but the additional saving, in most cases, and I believe in every case, would amply justify the cost.

The average California mill has not been planned with this object in view, and as a result there is generally too little head room between the plate floor and the concentrator floor of the mill. The difference in height rarely reaches 15 ft. and very often it is less than 10 ft., and these heights do not permit the placing of satisfactory classifying devices of any sort in their proper place.

This, however, does not make proper classification in such a mill an impossibility, for there are numerous mechanical devices for cheaply elevating mill pulp, and where there is insufficient head room the difficulty can be overcome by employing one of these in connection with a system of suitable launders to distribute the classified material from the classifiers to the concentrating machines. In Colorado this very important part of gold milling is much better understood than in California, and in the former State may be seen many mills which would serve as an excellent copy for the mills of California.

There is one innovation in mill construction to which I wish to call attention, and this is found in the mill of the Original Amador Gold Mining Company, at Amador City. In this mill, which was built in 1900, there are twenty stamps in two units of ten stamps each. The separate units consist of five stamps arranged on either side of the cam-shaft pulley, this requiring four battery posts to each ten stamps, and a cam shaft a little longer than usual, but the even distribution of stress more than makes up for the strangeness of the new departure, and I think that as soon as the advantages of this style in construction are appreciated there will be many more mills built along similar lines. In this mill also are found classifying devices—one of the very few places in California where they can be found.

Berkeley, Cal.

The process of making sand-lime brick was invented in Germany, where it probably has had its greatest development up to the present.

Observations made there seem to prove that sand-lime brick is a building material which will resist shining soot. Three years ago an inn was built in Greifenhagen, in which sand-lime brick was used for exerything except the lining of the chimney flues, which were built of common brick because at that time the question whether sand-lime brick was equally resistant to fire had not been settled. In spite of the fact that lignite briquets were burned, shining soot was found in the flues in a short time, and the flue bricks were permeated as high as the rafters of the ground floor. When the flues were pulled down, however, it was found that the sand-lime brick were unharmed and white in color.

This experience seems to indicate that sand-lime brick will be found in general practice the best building material to withstand shining soot.

The Determination of Gold and Silver in Copper.

BY EDWARD F. KERN AND ALBERT A. HEIMROD.

The determination of gold and silver in copper bullion is accomplished by either the direct-fire assay method or else by a combination wet and and fire method. There seems to be no conventional standard method, as at some plants the former is used whereas at other plants the latter one is used, or else a more or less modification of either.

The authors, having undertaken an investigation which required a standard method for the determination of gold and silver in copper-gold and copper-silver alloys, encountered the difficulty of finding a method which would give duplicate check results. The reason for the lack of agreement in the assays, which were made by these methods, could not be charged against anything definite, so the working out of an accurate method was undertaken.

As the chances for losses of gold and silver by volatilization are greater by the direct fire method, and because the proper temperature conditions of scorification are difficult to control, the combined wet and fire method was favored for the determination of the gold, and an entire wet method for that of the silver.

Assay of Copper-Gold Solutions.

One of the main sources of error in the determination of gold in copper bullion (or an alloy), by the combined wet and fire method is the loss of some of the finer particles of gold when the bulky copper solutions are filtered. A means of preventing this loss is to add to the solution some salt that will produce a heavy precipitate and which while precipitating will collect all of the suspended particles of gold. The salts generally used for this purpose are either lead acetate which added to the solution containing sulphates gives a precipitate of lead sulphate, or else silver nitrate which added to the solution containing a chloride gives silver chloride. Whether the one collecting agent possesses any advantages over the other was not known, so the first series of assays was conducted with the idea of finding out which salt is the more suitable one to use.

With this point in view, a solution of gold and copper was made up, each cubic centimeter of which contained 0.17654 gram of copper and 0.000205 gram of gold. Samples of 50 c.c. each of this standard solution were taken and assayed. The general method of procedure, after the sample had been measured out, was to add 10 c.c. of concentrated sulphuric acid and evaporate to dryness. The mass was then taken up with distilled water and diluted to 250 c.c. Ten grams of ferrous sulphate crystals ($FeSO_4.7H_2O$) dissolved in distilled water was added, which precipitated the gold in solution as finely divided metallic particles. In order to collect these particles, the first reagent used was from 10 c.c. to 20 c.c. of a saturated solution of lead acetate which gave a heavy precipitate of lead sulphate. The solution was filtered and the precipitate washed, dried, and scorified with 20 to 40 grams of test lead. The button was then cupelled and the gold bead weighed. Results of these assays are given in Table I.

It was found, however, that more satisfactory results were obtained when a silver nitrate solution was used instead of lead acetate, and the silver precipitated as a chloride. The beads obtained by scorification and cupellation, when silver nitrate was used, were parted, and the gold annealed before weighing.

The table (No. 1) shows the amount of collecting reagent used and the results obtained. Although the results on the whole are fair, the errors are not constant; the greater variations occurred when lead acetate was used, and the lesser variations when silver chloride was the collecting reagent. The results, however, gave assurance that for the assay of copper-gold alloys, the latter collecting agent would give the most ac-

curate results. With this as a starting point, the working out of a standard method for the determination of gold in copper was undertaken.

Preparation of Standard Copper-Gold Alloys.

The standard alloys were prepared by melting from 1500 to 2000 grams of electrolytic copper in a graphite crucible, the copper being completely covered with charcoal. A calculated amount of gold was added to five to ten times its weight of molten copper in a small graphite crucible. After maintaining the alloy in a molten condition for a few minutes, it was poured into the larger crucible containing the major portion of the copper. The larger bulk of copper was first thoroughly poled to tough pitch and then the rich alloy added. The alloy was well stirred with a stick of graphite, and then poured from an elevation of from 6 to 8 feet into a tub of cold water, having a depth of 12 inches. It was found that by granulating the alloy, segregation of the gold (and of silver) was overcome. These granules, varying from less than 1 mm. to 1 cm in diameter, were the standard alloys used in the experiments.

Assay of Copper-Gold Alloys.

An alloy (No. 1), containing approximately 100 oz. of gold to the ton of copper was used, for the first series of assays. As close to an assay ton (29.166 grams) as possible was weighed out, and dissolved in 90 c.c. of concentrated nitric acid. The residue of gold particles were then dissolved by adding 2 c.c. of a mixture of 4 parts nitric acid and 1 part hydrochloric acid (aqua-regia). When all the metal was in solution, 37.0 c.c. of concentrated sulphuric acid were added and the solution carefully evaporated to dryness. The mass of crystals was dissolved in distilled water, and the solution diluted to 300 c.c., then 10 grams of ferrous sulphate crystals ($FeSO_4.7H_2O$) dissolved in water was added in order to precipitate the gold.

In the third assay, of Table II, the fine particles of metallic gold were collected in filterable form by adding 10 c.c. of a saturated solution of lead acetate and 0.5 grams of silver nitrate dissolved in water. This gave a mixed precipitate of lead sulphate and silver chloride. In the other experiments the gold particles were collected by adding 0.5 grams of silver nitrate dissolved in water and precipitating the silver with a solution of hydrochloric acid. In all cases the solutions were filtered, the precipitate washed, dried, and together with the filter paper were scorified with 45 grams of test lead. The resulting buttons were cupelled and the beads parted with nitric acid. Results are tabulated in Table II.

The errors in this series of assays (No. 1 to 7) were attributed to the fact that the ferrous sulphate did not throw down all the gold, as it was partially oxidized by the presence of aqua-regia. The reason for adding aqua regia was in order to get the alloy entirely in solution, thus finally obtaining a complete separation of the gold from the copper. By following this procedure it was thought that if no copper was present with the gold during cupellation, the errors of assaying would be reduced.

7	1	29.1685	10	5	0.5	45	0.09725	97.24

In the next series of assays (No. 8 to No. 13), the gold was not dissolved in aqua-regia, and only silver nitrate used as the collecting agent for the gold particles, it being precipitated as chloride with hydrochloric acid. The errors in this series of assays were accounted for by the presence of aqua-regia formed by free hydrochloric acid and traces of nitric acid in the solution. Table III shows the tabulated results. Alloy No. 1 contained approximately 100. oz. of gold per ton, and alloy No. 2 approximately 10. oz. of gold per ton.

The next set of experiments gave us the method which was adopted for the determination of gold in copper-gold alloys.

Standard Method for Determining Gold in Copper-Gold Alloys.

The method finally adopted and used for assaying copper-gold alloys is as follows: About 1 assay ton (29.166 grams) of the alloy was carefully weighed, placed in a 900 c.c. beaker, and 20 c.c. of distilled water added. The beaker was covered with a watch glass and 90 to 100 c.c. of concentrated nitric acid (sp. gr. 1.42) was added in small quantities of 20 to 25 c.c. from time to time. After all the alloy was dissolved, 40 c.c. of concentrated sulphuric acid (sp. gr. 1.84) was added in order to transform all the copper nitrate into copper sulphate. (0.87 c.c. conc. H_2SO_4 theoretically required for 1 gram of copper). Light blue needle-like crystals were formed by the addition of the sulphuric acid, but were easily broken up by stirring and by subsequent evaporation of the supernatent liquid to sulphur trioxide fumes.

The solution was evaporated to dryness and fumes of sulphur trioxide by placing the beaker on a sand bath, so regulating the heat as to prevent bumping. This left a mass of copper sulphate crystals absolutely dry with part of the water of crystallization driven off. The beakers and contents were allowed to cool, and 500 c.c. of distilled water was added, which readily dissolved the salts on heating. Then 10.0 grams of ferrous sulphate crystals ($FeSO_4.7H_2O$), dissolved in water, was added for the purpose of destroying any free nitric acid present and to precipitate any gold in solution. Twenty-five c.c. of a saturated solution of sodium chloride, and enough silver nitrate to make a bead weighing about eight times the weight of gold present were next added. If a greater amount of silver nitrate is used, the bead obtained by scorifying and

cupelling will be too large to part, that is, the gold will be left as a powder instead of a single porous mass.

1.5 gram $AgNO_3$ is equivalent to 1.0 gram Ag.

The silver nitrate was added when the copper sulphate solution was hot, and the solution rapidly stirred in order to make the silver chloride coagulate and settle, thus collecting all the finely divided gold in the precipitate on the bottom of the beaker. The solution was filtered and the precipitate washed until all copper salts were removed from the filter paper. The beaker was then thoroughly wiped with a piece of filter paper which was added to the main precipitate.

The silver chloride precipitate containing the gold, together with the filter paper, and about 20 grams of test lead were placed on a litharge glazed scorifier. The filter paper was slowly burnt off, and about 20 grams more of test lead added, making a total of 40 grams. A pinch of borax glass was placed on top of the lead and the scorification made in the usual manner. The resulting lead button was cupelled on a medium hard bone-ash cupel, and the gold-silver bead parted with dilute nitric acid (1 part conc. HNO_3 and four parts water). The residue was washed with distilled water, annealed and weighed.

Glazed scorifiers were used in order to prevent loss of gold by particles of the ignited filter paper becoming attached to the sides of the scorifier which prevented their collecting in the lead button. The melting of the glaze washed the particles of ash into the lead bath, which collected any gold which it contained. The glazing was done by putting from 10 to 15 grams of litharge on the scorifier, placing same in a muffle furnace and heating to fusion of the litharge; the excess of litharge was then poured off and the scorifier allowed to cool for subsequent use.

Results of assays made by the above method are given in Table IV. Alloy No. 2 contained approximately 10 ounces gold per ton, alloy No. 3 approximately 36 ounces per ton, and alloy No. 4 approximately 96 ounces per ton.

Determination of Silver in Copper-Silver Alloys.

The standard copper-silver alloys were prepared in the same manner as the standard copper-gold alloys, as outlined previously.

Samples of the alloy weighing approximately five, ten and twenty grams were used for the assays. The amount of alloy taken in each case depending upon the quantity of silver the alloy contained. The samples were dissolved in concentrated nitric acid (3 c.c. per gram of alloy) in a covered beaker, the excess of acid was evaporated off, and the evaporation continued until copper nitrate commenced to crystallize out of the hot solution. At this point all of the oxides of nitrogen, which are harmful to the precipitation of the silver by means of alkali sulphocyanate, were removed. The solution and salts were taken up with 400 c.c. of cold distilled water, and 25 c.c. of a saturated solution of ammonium sulphyocyanate (25 grams per 1 liter) was added to the cold solution as quickly as possible and with constant stirring. The silver in the form of silver sulphocyanate coagulated and settled rapidly to the bottom of the beaker. The solution was filtered, and the precipitate washed free from copper salts by means of distilled water. The filter and precipitate were placed in the original beaker in which the precipitation was made and digested with 80 c.c. of concentrated nitric acid. The beaker was covered with a watch-glass and placed on a hot plate and allowed to remain until all of the paper was decomposed and the precipitate was entirely dissolved. The solution was evaporated to small volume before all of the oxides of nitrogen were driven off, which is essential for the success of the analysis (did not take to dryness). After cooling, the salts were taken up with 300 to 350 c.c. of distilled water, and 20 c.c. of a saturated solution of barium nitrate was added, which precipitated the sulphuric acid present:

$$Ba(NO_3)_2 + H_2SO_4 = BaSO_4 + 2HNO_3.$$

The presence of sulphuric acid is the result of oxidation of silver sulphocyanate by nitric acid.

About 3 cu. cm. of a saturated solution of ferric alum was added, as an indicator, and the solution titrated at ordinary temperature with a standard solution of ammonium sulphocyanate (3.2 grams NH_4CNS per liter). The standardization was obtained on samples of pure electrolytic silver, dissolved in nitric acid, boiled, and the solution diluted to about 100 c.c.

1.0 c.c. NH_4CNS solution was equivalent to 0.004465 gram silver.

$$AgNO_3 + NH_4CNS = AgCNS + NH_4NO_3.$$

The end point is readily distinguished by the appearance of a faint orange color, which the solution assumes as soon as all the silver is precipitated, due to the formation of ferric sulphocyanate.

The accuracy of this method, as described, was first tested on standard copper-silver solutions as follows, and later on on copper-silver alloys. About 60 grams of the standard alloy was dissolved in 180 c.c. of concentrated nitric acid in a covered beaker, and the oxides of nitrogen expelled by evaporation. The solution was diluted to 1000 c.c. with distilled water and three samples of 300 c.c. each were accurately measured out and assayed as already explained. These solutions were titrated with two standardized ammonium sulphocyanate solutions, namely: A solution 1.0 c.c. of which was equivalent to 0.004465 gram of silver was run in to within about 1 c.c. of the end point, then the titration was finished with a second standard solution, 1.0 c.c. of which was equivalent to 0.000584 gram of silver.

It was thought that by using the two standard solutions the determinations could be made more accurately. This procedure was, however, found to be unnecessary, so in the later titrations only the stronger standard solution was used (1.0 c.c. equivalent to 0.004465 gram silver). The results of this series of determinations are recorded in Table V.

Table V. Assay of Standard Copper—Silver Solutions.

Assay Number	Grams of Standard Alloy in 1 Liter Solution	c.c. of Solution Titrated	NH_4CNS solution		Gram of Silver in 300 c.c. Solution
			1.0 c.c. = 0.004465 Gram Ag	1.0 c.c. = 0.000584 Gram Ag.	
1	60.0083	300	18.9	12.0	0.09140
2	60.0083	300	18.9	12.3	0.09157
3	60.0083	300	18.9	12.1	0.09146
4	60.0091	300	19.0	10.8	0.09120
5	60.0091	300	19.0	10.7	0.09108
6	60.0091	300	19.0	10.8	0.09120

The results of determinations made on the copper-silver alloys are given in Table VI. The method of analysis was carried out as described.

In order to obtain accurate results by this method of assaying copper-silver alloys, the following precautions should be observed:

If all the oxides of nitrogen are not expelled, and if the solution is too hot during the precipitation of the silver, then the solution will not retain a green color after the excess of

Table VI. Assay of Copper—Silver Alloys.

Assay Number	Alloy Number	Grams of Sample Taken	NH_4CNS Solution. 1.0 c.c. = 0.004465 Gram Ag.	Gram of Silver in Sample	Oz. of Silver per Ton
7	6	20.0279	17.50	0.078140	113.76

10	7	10.0036	40.45	0.180609	526.57
11	8	5.0306	50.60	0.225930	1309.90
12	8	5.0213	50.60	0.2.5930	1311.50

ammonium sulphocyanate has been added, when the silver is precipitated from the copper solution. In the first case the solution will change to the original color, namely, blue, at the same time brown fumes of nitrogen tetroxide (N_2O_4) will be given off, causing some of the silver to go back into solution. In the second case on adding the sulphocyanate to the hot solution, copper is reduced and a precipitate of cuprous sulphocyanate forms which interferes with the accurate titration of the final silver solution.

If the final solution, obtained by dissolving the silver sulphocyanate and the filter paper in conc. nitric acid, is evaporated too far (during the operation of expelling the nitrogen oxide fumes) a brown coating of burnt organic matter from the filter paper forms on the bottom of the beaker, and when the solution is diluted it assumes a brownish color which interferes with detecting the end point of the titration.

The dissolving of the alloy, the evaporation of the resulting solution, the dissolving of the precipitate, and the final evaporation of this solution should be carried out carefully in a covered breaker, in order to prevent error as result of spattering.

Metallurgical Laboratory, School of Mines, Columbia University, New York, N. Y.

Exploitation of Scandinavian Water Powers.—The London *Electrical Review* of April 1 reports from Berlin that negotiations are being conducted by an Anglo-German-Scandinavian financial group with regard to the consolidation into a company of a number of Norwegian and Swedish water-powers, under the title of the Hydraulic Power and Smelting Corporation, and with a share capital of $5,000,000 and debentures of $5,000,000. The scheme relates to water falls already in use and yet to be used, as well as to some of the establishments supplied by them. The assets to be brought into the undertaking include the zinc smelting works and zinc refinery at the Trollhattan Falls and in Sarpsborg, and the water-power of 126,000 hp at the mouth of the Tysse mountain stream in the Hardanger Fiord. The latter installation is already equipped or in process of being equipped, for 57,000 hp and the turbo-generators have been used for years past for supplying the carbide and cyanamide works in the neighboring Odda, in which the German Siemens group is interested. As concerned with the scheme in Germany are mentioned the Allgem. Elek. Ges. the Siemens-Schuckert Works, and the Berlin Electrical Enterprises Co., together with the banks associated with them under the lead of the firm of S. Bleichröder.

Nevada Consolidated Copper Company.—In the quarterly report of this company covering the second quarter of 1911 it is shown that an unusually low grade of ore was handled owing to the advisability of milling a large tonnage of ore removed for the purpose of arranging permanent tracks into Eureka pit. The grade of ore milled during the quarter averaged 1.59 per cent copper. During June all operating reverberatories were fired with oil, except one which was fired with coal and oil. The results have fully justified the use of oil instead of coal at the Steptoe plant. The first basic lined converter was scheduled to go into commission about Aug. 1.

Notes on the Chemistry and Metallurgy of Vanadium—III.

By Warren F. Bleecker.

The Metallurgy of Vanadium Ores.

In the United States the metallurgist may be called upon to treat the following vanadium bearing ores:

Carnotite.
Impregnated Sandstone.
Patronite.
Roscoelite.
Vanadinite.

In addition to the above there have been described a number of vanadium minerals which have not as yet been found in commercial quantities. These are:

Brackebuschite, a lead-zinc vanadate; Dechnite, a lead vanadate Pb (ZnCu) V_2O_6; Descloizite, a lead-zinc vanadate with formula 4 (PbZn) O . V_2O_5 . H_2O; Endlichite, a lead vanadate with V : As : : 1 : 1; Eusynchite $(PbZn)_3V_2O_8$, massive descloizite; Tritochlorite, a lead-copper vanadate; Mottramite, a copper-lead vanadate with formula $(CuPb)_5V_2O_{10}$. $2H_2O$; Psittacinite, a pulverulent copper-lead vanadate; Pucherite, a vanadate of bismuth with formula given as $BiVO_4$; Ramirite, a lead-copper vanadate, and Volborthite, a copper-calcium vanadate with formula given as $(CuCa)_3V_2O_8$.

The pure carnotite mineral is said to contain 18 per cent V_2O_5 and 56 per cent U_3O_8. It occurs as impregnated sandstone, the ore being usually yellow or yellowish green. If the vanadium content of the ore is low the color is canary yellow, while if the vanadium content predominates (which often occurs) the color may be a dark green, almost black.

Carnotite ores are by far the most soluble of vanadium bearing ores under metallurgical treatment. Decomposition may be effected by roasting with sodium chloride or fixed alkalis, after which a large percentage of each metal is soluble in water. The ore is quite soluble in boiling alkali or alkaline carbonates, there being a patented process based upon this property. Decomposition of the ore also may be effected with mineral acids, sulphuric being preferably used. A very comprehensive report of a proposed process for the treatment of carnotite with sulphur monochloride has been published. The difficulties of treatment are therefore not in decomposition, but in the final separation of the uranium and vanadium values and the economical production of compounds or alloys suitable to the consumer. Although it is not the purpose of this paper to discuss the metallurgy of uranium, it may be said that the behavior of the two elements with reagents is in many respects so different that very little study should at least result in an efficient method of separation; and with the uranium once freed from vanadium there will be little difficulty in getting it into a desirable form.

Sandstone impregnated with vanadium has become an important source of vanadium. The ore is somewhat complex and a dried specimen disintegrates with ease into three general components. The first is a green fine substance which has been carefully studied by Hillebrand; second, a coarse white quartz product, apparently containing some vanadium, and third, a further cementing material consisting of vanadium compounds containing lime, silica, alumina and fixed alkalis, together with probable traces of other elements.

In metallurgical processes the usual procedure is to grind to 20 or 30 mesh and roast with sodium chloride. The best results are apparently obtained by roasting at a temperature of 1100-1200° Fahr. Depending upon the oxidizing conditions in the roast, the product, when cold, may be colored yellow, red, green or even black. If the temperature is allowed to run too high the mass will fuse together, with the result that vanadium compounds insoluble in water are formed. The roasted ore is leached with water by a counter-current system of enriching weak liquor by passing it over fresh ore, and finally

washing the ore with fresh water. The solution cannot be enriched in this particular manner beyond a certain limit, about 8g per liter, because of reprecipitation brought about by the soluble basic matter in the ore. I have obtained the best results by keeping the solutions alkaline. One of the methods I use consists in adding a small quantity of crude lye to the sodium chloride before mixing with the raw ore. This has the disadvantage, however, of decomposing a considerable amount of silica, which must be accounted for later on.

Sodium carbonate may be used for decomposition instead of sodium chloride, but does not give good results unless the ore is of especially high vanadium content.

Merely washing the roasted ore with water will not result in complete extraction in any event. The reasons for this are apparent if it is remembered that the ore also contains a small amount of iron, quantities of lime, alumina and silica. Iron vanadate, calcium vanadate and aluminium vanadate are all insoluble in water, while sodium vanadate will unite with soluble silica to form a compound insoluble in neutral solutions. I arrived at the latter conclusion by mixing solutions of sodium silicate and sodium vanadate and neutralizing with hydrochloric acid. A white precipitate results which, while somewhat gelatinous, may be washed quite readily. Repeated washing did not remove the vanadium.

A good commercial extraction of the vanadium values is obtained if the water leaching is followed by washing with either dilute hydrochloric or sulphuric acid. This has the disadvantage of extracting large quantities of lime and alumina.

It may be said that the fine green substance mentioned above as one of the three components of the ore is much more difficult to decompose than the other two, although the fine is originally the richest in vanadium.

I have read several statements relative to the roaster gases containing chlorine and vanadium. A number of careful examinations of the gases from a muffle furnace under different conditions of oxidation failed to show the presence of either free chlorine or vanadium in any form. Free hydrochloric acid, ferric chloride and sodium chloride were the principal compounds evolved during the roasting when sodium chloride alone was used.

In the treatment of vanadiferous sandstone the chief difficulties are overcome if a good extraction has been obtained, and this may only be done by long and careful experimenting with the particular grade of ore to be treated, because the varying amounts of impurities in the different grades of ore will modify the extraction to a greater extent than might at first be imagined.

Patronite is a carbonaceous sulphide of vanadium occurring with iron, nickel, silica and small amounts of other impurities. There is said to be a large body of this ore in Peru, and it is now being economically treated in the United States by the American Vanadium Company. I have recently received a small sample of non-carbonaceous vanadium sulphide from San Miguel County, Colorado. Analysis showed the presence of other vanadium mineral in addition to the sulphide, since the vanadium content was 15.08 per cent V_2O_5, while the sulphur content was 4.30 per cent.

The sulphide ore, after roasting to the oxide, may be decomposed with mineral acid, preferably sulphuric. Only a fair extraction is probably obtained, but since the ore is of such high grade the present methods may be the most economical in the long run. Extraction also may be made by roasting the oxidized ore with crude lye and leaching with water. The problem in this case will be to keep the solutions strongly alkaline without using an excessive amount of alkali, although this may be done by any one of a number of regenerative methods.

Where the metallurgist is having difficulty with extraction, I think it is a good rule to use alkalis, since the behavior of the alkaline vanadates is much more uniform than that of the vanadyl compounds, and in most cases the alkaline vanadates are much more soluble in water, while in dilute solutions vanadyl compounds may be more readily precipitated by impurities than the alkaline vanadates.

Roscoelite is an impossible sort of a mineral to work with commercially. The only agent which I have found to give good results in effecting decomposition is sodium peroxide. Commercially this is out of the question. The best extraction with allowable reagents I obtained by using a mixture consisting of 50 per cent each of sodium chloride and crude lye. Three hundred pounds of this mixture per ton of ore resulted in an extraction of 60 per cent of the vanadium. The raw ore assayed about 3.50 per cent V_2O_5. The mineral is but slowly attacked by concentrated mineral acids, aqua regia not effecting a complete decomposition upon several hours' boiling. Among the reagents tried with roasting were sodium chloride, sodium hydroxide, nitre cake and sodium carbonate. If there were not much greater quantities of more easily treated ores, or if the available quantities of roscoelite were greater a method of treatment would surely be developed, but at the present time it hardly seems worth while. An additional difficulty in the treatment of roscoelite is presented in the saving of the noble metal content, which in Boulder County ore is often of greater value than that of the vanadium.

Vanadinite is a more or less important mineral, the formula being given as $3Pb_3 \cdot V_2O_5 \cdot PbCl_2$. This is the only vanadium ore (at least of present commercial importance) which can be treated by concentration. A company proposing to operate at Cutter, N. M., claims to have considerable quantities of vanadinite, the concentrates containing 15 per cent $BaSO_4$. I am indebted to Mr. Herman A. Prosser for this information.

Lead vanadate may be decomposed by concentrated sulphuric acid with the formation of divanadyl sulphate under the commercial conditions of treatment. It is apparent that the extraction will not be complete and that there will be large quantities of impurities in the tank liquors. The difficulties of treating ore with sulphuric acid in large quantities render such processes unattractive, although it is claimed by those who are more familiar with the sulphuric acid methods of treatment than I that no difficulties are met with and such processes are satisfactory. In order finally to get rid of the greater part of the impurities, the concentrated vanadyl sulphate solutions are evaporated and finally calcined with sodium carbonate with the formation of sodium vanadate. A good extraction may be obtained by treating vanadinite with strong, hot solutions of lye. The ore must be ground to extreme fineness and the leaching continued for some time. Lead and other impurities are more or less soluble in the mill solution, but the matter of purification is very simple as compared with the purification of acid liquors.

Sodium chloride does not seem to give good results as a decomposing agent for vanadinite, although a fair extraction may be obtained by chloridizing in a muffle furnace.

Numerous patents have been taken out both in this country and abroad for the extraction of vanadium from the various ores and slags in which vanadium occurs. I have never read of a process that seemed more than moderately efficient under the conditions described by the author. Since vanadium has many laboratory peculiarities that are not apparent on a mill scale, most of the processes devised are almost totally inoperative. For example, one inventor has tried to patent a method for recovering vanadium from acid solutions by boiling. The phenomenon of vanadic acid precipitating from a boiling acid solution is of course familiar to all chemists, but those who have taken the trouble to compare the amount of vanadium in solution to that precipitated have not wasted money on trying to patent a process based on the reaction. Again, there have been patented processes for the extraction of vanadium by boiling the ore with sulphuric acid. As a metallurgical operation this has never appealed to me on account of the mechanical difficulties; easy enough in a test tube, perhaps, with five times as much acid as ore, but less easy in tanks of

standard materials and with the human equation of the workmen forever to be taken into account.

Smelting methods have been patented, but since vanadium is essentially a slag-forming element there does not seem to be much hope in that direction, especially in the treatment of ores carrying as low as 1 per cent V_2O_5. Although there have been patented processes for the extraction of vanadium by fusion with various agents, such as nitre, potassium bisulphate and the like, the tremendous excess of reagent required, together with the additional heat to effect fusion, and finally the difficulties of dissolving the fused material, should make one very cautious in recommending such a method.

Chemical Methods Necessary.

After the entire field of theory, backed up by thorough experimental evidence, has been canvassed, the metallurgist must be convinced that the sole method of attacking the problem of vanadium extraction is chemical. Expensive reagents cannot be used, nor can cheap ones be used in large excess unless a well tried method of recovery of used materials is without question available. While acid processes of extraction may at present be used profitably in treating low-grade vanadium ores, competition may, in the near future, cause valuable property based on these methods to become idle and worthless.

As before stated the greatest difficulty of vanadium production will have been overcome when the vanadium is in solution and free from gangue. The removal of impurities from this point on may in some cases be more expensive per ton of material handled, but the vanadium will be in a condition in which it is readily handled, either by precipitation or otherwise. Specifically I shall discuss only vanadium solutions obtained from the leaching of vanadiferous sandstone, because those interested in solutions obtained by acid leaching will find data bearing directly upon the treatment of such solutions as well.

Nature and Composition of Mill Solutions.

The compounds present in mill solutions will be sodium vanadate and salts of lime, alumina, silica, titanium and sodium, particularly sodium chloride. In addition, some of the vanadium will be combined with each and every other element present, probably including vanadium itself. In neutral solutions there will be a little, and of course in acid solutions there will be a great deal.

In beginning to leach the first solution from the ore will be very low in vanadium, 1.1 g per liter, and will be rich in calcium chloride, calcium carbonate and sodium chloride. This solution is usually colorless and its content depends upon many conditions, such as character of roasting process, fineness of ore, rapidity of leaching, etc. Following the clear liquor will percolate a yellowish solution containing a maximum amount of vanadium, together with sodium chloride and all of the other impurities. Treating one ton of ore with a ton of water, approximately 10 per cent of the solution will be of the first variety, 20 per cent of the second and the remainder which will percolate through will have a decreasing vanadium content following the parabolic law of leaching. The richest liquor should have a vanadium content of about 8 g per liter under favorable conditions. If the liquors are allowed to mix as they come from the ore precipitation of calcium vanadate will occur in the receiving tank. This vanadate of lime usually carries about 18 per cent V_2O_5 and may be filtered and washed.

The greater part of the basic impurities contained in the solution may be removed by the careful addition of a slight excess of sodium carbonate and heating the solution to 90° C. Enough carbonate must be added to make the solution distinctly alkaline. The impurities will settle to the bottom of the tank and the purified solution may be removed by decantation. The residue is of a dirty gray color and contains usually about 10 per cent vanadic acid. While practically all of the lime and alumina may be removed in this manner, the silica usually remains in solution. I have found no certain method of removing the silica and except where products of exceptional purity are required there is no necessity for removing it. As a matter of fact there is no need of removing any of the impurities unless a very pure product is to be finally extracted from the solution.

In case the solutions are acid with sulphuric acid, the principal impurity will usually be alumina, the other impurities being obviously lime and iron, together with any fixed alkali which may have been present in the ore either originally or added for purposes of extraction. The vanadium is present as vanadyl sulphate, at least 15 different forms of which have been studied, representing the various states of oxidation of both the vanadium and the sulphur. In mill practice the sulphuric acid solutions of vanadium are either green or blue, which colors show a lower state of oxidation of the vanadium than the pentoxide. If to such an impure solution peroxide of hydrogen is added a yellow precipitate is thrown down, which, if filtered off and dried, turns red. Analysis shows it to be a vanadate of iron. This same precipitation may also separate after the solution has stood for several days in an open tank. There is of course some significance to be attached to this reaction, but it is too remote to be readily observed. It is only mentioned here to illustrate the tendency of vanadium compounds to do the unusual thing, as compared with the better known elements.

The removal of the impurities from an acid solution without the addition of alkali in excess is difficult, if not impossible. Sulphate of calcium, insoluble under most conditions, is here held in solution in considerable quantities and may be removed only by an expensive electrolytic method.

If the acid of the solution in hydrochloric, the vanadium is present as vanadyl chloride, in which two atoms of chlorine are united with one vanadyl group. The same impurities are present, lime, of course, being in considerable quantity.

It should not be forgotten that most vanadium ores contain traces of titanium which is extracted with alkali and remains with the vanadium through the various stages of purification, and in some instances the removal of this element may necessitate a modification of the process.

It is of course obvious that it is as necessary to get the vanadium out of solution completely and efficiently as it was to obtain a complete extraction. Not only is it desirable to precipitate all of the vanadium from the solution, but it is necessary that it should be in a chemical combination and physical state suitable either for further refinement or for use by the ultimate consumer. Upon these conditions depends the method of precipitation or whatever refinement of the liquor is necessary.

Since the most important vanadium product is ferrovanadium, the various methods of preparing vanadate of iron, from which ferrovanadium may easily be made, will be discussed.

Preparation of Vanadate of Iron.

The method now in general use for the production of vanadate of iron is to add ferrous sulphate to a neutral or nearly neutral solution of sodium vanadate. The compound is precipitated as either a yellow or dark green, bulky mass, which settles to the bottom of the tank, and from which about 75 per cent of the liquor may be decanted. The usual practice is to filterpress the sludge and dry the cakes in a suitable oven.

There are a number of things about this method which are undesirable. In the first place vanadate of iron, like all other vanadates, is soluble in mineral acids. The first requirement, therefore, is that no free acid be present in the solution or be formed there during the precipitation. The sodium sulphate formed in the solution by substitution is a powerful solvent for the vanadate of iron unless the iron sulphate be present in considerable excess, and even then it is doubtful if a quantitative reaction takes place. If the solution should be slightly alkaline the hydroxide of iron is formed at the same time, thus lowering the grade of the product. Another serious objection to the method depends upon the fact that most of the vanadium in the mill solution is reduced; that is, there are vanadic and hypovanadic salts combined with the sodium after roasting, and

these salts are apparently unchanged in the leaching process. Again, the iron is added in a ferrous condition which does not improve matters. The result is that a small per cent of colloidal precipitate is formed, which makes filtering a difficult problem.

At the same time there are formed certain sulphates of vanadium and iron which are more soluble in water than in the mill solution, so that after the washing has reached a certain stage, provided the precipitate can be washed at all, the vanadium begins to appear in the wash water. This would not be so serious if it were not for the fact that, unless removed by washing, the impurities remaining in the vanadate of iron mean havoc in the electric furnace at the time of final reduction. The vanadate of iron as removed from the filterpress carries in the neighborhood of 90 *per cent of the mill solution.* It is obvious that the dried, unwashed product must contain an enormous amount of the salts originally contained in the mill solution.. These consist mostly of sodium chloride, sodium sulphate, calcium salts, titanium salts and salts of silicon and aluminium. As stated above, some of these salts are in combination with the vanadate of iron and some held mechanically by the sludge. That the presence of these salts is detrimental to electric furnace reduction is easily shown by the heating of the impure product in an open crucible; indeed, it is claimed that a loss of 10 per cent of the vanadium has been known to occur in the simple process of driving off the moisture at a moderate temperature. An instance was cited me in which the appalling loss of 70 per cent of the vanadium value was experienced in trying to reduce some vanadate of iron to ferrovanadium.

Unless special precautions have been taken to remove them, silica and alumina as well as lime are always present in the commercial product. Producers of ferrovanadium say that small quantities of these impurities do not affect the value of the vanadate.

Electrolytic Methods of Precipitation.

While it is a well-known fact that salts in solution can be acted upon and changed to desirable forms by the proper application of the electric current, the importance of this in metallurgical operations has not until recently been fully realized. The deterioration of anodes is one of the serious defects of many proposed metallurgical schemes, but there are many instances in which this fact may be used to advantage, and there are processes in operation at the present time in which highly desirable anode products are economically and efficiently turned out.

If two iron plates with a difference of potential of two or three volts are suspended in a receptacle containing vanadium liquor, immediate precipitation of iron vanadate takes place at the anode and continues until all of the vanadium is precipitated. The reaction is efficient and occurs with great rapidity, as will presently be noted.

In case vanadate of iron is to be made from the mill solutions, the acid wash water, if such is used, is led into the same storage tank as was the rich water solution. The water solution is but very slightly alkaline and the mixture is practically neutral, but the fact of its being either slightly acid or alkaline does not seriously affect the electrolytic precipitation. There will separate out and settle to the bottom of the storage tank a yellow vanadium compound containing iron and calcium. This may be allowed to run into the precipitating tank, as lime is not a deleterious impurity in vanadate of iron.

The precipitating is done in wooden tanks 8 ft. long and 4 sq. ft. in cross-section. Each tank is provided with copper busbars running along the top just inside and supported by porcelain insulators. These bars are supplied with current generated at a pressure of from four to five volts. The electrodes are all of iron, although the material of the cathodes may be copper, or, in fact, any other metallic conductor, even carbon. The anodes are made of cast iron, the dimensions being 18 in. x 18 in. x 0.5 in. They may be made from scrap if desired. The cathodes are also 18 in. square, but are only 1/16 in. thick. Since the thickness is not important, so far as their work is concerned, they should be as thin as possible on account of the weight and expense.

In the electrolytic production of vanadate of iron from mill solutions the phenomena have been studied at some length It has been observed that the presence of acid radicals other than vanadium aids the precipitation very materially by exerting a solvent action on the anode during electrolysis. In this case a salt of iron is formed which immediately reacts with the sodium vanadate, with the chemical precipitation of vanadate of iron as would be the case if the same iron salt were added from the outside. If there are no other acid radicals than the vanadium present the precipitation occurs more slowly and the precipitate adheres quite firmly to the anodes, necessitating removal either by scraping or violent agitation. The presence of iron oxide on the anode is beneficial because of the ease with which it is attacked by the vanadic acid radical, and in this case the precipitate is the yellow vanadate of iron instead of the green vanadate. A portion of the lime contained in the solution will be precipitated during electrolysis as vanadate of lime, and this is recovered with the iron vanadate. Some of the calcium is precipitated on the cathode, partly combined with vanadium and partly combined with carbonic acid. In all cases of moderate anode density the precipitate is very easily filtered and washed, but if a very high anode density be used the precipitate will be colloidal.

As stated above, the precipitation begins immediately upon the passage of the current, and under favorable conditions proceeds with extreme repidity. It is possible to precipitate 95 per cent of the vanadium content from a ton of solution carrying 5 g per liter in five minutes with a current of 300-400 amp at a difference of potential of four volts. It is neither necessary nor desirable to remove all of the vanadium from the solution, because the solution which has been electrolyzed is more active as a solvent upon the ore than pure water.

The temperature at which the reaction takes place most efficiently is about 40° C., although good results have been obtained at 0° C. and at the other extreme of 100° C. The distance between the electrodes may be a matter of convenience, although a distance of about 4 in. was used throughout most of my experiments.

The impurities in the vanadate of iron will be sodium chloride, salts of calcium, iron, aluminium, silica and titanium. As a rule any impurity present in the solution will be found in part in the product. If an especially good grade of vanadate is to be made it would be necessary first to purify the solution, which may be done with little expense.

It will be noted that vanadium is always an anode product in hydroelectrolytic operations. Use is made of this property in several methods for producing vanadium compounds besides vanadate of iron. From a sodium vanadate solution the vanadates of almost all of the metals may be made, including vanadate of gold, but not platinum. Copper vanadate is very easily produced, although conditions are much more limited than when precipitating vanadate of iron.

Copper vanadate is either blue or green, and is usually diluted with oxides of copper. It may be filtered and washed in wooden tanks and dried in copper pans. The compound fuses at about 700° C. and becomes very fluid unless a portion of the vanadium is reduced by the action of the graphite of the crucible used for melting. In this case the melt becomes very pasty with the separation of metallic copper. In this connection it is interesting to note that the copper so reduced carries but a very small percentage of vanadium and the vanadium (copper vanadate) carries much carbon. Copper vanadate is the basis of two processes for the production of vanadic acid.

Production of Vanadic Acid.

One of these methods is electrolytic only in the recovery of

the copper to complete the cycle of reactions. I shall describe the method because it affords an opportunity to call attention to some difficulties which may not at first be apparent.

The vanadate of copper is freed as much as possible from solution by washing on canvas filters. It is then placed in suitable containers and treated with sulphuric acid (1-1). The mass turns green at first, then brown and finally red. Upon the addition of the proper amount of acid, which is a matter of experience, the residual vanadic acid is filtered on canvas filters. It may be washed with pure water until the washings show no copper. If an insufficient amount of acid was used the residue will contain copper, while if too much acid was used the recovery of vanadic acid will be small. Not more than 25 per cent of the vanadic acid content of the copper vanadate can be recovered by the first operation.

The solution containing sulphate of copper and vanadyl sulphate is neutralized by passing it over fresh copper vanadate and is then subjected to electrolysis for the recovery of the copper. The copper is precipitated on plates of size suitable for anodes to be used in the precipitating tanks. The solution containing vanadyl sulphate and free sulphuric acid is used for the final decomposition of copper vanadate, and the cycle of reactions is complete. The process is not particularly efficient for several reasons, which, as stated above, are not obvious. The precipitation of copper from copper-vanadyl sulphate solution is not efficient, although perhaps it could be made so, but the mechanical difficulties of handling are great and so numerous that the method is too expensive. The greatest difficulty is in the accumulation of impurities in the vanadyl sulphate solution, the greatest of which is sulphate of calcium. This salt is very soluble in the copper-vanadyl sulphate solutions and soon loads up so that fresh acid has to be used. The process is operative and is actually continuous as outlined, but it is doubtful if it can ever be used commercially.

If an ingot of fused vanadate of copper is attached to a source of electricity so that it becomes the cathode in a simple cell, in which a dilute solution of vanadic acid is the electrolyte, the vanadium tends to pass to the anode, while the copper tends to remain at the cathode in the metallic state. The copper will remain more or less firmly on the cathode, but the vanadic acid in excess of saturation of the electrolyte falls to the bottom of the cell, owing to its inability to adhere to the anode. The anode must be inert, preferably platinum. Any mineral acids present in the solution exert a deleterious action and for this reason the copper vanadate should be as pure as possible. Pure water may be used in the cell because the vanadate of copper is soluble enough to allow the action to proceed to some extent, and as the water becomes saturated with vanadic acid the current passes very readily and the precipitation takes place rapidly. As the action in the cell begins spots of metallic copper appear on the surface of the cathode and the solution becomes yellow, due to the dissolved vanadic acid. As soon as the solution becomes saturated a film of the yellow pentoxide appears on the anode and soon the acid begins to settle out of the solution on the anode and on the walls of the cell. The precipitate is of a rich yellow color and settles to the bottom of the cell in a curdy mass, in which condition it may easily be removed by filtration. No washing of the precipitate is necessary, since the solution contains no impurities if a pure copper vanadate was used. The vanadic acid obtained in this way is easily melted and cast into ingots and should assay 100 per cent V_2O_5. The method is expensive as compared with other electrolytic methods for the production of vanadic acid on account of the large number of operations necessary to prepare the copper vanadate for electrolysis. However, if a pure product is required the method is far cheaper than any method of chemical separation. It must be remembered that vanadic acid may be obtained pure and yet be contaminated during the final operations of getting it into the desired physical state. This is especially true if it is to be melted and cast into ingots.

Any method of producing vanadium compounds by strictly chemical means is uncertain and expensive. I refer to methods of which the general public, including myself, are aware. Vanadic acid, for example, may be produced chemically in a number of ways, of which I shall mention two or three as examples.

If a dried sample of vanadate of calcium be treated with the proper quantity of hot hydrochloric acid, either concentrated or dilute, there results a separation of the red pentoxide of vanadium, which may be filtered and washed first with hydrochloric acid and finally with pure water. The vanadic acid made in this manner will contain a small quantity of lime salts and traces of any other impurities that were originally present in the calcium vanadate. It will also contain a considerable quantity of hydrochloric acid combined with the vanadium as vanadyl dichloride. The chlorine content as well as the 10 per cent moisture present may be removed by fusing the product in either platinum or fused silica. Depending upon the experience of the chemist a practically pure vanadic acid may be made from vanadate of lime.

Small quantities of an excellent grade of vanadium pentoxide may be made by precipitating the vanadium with a salt of mercury and finally driving off the mercury by heat. The only waste of mercury occurs in the handling of the precipitate, since all of the metal may be recovered as in the practice of gold retorting.

Perhaps the oldest and best known method of making vanadic acid is by first making ammonium metavanadate and driving off the ammonium salts by heat. The operation is conducted by having a concentrated solution of sodium vanadate which has been previously freed from a large percentage of the impurities originally present. To the sodium vanadate solution is added solid ammonium chloride, previously purified, to supersaturation. The white, crystalline ammonium-vanadium salt separates out and may be filtered and washed. If care is used in preparing the solutions the first metavanadate obtained will yield about 97 per cent V_2O_5 upon ignition. By dissolving the ammonium metavanadate in caustic soda and reprecipitating the vanadic acid may finally be obtained practically pure. In this method the expense of the reagents is prohibitive, besides, the reactions are slow and not quantitative.

Vanadic acid can be prepared by the continued boiling of acid solutions containing vanadium salts. The vanadium separates out of the solution in small quantities at various concentrations. Starting with a given amount of vanadium, perhaps a maximum of 10 per cent may finally be recovered by continued boiling a dilute solution. The pentoxide so recovered is not pure and the method apparently has no commercial value.

Vanadic acid may also be prepared by the treatment of dried sodium vanadate with acid, but as in the above instances, the yield is so small as compared with the expense that totally new methods must be devised if vanadic acid is demanded as a commercial product in large quantities.

Author's Electrolytic Method for Vanadic Acid.

I have devised an electrolytic method which is operative and which may be depended upon for economical production of a very high grade oxide. The method consists in taking advantage of the different solubilities of sodium vanadate and vanadic acid in the same bulk of water, and the procedure is as follows:

Sodium vanadate liquor which does not contain chlorides is purified by heating to 90° C. and making slightly alkaline with sodium carbonate. This liquor is decanted into an evaporator and concentrated to 30° Baumé. At this degree of concentration it will contain about 200 g per liter vanadic acid, depending upon the amount of sodium salts present. This concentrated solution is electrolyzed in a compartment cell consisting of a porous cup with a capacity of 8 liters inside a suitable jar or tank with a capacity of 5-10 gal. The vanadium liquor is poured into the porous compartment and water containing a little lye is poured into the outer compartment. The anode is of platinum foil 6 in. x 6 in., and the cathode is of either iron or copper, preferably the latter. A difference of

potential of 6-8 volts, depending upon the resistance of the porous cell, is taken from a low-voltage generator. A current density of about 30 amp per square foot at the anode will result. The sodium ions pass through the porous cell into the cathode compartment, leaving the vanadium ions in the anode compartment. Since sodium vanadate is very soluble in water, and vanadic acid is almost insoluble in water, a precipitation results upon the removal of the alkali. The presence of mineral acids interferes seriously with this reaction, since the vanadium is soluble in dilute solutions of mineral acids. If a small amount of chlorine is present it is evolved partly at the anode and that which is not evolved causes the formation of various complex compounds which result in a very low grade product. The presence of sulphuric acid in the anode compartment causes the precipitation of sodium vanadyl sulphate containing 73 per cent V_2O_5.

Any silica or lime salts not removed by the preliminary purification treatment will precipitate in part in the anode compartment just as the solution becomes neutral and may be removed by filtration. In spite of every precaution some impurities will find their way into the product, and not a little of this comes from the disintegration of the porous cell. The greatest objection to this process is the necessity for using platinum in such large quantities, one ounce of platinum being required for every pound of vanadic acid produced per day of 24 hours. There is no loss of platinum, however, and it is probable that platinum plate electrodes would greatly reduce the actual weight of platinum required.

The vanadium pentoxide produced by this method is of the red variety and presents a tough leathery appearance, and may be filtered and washed with ease. Without taking more than the usual precautions, the grade should be 98 per cent V_2O_5, the impurities being principally lime and silica. The current efficiency is as high as could be expected with a compartment cell. There is no apparent reason why the units may not be of any desired capacity, and it is very probable that the process could be made continuous.

From the foregoing statement, that chlorine interferes with the recovery of the vanadium pentoxide, it is obvious that the salt roast is out of the question. Therefore if vanadic acid is the required product another method of extraction from the ore will have to be used. A modification of the sodium carbonate roast will be found satisfactory, although the extraction will not be so high, nor will the operation be as cheaply performed. A small amount of chlorine will be present even in this case because the commercial sodium carbonate carries about 1 per cent sodium chloride and the commercial sodium hydrate sometimes carries as high as 3 per cent.

Presence of Titanium in Vanadium Ores and Products.

Since titanium is present in almost all vanadium ores, although the percentage is usually very small, its extraction is excellent. This element resembles vanadium in a large number of reactions, and it is natural to expect that titanium should be found as an impurity in commercial vanadium products. I have found titanium in vanadic acid of supposedly high purity, and in some cases the percentage has been higher than one would suppose. The fixed alkalis are good solvents for titanium and this element may in some cases interfere with assays for vanadium. From alkaline or neutral solutions lead acetate precipitates lead titanate, which exactly resembles lead vanadate excepting that the precipitation is not quantitative under the same conditions that lead vanadate is. This precipitate is soluble in nitric acid and in sulphuric acid solution is apparently reduced to sulphur dioxide to the same extent that iron would be if present. The orange red color of titanium with hydrogen peroxide in nitric acid solution may in some cases so nearly resemble the vanadium color that the chemist is at a loss to understand why he cannot precipitate all of the vanadium out of the solution.

In connection with the presence of titanium in vanadium products, the phenomenon of the evanescent end point when titrating with potassium permanganate may be due to this element.

Vanadium for Steel Making.

Since practically all of the vanadium produced at the present time is finally to be used in making vanadium iron and steels, it is proper to say a word regarding the preparation of the vanadium for use by the steel maker. The vanadium must be added in a metallic form because a portion of its value lies in its property of removing traces of oxygen and nitrogen and uniting with carbon to form carbides in the metal. Any vanadium present as oxide will probably be totally lost in the slags. The form in which vanadium is now added to the steel is an alloy of vanadium and iron carrying from 25 per cent to 50 per cent metallic V. There are difficulties in the production of ferrovanadium which at the present time have not been overcome.

Ferrovanadium may be produced from either vanadate of iron or vanadate of calcium (and of course vanadic acid) by reduction with carbon at a temperature of about 1500° C. The reduction is most efficiently carried on in an electric furnace of any type that will give the proper temperature. The alloy, which melts between 1300° C. and 1400° C., depending upon the percentage of vanadium, settles easily to the bottom of the crucible, and may be tapped and cast into ingots. Ferrovanadium made in this way will contain a high carbon content, some silicon and aluminium. Steel makers do not want ferro with carbon over 1 per cent at the outside, while the alloy obtained by the above method will contain much more than this.

A passable grade of ferro is being made by reduction with metallic aluminium. The process is necessarily expensive on account of the price of the reducing agent and certain losses not incident to other processes.

Although I have never seen the process in operation, the reduction of vanadium by metallic silicon or ferrosilicon appears to me to be one of the best yet devised. Mr. F. M. Becket, of Niagara Falls, is the inventor of the process. Mr. Becket was the first man in the United States to produce vanadium alloys in commercial quantities, and he probably knows more about this end of the game than any one else. Therefore I have no hesitation in accepting his statements relating to his process, which is based upon sound metallurgical principles.

A recent process patented by Mr. Boericke ought to give a very high-grade alloy and should be efficient. Mr. Boericke uses either metallic manganese or ferromanganese as a reducing agent, thus avoiding the presence of carbon, silicon or aluminium in the final product.

Numerous other processes have been patented, but none appear to be of any considerable importance.

To sum up, it may be said that great advances have been made during the last few years in every branch of vanadium metallurgy. Efficient processes of extraction, precipitation and producing alloys have been developed and these, at the present prices of vanadium products, allow the various ores to be worked at a profit. As with problems concerning other metals, none of the processes are entirely satisfactory in the fullest sense. Owing to the fact that vanadium seems to be firmly established in the steel industry, and promises to be of great value in other lines as well, and since competition is going to force the prices steadily downward, one is compelled to predict that processes of extraction and refining of high efficiency will be developed in the near future. The time when operators can slop a little acid on picked ore and make a profitable extraction, or throw away 1 per cent roasted tailings, or gracefully accept a penalty for uranium values in vanadium products will soon be past, and so much the better for metallurgical intelligence and really careful experiment.

I wish to thank my assistant, Mr. Arnold J. Guerber, for months of painstaking work on the problems here discussed and for carefully prepared analytical data upon which many

of the conclusions are based. In papers of this character, because of the newness of the subject, there must have crept in some misstatements and hasty conclusions. I shall be very glad to have attention called to those which may be observed.

Boulder, Col.

The Electric Pig Iron and Steel Plant at Trollhättan, Sweden.

In the July issue, page 368, and in the September issue, page 459, the first parts were published of the important paper presented by Mr. J. A. Leffler to the Jornkontoret (the Swedish Association of Iron Masters) at their meeting at Stockholm on May 31 on the electric iron ore reduction plant at Trollhättan, Sweden. In the following we give an abstract of the concluding portion of Mr. Leffler's paper, together with an abstract of a paper by Mr. E. Odelberg on the conversion of the electrically reduced pig iron into steel.

Electrodes and Electrode Consumption.

Part of the electrodes used at the works were supplied by the Planiawerke, Ratibor, Silesia, and a part by the Höganäs-Billesholm Company, Sweden. The purpose in using both was to obtain a comparison between the well known Planiawerke electrodes and electrodes of Swedish manufacture. Results of the analyses of the electrodes are shown in Table I:

TABLE I.

Analysis of Electrodes.

	Electrodes from Plania.	Höganäs.
Ash	2.80%	3.96%
S (total)	0.79%	1.06%
P	0.27%	0.16%
Composition of the Ash:		
SO_3	0.44%	0.97%
P_2O_5	0.627%	0.37%
SiO_2	37.80%	42.00%
$K_2O + Na_2O$	1.21%	0.45%
CaO	6.08%	10.20%
MgO	2.62%	2.16%
Fe_2O_3	28.04%	21.70%
Mn_3O_4	0.52%	0.38%
Al_2O_3	21.22%	19.80%
Total	98.557%	98.03%

The rather large difference in the ash analyses is probably due to the difficulty to burn the last traces of carbon by ignition.

From the above will be seen that the Höganäs electrodes contain a somewhat high percentage of ash and sulphur. In producing iron of high quality it is, of course, necessary that especially the percentage of sulphur should be kept as low as possible. With the electrode consumption found in actual operation and assuming that all of the sulphur combines with the iron, 1 per cent sulphur in the electrodes corresponds to 0.005 per cent to 0.006 per cent sulphur in the iron.

The electrodes in the furnace are four in number. Each electrode is built up of 4 cartons, 2 m long and 330 x 330 mm in cross-section arranged to form an electrode of 660 x 660 mm cross-section. Before being bound together the sides forming the joints are planed to a flat surface and the joint is made with a thick paste of molasses and graphite, so that the closest joint possible is formed. The upper part of the electrode is covered with asbestos paper and thin sheet iron and the top surface is covered with a thick layer of ground asbestos and silicate of potash.

The sides of the electrodes are carefully planed smooth at the upper part for a distance of about 250 mm in order to make a good contact surface for the electric contacts. Between these and the electrode is also placed a fine mesh copper wire cloth.

In order to observe the quality of the different makes, electrodes were built up of carbons from the two factories and each kind used under similar conditions. No difference in durability could be discovered.

FIG. 1.—FURNACE HOUSE AT TROLLHÄTTAN.

Table II gives the complete record for two electrodes (called No. 1 and No. 2), also the average for ten electrodes.

TABLE II.

Average of 10	906	6	1313.3	635.8	677.5	51.61	2.28	1.16

The Charges.

During the time which this report concerns 29 different qualities of charge were used, which, however, may be regarded as four main groups, viz. unroasted Tuollavaara, roasted Tuolluvaara, Borgvik and Uddeholm ores.

Referring to Table III it will be noticed that the variations in the first group mainly concerned modifications of the silica contents of the slag and also varying proportions of Tuolluvaara ore in the charge.

In the third group a complete change was made in the mixture of the ore at the request of the iron works from which

it was sent and a gradual increase of lime was necessitated on account of the sulphur contents of the iron.

The fourth group shows a gradually increasing percentage of concentrates from Persberg which was mixed with the ore.

Table III forms a summary report of the various quantities of ore, charcoal, energy and electrodes used for respective charges and also the amounts of pig iron and slag produced from four groups of charges.

The Durability of the Crucible and Roof.

The roof of the crucible was at first considered as being a weak point of the construction, but it may be stated that it has stood the test in an excellent manner, as only two repairs of any importance have been necessary.

In the neighborhood of the electrodes the arch became red hot in a few places after protracted working, but it generally proved possible to prevent the bricks from burning through by cooling them with an air blast.

It is probable that the roof would have lasted still better if the furnace could have been worked the entire time with both phases. The second phase was, however, at times out of action. In this way the heating of the roof became uneven and it was damaged by cracks resulting from the stresses.

In the morning of April 6 when the charge contained 70 per cent concentrates a settling occurred from the shaft into the crucible which was accompanied by so violent a development of gas that the roof was damaged between two electrodes. At the time the loose bricks closing the holes in the roof were so tightly sintered into their places that they did not act as safety valves. Repairs were, however, effected in less than two hours. Once the iron cut through the lining of the hearth and the iron shell, causing an interruption of about two hours.

Iron and Slag.

Analysis of the iron was made from each tapping and analysis of the slag and the gas at very frequent intervals. The accompanying tables IV and V show four different analyses which may be taken as averages for those taken and the average of all the analyses are also given. The complete tables are of great interest as showing the continuous and regular working of the furnace, but are too extensive to publish in these columns.

A subject of great interest is the question whether by this process iron of a uniform composition can be produced for any desired length of time.

As no O and C, except what is contained in the ore, the fuel, and the electrodes, is introduced into the furnace, it is evident that the process is to a large degree dependent on the relative proportions between the quantities of O and C so introduced. It is also apparent that these proportions are apt to vary owing to variations of the fuel and ore and the gas circulation. These conditions must be watched carefully and the charges proportioned accordingly. Irregularities of work-

ing can also be remedied by additions of ore and charcoal through the openings in the roof of the crucible.

The problem of even gas circulation cannot yet be considered satisfactorily solved. It is apparent that the CO_2 percentage of the escaping gas is largely dependent upon the gas circulation and for same reason if the latter is disturbed, as for instance by choking charcoal or ore dust in pipes, etc., the CO_2 percentage will change with consequent effect in the supply of C.

In studying the iron and slag analysis these facts should be taken into consideration and the results appear better.

The analyses of slag show that these have been kept more siliceous than desirable for the basic lining of the hearth. This has, however, been done for the purpose of obtaining results as closely comparable as possible with the treatment of the same ores by the ordinary blast-furnace process.

A few observations of the temperatures of iron and slag taken by means of an optical pyrometer are given in Table IX. In the table is also shown the percentage of Si and Mn in order to show the connections between these and the temperatures.

In spite of the large number of analyses made it would be premature to draw any definite conclusions concerning the action of the gas under different conditions. It is, however, apparent that currents of varying composition are apt to pass through different parts of the shaft so that, for instance, the gas at the centre of the furnace and at the side in the same section may show a different composition.

The outside temperature of the furnace was kept constant and normal but in a couple of cases when some damage was done by overheating.

An average of 110 liters per minute of cooling water was used for cooling the electrodes with a loss of an average of 97.8 kw, which is nearly 7 per cent of the total load on the furnace.

Working Results.

While it may not be advisable to draw final conclusions on the basis of the results obtained it is nevertheless of interest to examine these results with a view to find indications for the continued development and improvement of the process.

As a definite and highly satisfactory experience it should be noted that the need of repairs of the crucible has been very slight. During a period of nearly 5 months of continuous working only about 18 hours have been required for repairs which must be regarded as an eminently satisfactory result.

It is also satisfactory to note that the height and other dimensions of the shaft have in the main proved correct for normal conditions for fuel and ore.

If, however, earthy ore or concentrates or too fine fuel is used, or if the charge contains too much moisture the working is injuriously affected as would equally be the case with an ordinary blast furnace, and the design of the shaft does not appear to be well suited for such conditions. This is because it is then especially important to maintain a strong circulation of gas.

If this cannot be done the moisture is not evaporated, but gradually penetrates further down in the shaft causing a lowering of the temperature. The reducing power of the CO is then decreased and the percentage of CO_2 in the resulting gas decreases. But this percentage of CO_2 is the indicator of the degree of ultilization of the fuel used and must, therefore, under all circumstances be maintained as high as possible.

For the conditions mentioned a shaft with a wider neck would be more suitable, as it leaves a larger space for the gas to pass up and a reduction of the temperature would be counteracted. Possibly it would also be an advantage to make the shaft wider and lower.

In order to produce an effective and uniform circulation of the gas it is in the first place necessary to purify it by washing, so that the frequent interruptions for cleaning may be avoided. Further the gas pipes must be quite tight so that the gas drawn by the fan is really blown into the crucible, which must also be made as tight as possible. Alterations in these respects are at present in progress at the works.

The circulation of gas which is so useful and necessary for the purpose indicated above and which moreover is a protection for the roof, has, however, the disadvantage that the electrodes are attacked by the carbonic acid in the gas. Nevertheless, the electrode consumption has been low. The average for the entire time per ton of iron has been 10.28 kilogrammes gross and 5.27 kilogrammes net. Electrodes with screw joints are now being adapted for the furnace and the gross consumption may then be reduced—under most favorable circumstances to equal the net consumption.

The experience with this furnace appears to indicate that with this size four electrodes is a minimum number. It would probably be better to use six electrodes with three-phase currents. This would distribute the heat more uniformly and the risk of disturbances of the work on account of defects in the transformers would be reduced. Losses through cooling water would in this case probably be increased, but this would undoubtedly be more than counterbalanced by the advantages gained.

During the time to which the report refers only unburnt limestone has been used. In view of future comparisons with ordinary blast furnace results it was desired to maintain the conditions very much similar to those under which the same ores are usually treated. It is, however, evident that by the use of burnt lime the economy of the process will be improved and this improvement would increase in proportion as the quantity of lime required is increased. Whether unburnt or burnt limestone is used the percentage of CO_2 in the gas remains the same. This proves that the CO_2 derived from the limestone may be replaced by CO_2 formed by the reduction of the ore by CO. The power required for burning the limestone is, therefore, saved and the same quantity of fuel reduced more ore.

* * *

While Mr. J. A. Leffler's paper dealt with the reduction of pig iron from iron ore in the electric furnace at Trollhättan, Mr. E. Odelberg presented a paper on the results obtained in the conversion of this electrically produced pig iron into steel. An abstract of Mr. Odelberg's paper is herewith given.

As the manufacture has been in progress only for a short time, and as further the appearance and analysis of the pig iron were in some respects not the best that could have been desired during the first period of working, it was with some hesitation that the steel works received and treated the product.

The results up to the present time are, therefore, few and of indifferent interest and perhaps somewhat one-sided.

The Behavior and Qualities of the Electric Pig Iron in the Open-Hearth Process.

For acid furnaces it is desirable to have a pig iron with 0.4 to 1.0 per cent. Si or more, and many manufacturers consider that they require at least the same quantity of Mn to obtain a fully satisfactory product.

At the Trollhättan plant there was at first produced a considerable quantity of iron which as regards surface and fracture had the characteristic appearance of spongy iron and of which the analysis showed only a very small fraction of Si and Mn. At that time there was, therefore, some hesitation about the treatment of this iron, the material for which was the same as ordinarily used for the production of a high-grade steel.

The first test of using this iron at Degerfors was made in a basic furnace with addition of ordinary grey iron and a smaller quantity of scrap than usual in order to make sure of an acceptable product of hot iron. The result was, however, so satisfactory that already at the third charge only white electric pig iron was used, together with 50 per cent. scrap. The somewhat surprising observation was then made that the expected boil of the material immediately after the melting did not occur.

The tests with melting of spongy pig iron were then transferred to an acid furnace. Small quantities were used at first but these were very soon increased to the ordinary proportions of 64 per cent. pig iron and 36 per cent. scrap.

As anyone acquainted with the open-hearth process is aware there occurs immediately after, and even during the melting, a violent boil of the material. This is especially the case in an acid furnace if iron too poor in silicon is used (even if this is not what is called spongy iron). A similar partial boil occurs again on teeming the charge into the ladle and moulds and this is invariably the case with hard steel. It was, therefore, surprising that this partial boil did not occur, but instead the regular "boil" commenced immediately after the material was melted and before the oreing.

The charges of such iron were finished in considerably shorter time than the ordinary (about 8 hours). They also required considerably less oreing, but nevertheless were quite hot and liquid when teemed. With equal additions of Mn and Si as ordinarily a product was obtained with the same percentage of Mn and Si as is generally obtained with pig iron of normal analysis from an ordinary blast furnace.

When, however, the same open-health furnace was charged with electric pig iron of correct appearance and normal percentages of Mn and Si, together with the same proportion of scrap as before the treatment required considerably longer time and more ore than can be regarded as desirable.

These conditions are elucidated in the working results of Degerfors which show that the time and oreing of the charges vary generally in accordance with quite small variations of the Si and Mn contents in the ore.

At Degerfors a decided opinion was soon arrived at that electric pig iron of spongy nature was that most suitable for the open-hearth process, whereas the refining of pig iron of normal fracture and analysis proved costly and requires too much time. In regard to the finished product from these apparently so different qualities of pig iron no difference has been found at Degerfors either in teeming or in use.

On the strength of this experience and as on account of decreased output it proved more difficult and costly to produce in the electric reduction furnace pig iron of so-called normal silicon contents, it was decided that the manufacture should be arranged for producing spongy pig iron and that there should be no hesitation about producing the spongy quality, which it is considered desirable to avoid in ordinary blast furnace practice.

Various explanations have been put forward to explain the cause of the rather surprising result of the refining of electric pig iron, which in appearance as well as composition, has been the opposite of pig iron produced in the ordinary blast furnace.

The true explanation is probably that the electric pig iron, even of the white spongy quality, is practically free from rests of ore and iron reoxidized by the blast. This is also proven by the fact that the fracture of very thick flowing spongy iron from the electric furnace is perfectly white and free from tarnished bubbles, while the bubbles in spongy iron from the ordinary blast furnace usually show all the colors of the rainbow. On account of this freedom from oxygen the partial boil in the open-hearth furnace during and after the melting does not occur and it is possible to at once decarburize the charge by oreing. The presence of silicon in such pig iron is therefore unnecessary during the first portion of the open-hearth process.

The slowness of the open-hearth process with electric pig iron of normal appearance is due to the silicon not being oxidized at once by oxides in the iron, so that the refining must be accomplished principally by means of ore and only after this is accomplished the decarburizing proper can commence.

In proof of the above it may be mentioned that for a charge of pig iron with 0.61 per cent. Si and 0.68 per cent. Mn a time of 50 minutes was required to reduce the Si and Mn to the low percentages necessary for beginning the decarburization. If the Si and Mn contents are reduced below these limits in an acid furnace, it would appear that they are again absorbed and not again reduced during the decarburization. The carbon contents in the pig iron used for the charge then determines the time and the quantity of ore required for the decarburization to obtain the desired product. As a higher, and according to the ordinary rules, normal percentage of silicon cannot occur in spongy iron from an electric reduction furnace, the Si contents alone has been referred to in this connection as determining the quality of the pig iron. But this iron is also distinguished by being so low in carbon as to approach steel and it should be remembered that the higher percentage of carbon which occurs at the same time with a higher percentage of silicon also has the effect of prolonging the time for decarburizing in the open-hearth furnace.

The charge above referred to, the pig iron for which was mottled and contained 3.69 per cent. C, 0.61 per cent. Si and 0.68 per cent. Mn, required a time of 6 h. 25 min. for a product with 0.60 per cent. C. Another charge for which the pig iron (spongy iron) held 2.75 per cent. C, 0.04 per cent. Si and 0.19 per cent. Mn required, however, a time of only 4 hours for yielding a product with 0.45 per cent. C. In these times mentioned the time for cleaning and repairing the hearth is not included.

A higher percentage of silicon than 1 per cent. in pig iron from an electric reduction furnace is, therefore, if not detrimental to the quality of the final product, an obstruction to the progress of the open-hearth process, and to a certain extent the presence of manganese in such iron has a similar effect.

It is well known that a certain amount of silicon (many manufacturers also demand a considerable percentage of manganese) is necessary in pig iron from an ordinary blast furnace in order to make the iron suitable for the open-hearth process. It is also well known that if the Si and Mn contents in the iron are too high the open-hearth process is protracted, which is undesirable from an economical point of view. The quantities of Si and Mn required for carrying through the process with pig iron from an ordinary blast furnace, are just those needed during and immediately after the melting of the charge to free the iron from the oxides and gases formed by the influence of the blast. Whatever surplus of Si and Mn may be present only protracts the open-hearth process unnecessarily.

The partial boil frequently mentioned in this connection is a premature and gradually increasing partial decarburization of detrimental effect, but it does not occur if the pig iron contains sufficiently large quantities of Si and Mn. The fact that it does not occur in the case of "electric" pig iron with practically no Si and Mn must be explained by this pig iron being free from oxides.

It may therefore be maintained on the strength of the experience gained with electric pig iron treated by the open-hearth process that high silicon contents are detrimental rather than advantageous, while with ordinary pig iron a certain quantity is necessary to neutralize the defects of a reduction process less perfect and ideal than the electric process.

Steel Produced from Electric Pig Iron.

As already mentioned, the steel made at Degerfors, whether produced from pig iron very poor in silicon or from what may be called more normal pig iron from the Trollhättan furnace, has always proved of very good quality when teemed. Such has also always been the case on rolling as indicated by forging and annealing tests as well as by the analyses.

The first product which was rolled to wire was sent to the Blombacka A. B., Lindfors, where tests were immediately made and the quality found to be very good in every respect.

Garpshytte Fabriks, A. B., have also tested a few small lots of rolled wire and obtained very satisfactory results.

A lot of 20 tons with 0.75 per cent. C was sent to one of Degerfor's largest customers for rolled wire for testing. They wrote as follows:

"We have tested the 0.75 per cent. C material you sent us and found that the wire is perfectly satisfactory, but we have not found any particular difference between this material and your usual quality with 0.75 per cent. C which we are in the habit of buying. Kindly note that we have no objections against the electric steel with 0.75 per cent. C. It is very satisfactory, but we cannot say that it is superior to your usual 0.75 per cent. steel."

A quantity of files and axes have been made from steel with 1.25 per cent. C and 0.55 per cent. Mn. The files are in use at Degerfors and have proved to be of good quality. The opinion of the file makers in regard to the behavior of the steel in working was that it was soft and good both for forging and cutting, but required very little annealing, although the carbon was as high as 1.30 per cent., and they were of opinion that 1.40 per cent. C would probably have been more suitable.

Fuel-Oil Specifications.

In consequence of the success that has attended the use of heating-value specifications in buying and selling coal there has arisen a demand for similar specifications, based on careful tests, to govern the purchase of fuel oils and the refined products of petroleum.

The Bureau of Mines has therefore issued Technical Paper No. 3, by Irving C. Allen, on "Specifications for the purchase of fuel oil for the Government," with directions for sampling oil and natural gas.

"These specifications, to be satisfactory," says the author, "should establish not only the heating value of the oil, and thus show, like the specifications for coal, the number of heat units the purchaser obtains for a given price per unit quantity of fuel, but also the physical character of the oil, its flash point and burning point and the quantity of extraneous matter it contains.

"It is evident that an essential feature of any such plan of purchasing oil in bulk is an equitable method of sampling deliveries—that is, a method that insures the taking of representative samples.

"The Bureau of Mines has received many inquiries from Government bureaus and from private concerns regarding fuel-oil specifications and the sampling of purchases. In reply to these inquiries the bureau issues this paper, which, although intended primarily for the guidance of Government officials, may be of service, the bureau trusts, to all persons who buy or sell fuel oil."

General specifications for the purchase of fuel oil are given as follows:

In determining the award of a contract, consideration will be given to the quality of the fuel offered by the bidders, as well as the price, and should it appear to be to the best interest of the Government to award a contract at a higher price than that named in the lowest bid or bids received, the contract will be so awarded.

Fuel oil should be either a natural homogeneous oil or a homogeneous residue from a natural oil; if the latter, all constituents having a low flash point should have been removed by distillation; it should not be composed of a light oil and a heavy residue mixed in such proportions as to give the density desired.

It should not have been distilled at a temperature high enough to burn it, nor at a temperature so high that flecks of carbonaceous matter began to separate.

It should not flash below 60° C. (140° F.) in a closed Abel-Pensky or Pensky-Martens tester.

Its specific gravity should range from 0.85 to 0.96 at 15° C. (59° F.); the oil should be rejected of its specific gravity is above 0.97 at that temperature.

It should be mobile, free from solid or semi-solid bodies, and should flow readily, at ordinary atmospheric temperatures and under a head of 1 foot of oil through a 4-in. pipe 10 ft. in length.

It should not congeal nor become too sluggish to flow at 0° C. (32° F.).

It should have a calorific value of not less than 10,000 calories per gram (18,000 British thermal units per pound); 10,250 calories to be the standard. A bonus is to be paid or a penalty deducted according to the method stated under section 21, as the fuel oil delivered is above or below this standard.

It should be rejected if it contains more than 2 per cent water.

It should be rejected if it contains more than one per cent sulphur.

It should not contain more than a trace of sand, clay or dirt.

Each bidder must submit an accurate statement regarding the fuel oil he proposes to furnish. This statement should show: The commercial name of the oil; the name or designation of the field from which the oil is obtained; whether the oil is a crude oil, a refinery residue, or a distillate; the name and the location of the refinery, if the oil has been refined at all.

The fuel oil is to be delivered f.o.b. cars or vessel, according to the manner of shipment, at such places, at such times, and in such quantities as may be required.

Should the contractor, for any reason, fail to comply with a written order to make delivery, the Government is to be at liberty to buy oil in the open market and charge against the contractor any excess of price, above the contract price, of the fuel oil so purchased.

Copies of this Technical Paper may be obtained by addressing, the Director of the Bureau of Mines, Washington, D. C.

Regulations on Papers for the Eighth International Congress of Applied Chemistry, 1912.

In the following we give the set of tentative rules on papers to be presented before the Eighth International Congress of Applied Chemistry. The Congress will be held in this country in 1912. Since the final rules are to be adopted during December of this year, any criticism of the tentative rules given

below should be made before Dec. 1, 1911, and should be sent to the secretary of the Congress, Dr. B. C. Hesse, 25 Broad Street, New York.

1. All papers must be in duplicate and legibly written, preferably typewritten.

2. Each sheet must be written on one side only and *not* on both sides.

3. Each paper must be accompanied by an abstract thereof, also legibly written, preferably typewritten, and which must be in duplicate.

4. Papers and their abstracts, both in duplicate, must be in the hands of the American Committee not later than June 30, 1912. All papers received prior to that time and accepted will be printed in their respective Sectional Volumes and distributed to such of the attending members of the Crongress as may desire them at or before the opening of the Congress. Papers received after that time, if accepted, will be printed, but may appear in an appendix which may or may not be ready by the opening of the Congress;. the Congress cannot then undertake to print them along with the papers of those sections to which they may be assigned.

5. All papers or like contributions must be as concise as possible, and must contain the full name and post-office address of their respective authors; further, what number, if any, of reprints of the paper or like contribution is desired.

6. Papers or other like contributions must be original and not elsewhere read or published, nor contributed or offered to any other society, association or publication for presentation or publication. The offer of any paper to the Congress is a tacit and understood agreement to the foregoing requirement. No paper should deal with historical matter any more than is needful for a proper understanding of the new subject matter presented, which subject matter, as far as practicable, should be of a date subsequent to June, 1909, the date of the Seventh International Congress of Applied Chemistry, except by special request. Nonconformity to this requirement may be a reason for rejection; a remedy herefor is offered in paragraph 18.

7. All authors, as a matter of course, agree not to publish their accepted papers in any other publication except as hereinafter provided, and, further, they automatically agree to abide by any final decision of the Congress with respect to such paper or papers, their presentation, discussion or printing.

8. The Congress obligates itself to have its final Report and Proceedings, including subject and authors' index, completed and ready for distribution on or before Dec. 31, 1912; in case those reports and proceedings be not ready for distribution by that date, authors of all papers received and accepted after June 30, 1912, may then publish in any journal or publication that they may elect. This refers only to the report and proceedings bound in paper; members desiring cloth-bound sets can obtain them at an advanced charge over the $5.00 membership fee; such advanced charge will be announced later, but will probably be $2.50; delivery of these cloth-bound sets will be about 90 days later than of the paper-bound sets. Authors of papers received before the close of June 30, 1912, may publish those papers in any publication they may elect after the paper is read or after the Congress has adjourned.

9. Authors of papers accepted and printed in full or in abstract will receive free of cost and all delivery charges, not to exceed fifty (50) reprints of each paper or abstract; additional copies of reprints can be had upon payment of the prices for such copies, which prices will be announced later. The Congress cannot undertake to furnish reprints of papers if the order for such reprints is not attached to the paper or abstract when received by the American Committee.

10. No paper offered to and accepted by this Congress can be at any time published elsewhere without giving credit to this Congress for such article or publication.

11. The Congress reserves the right to reject any paper or other contribution that may be offered to it.

12. Rejections by Sectional Committees will not be final; their decisions will be reviewed by the Committee on Papers and Publications, but rejection by that Committee will be final.

13. Authors of finally rejected contributions will be notified in writing of such rejection immediately after it has been made, and, as far as the Congress is concerned, such final rejection is strictly secret and confidential.

14. Any paper which is of a pronounced polemical, advertising or personal character may be thereby disqualified and for that reason alone rejected, regardless of whatever merit the paper may otherwise possess.

15. The Congress reserves the right to print the full paper only, or the abstract only, or the title only, in each case with the author's name and post-office address.

16. The Congress will not publish a list of rejected papers nor state what papers have been rejected; directly after the closing of the Congress all records relating to rejected papers and like contributions will be destroyed; any and all proceedings as to rejected papers or like contributions, so far as the Congress is concerned, will be strictly secret and confidential.

17. Authors are requested to state on the papers themselves their preferences for the sections in which they wish them to be read; the Congress will respect that request wherever practicable, but reserves the right to assign the paper to any other section that may be deemed more appropriate, and such disposition is final.

18. Authors will *not* receive printer's proofs of their papers or abstracts; nor will their papers or abstracts be revised after receipt by the American committees, except when express authority so to do is given in writing by the author and time and opportunity offer for such revision; authors of manuscripts so revised waive any and all right to complain of or rectify any such revision. (See paragraph 6.)

19. The time consumed in reading or presenting the substance of any paper by an author or his representative at a meeting of a section must not exceed ten (10) minutes; papers or presentations requiring more time than that must be suitably condensed so as to fulfill that requirement.

20. Anyone reading a paper of another's authorship must be fully equipped and prepared to defend the paper in discussion, and no one else will be permitted to read such a paper; an offer to read another's paper is an implied statement to the effect of such preparation.

21. In the absence of an author or his properly equipped representative the paper will be read by title only, and if there be any discussion it must be based upon the paper as printed, because neither the paper itself nor its abstract will be read; exceptions to this rule can be made only under regulations that may be adopted by each sectional executive committee.

22. Discussions of a pronounced polemical, advertising or personal character may be ruled out by the chair on that ground alone and not permitted to appear in the printed record; the ruling of the chair in such matters is final and is not subject to revision or appeal.

23. Participants in discussion will be given an opportunity of editing the manuscript reports of their remarks, but printer's proofs will not necessarily be submitted to them, although wherever practicable they will be so supplied.

The Reaction Between Hydrogen and Carbon Monoxide and the Effect of Steam on Carbon Monoxide at Elevated Temperatures.

In an interesting paper by Mr. Armand Gautier in the *Comptes Rendus*, vol. 150 (1910), page 1564, the author investigates the question of the possible reduction of CO by hydrogen, with formation of water.

Pure CO, mixed with three times its volume of hydrogen, was heated in a porcelain tube and the temperature recorded

by a Le Chatelier pyrometer. Many tests were made at temperatures from 300° C. to 1250° C.; the mixed and dried gases were circulating with a velocity of 450 cc. to 475 cc. per hour. The water formed was absorbed in a tube filled with P_2O_5, the CO_2 by potassium hydrate.

	H_2O per liter CO.		CO_2 per liter CO.	
Temperature.	mg.	cc.	mg.	cc.
400° C.	4.4	5.4	1.7	0.86
600° "	12.4	15.4	11.4	5.80
900° "	17.1	21.2	20.5	10.4
1220° "	22.2	27.5	19.2	9.7
1200° "	17.2	21.3	4.1	2.1

The results show that by heating CO in presence of hydrogen, water is actually formed. The reduction begins approximately at 200° C., before red-heat. The maximum formation of water is between 1100° and 1200° C.

During all the tests the volume of H_2O did not exceed 0.028 of the volume of CO used. At the same time the formation of CO_2 increases till 900°, and drops down when the temperature is increased above this point.

$$CO_2 + H_2 = CO + H_2O.$$

This equation also explains the stability of the water volume in this high-temperature interval, despite the reverse equation.

$$CO + H_2O = CO_2 + H_2.$$

Between 900° and 1000° the water and CO volumes may follow pretty closely the equation:

$$4CO + 2H_2 = 2H_2O + CO_2 + 3C.$$
$$4 \text{ vol.} \quad 2 \text{ vol.}$$

But no trace of carbon was found.

Two remarkable phenomena may be noticed, the decrease in CO_2 between 1200° and 1220° and a similar one during the period of formation of water.

By using a mixture of $CO + 3H_2$ and a consumption of ½ liter per hour, the author obtained at 900°, under the same conditions, the following results:

		H_2O per 1 CO.		CO_2 per 1 Co.	
	Temperature.	mg.	cc.	mg.	cc.
I.....	900°	17.10	21.2	20.5	10.4
II.....	900°	9.3	11.5	21.4	10.8

Test II gave some carbon according to the equation:

$$3CO + H_2 = H_2O + CO_2 + C_2.$$
$$2 \text{ vol.} \quad 2 \text{ vol.}$$

Test I showed no gain in carbon. During the latter the water volume was nearly twice the volume of CO_2, and the presence of some methan could be detected.

This equation may explain it:

$$4CO + 8H_2 = 2H_2O + CO_2 + 3CH_4.$$
$$4 \text{ vol.} \quad 2 \text{ vol.}$$

By heating a mixture of CO and hydrogen at 400° and above only a few thousandths per cent of methan were obtained whose presence had not been detected till then.

Gautier assured himself that during such a process no gas was formed which could be absorbed by bromine or condensed at a low temperature, and that no ethylaldehyde or formic acid was produced, except some traces of formol.

The test was repeated at 1200° with a mixture of $CO + 6H_2$ (1 liter per hour), and the following result was obtained:

$$H_2 = 99.8 \qquad CH_4 = 0.2.$$

At 1300° and 3 liters per hour:

$$H_2 = 98.65 \qquad CH_4 = 1.35.$$

The velocity of gas passing the tube seems, therefore, to prevent the destruction and prevents the formation of heavy hydrocarbons.

During this last test 8 per cent of the carbon had been transformed into methan. A perceptible formation of other hydrocarbons did not take place.

The results may be summed up as follows:

1. The reduction of CO by hydrogen begins approximately at 400°, resulting in the formation of water, carbon and some methan.

2. The mutual reactions are limited and equilibrium is reached at approximately 1000°.

3. The formation of methan is favored by a higher percentage of hydrogen and by a greater velocity to prevent the splitting off of CH_4 at red-heat.

4. Between 450° and 650° traces of formol are formed, but disappear again at 950°.

In regard to the effect of steam on CO at higher temperatures, Gautier made some preliminary tests, using 100 volumes CO with an excess of steam and received the following results:

$$CO_2 = 37.9; \quad H_2 = 38.9; \quad CO = 22.5.$$
$$N_2 \text{ (from air)} = .7.$$

To prove the probable appearance of formic acid and formaldehyde between 500° and 900° the test was repeated.

The steam condensed after leaving the apparatus contained in 2cc. —0.000005 formol at 550°, at 800° 0.000001 formol, and no formic acid could be found in 2.5 cc. condensed steam.

As to the practical application of the results of Gautier to our metallurgical processes, the reviewer is of the opinion that they may perhaps help to explain the question of formation of hydrogen and methan in blast-furnace gas, which problem has not yet been solved satisfactorily or completely.

They may also be of use in explaining the change in analysis of producer-gas in a long gas main and in the checkers of regenerators. Especially the marked influence of steam on CO seems worth consideration, since a considerable amount of steam is found in all producer-gases.

A similar case is known to the reviewer, where cold coke-oven gas was mixed with hot producer gas in the main of a heating furnace. A report on this is reserved for later.

Sharpening of Tools by Electrolytic Etching*

BY ERICH SCHNECKENBERG.

The attack of an acid on a metal is increased if an electric current is passed simultaneously from the metal into the acid. The current at once carries away all the metallic particles dissolved by the acid, so that the metallic object always presents a clean, fresh surface for the attack of fresh acid.

The current for this purpose may be produced in either of the following ways: 1. A piece of gas retort carbon is placed in the same acid as the metallic object, and the carbon and the metal are connected by a wire outside of the acid, so that the whole forms a short-circuited galvanic cell, in which the current flows from the metal through the acid to the carbon. 2. The metallic object may be connected with the positive pole and another electrode in the acid with the negative pole of some external source of direct current.

In electrolytic etching the attack of the acid upon the tool can be centered and localized on any desired part of the tool, in any direction and strength. All that is needed for this purpose is to form the negative electrode or cathode in a suitable manner and put it in the right position. For in electrolytic etching the quantity of metal etched and removed at any spot is dependent entirely (aside from the time of etching and the concentration of the etching liquid) on the current density at that spot in amperes per square centimeter, and this current density depends on the resistance of the liquid along the various current lines (or tubes of lines) between the positive object and the negative electrode.

For tubes of lines of current of the same cross section this resistance is determined by their length and by the geometrical and physical characteristics of the two opposite surface areas of the metallic object and the negative electrode. These conditions can always be arranged in a suitable manner on the basis of some experiments.

It is possible, for instance, to devise suitable arrangements for sharpening any sort of tool, precision millers, etc. The material for the negative electrode, as well as the acid, must

*Translated from *Werkstattstechnik*, August, 1911.

be chosen accordingly, so as to prevent too rapid destruction of these devices. First of all, I will show how this work should not be carried on.

Several years ago Barthel, in New York, tried the following experiment: He placed some tools, first freed of rust and grease, into a mixture composed of 100 parts of water, 3 parts of 66 per cent sulphuric acid and 6 parts of 44 per cent nitric acid. In the case of tools with two flat surfaces he placed a flat carbon plate opposite to each side surface of the tool. Where round files, millers and drills were to be sharpened he used a cylindrical, hollow carbon tube. When he connected carbon and tool by a wire outside of the acid an electric current passed from the tool through the acid to the carbon.

The etching was, however, different at different spots of the objects, according to the distance and relative position of metal and carbon. Further the carbon also was attacked by the acid; the acid became black in color and the tool was covered with a layer of slime. The tool had, therefore, to be removed after a short time and cleaned, then again placed back and adjusted in position, and etching was resumed, repeating the entire process until the tool had been etched to sufficient sharpness. Then it was rinsed in water, cleaned with a brush, laid in lime water in order to neutralize any possible acid residue and dried with sawdust.

In this form the process was too complicated for workshop use. Moreover, the strength of the current always differed, depending on the surface characteristics, size and number of tools dipped and of the carbon pieces. Since the necessary time of etching depends on the current strength the sharpness of the tool attained by the process can only be estimated from the time consumed, if the current strength is always uniform. The strength of the current could, of course, have been brought to a standard value by connecting several resistances in the exterior circuit, and cutting out some of them when the emf between tool and carbon decreased. But this would have meant that since at the beginning of each etching period the emf was greatest, decreasing then rapidly, a large portion of the emf was to be consumed in the resistance. This, however, had to be avoided since the energy in this cell was anyway rather low.

The introduction of current from an external source (by method two) offers a much simpler and safer process. A storage battery giving 2 to 3 volts is suitable. With this method it is, of course, not necessary to use the most powerful electronegative element, carbon, in order to obtain a sufficiently high emf, but any suitable inert material can be chosen, without any consideration of its position in the contact series. The result is a good, proper etching process for shopwork use.

Grathwol, in Herisau, for example, succeeded in sharpening very dull files within one hour in this way. A patent was allowed him for a file-etching process in which the negative electrode, the cathode, is made of lead, and the electrolyte is sulphuric acid of about 1.18 specific gravity.

Since the quantity of metal etched away at any one place increases with the etching time, it is possible to subject an article to an etching process varying in strength at different places by withdrawing the object gradually from the bath.

Hall and Thornton, in Birmingham, sharpen metal tubes and rods to a point by connecting them with the positive pole of a battery, dipping the end to be pointed into the acid solution connected to the negative pole, and then slowly and gradually withdrawing it from the bath. In this way the rods become thinner and thinner the nearer to the end. This process can be applied to the sharpening of needles, so that thousands of these can be sharpened at one time. All that is needed is a simple trough, and instead of raising the needles gradually from the trough the level of the solution in the trough may be gradually lowered. Another advantage of this method is that the solution in which the metal is dissolved may afterwards be used for electroplating purposes.

Another modification of tool sharpening by electrolytic etching is possible if the tool is brought in contact with the electrolytic acid solution at those places only which are to be etched off, instead of placing the whole tool into the acid solution. This is accomplished in the following way: A mold is made of porous calcined clay corresponding to the desired form of the metal to be etched and is saturated with the etching solution and connected with the negative pole of a battery, and pressed with a slight pressure against the tool, which is connected to the positive pole. After a short time the mold electrode is removed, the tool brushed free of the solution, the mold electrode again dipped into a fresh acid solution, and again pressed against the tool. This method was used successfully by a large electrolytic engraving firm in Leipzig to etch reliefs into metal.

To what accuracy and precision this electrolytic etching process can be brought is proved by the die process of Burdett in Hartford, who etched whole designs, inscriptions and patterns into knives or other metallic surfaces. The metallic surface is covered with a thin layer of a mixture of 10 liters (2.6 gal.) naphthalene, 0.125 kg. (0.27 lb.) carbon disulphide, 2 kg. (4.4 lb.) powdered resin and 1.5 kg. (3.3 lb.) copper chloride. A thin coat of this is put on, and by means of a die which had first been cleaned with a weak caustic potash solution the design is pressed into the coating. Then the particles pressed out by the die are washed off with water; the entire coating is covered with a weak solution of ammonia or brine, a clean metallic surface laid on top and connected to the negative pole of a battery, while the metallic object itself which is to be etched is connected with the positive pole.

Then the electric current passes between the object and the metallic surface, through the ridges cut into the resin coating, so that after a short time the pattern is etched in sharp, clear, deep lines, after which the surface is washed with soda solution. This process also needs only very simple devices to make it fit for operation on a large scale.

Summary.—Electrolytic etching, in which the tool forms the positive electrode for the etching solution in contact with it, permits rapid etching in a simple way, on a definite spot, in a definite direction and strength, depending on the position of the negative electrode, which determines the current flow. It is much better to use an external battery as source of current, instead of generating a current internally from a reaction between tool, acid and carbon. An example for the practical application of tool sharpening by the electrolytic etching method, the electrolytic file sharpening, needle-point sharpening and relief production as well as die sinking work may be mentioned.

Notes on Chemistry and Metallurgy in Great Britain.

(*From our Special Correspondent.*)

Drawn-Wire Tungsten Filament Lamps.

Your correspondent was one of a party of representatives of the technical press who visited the British-Thomson-Houston Company's works at Rugby in August to inspect that company's lamp works and to be one of the intermediaries whereby the announcement was to be communicated to all concerned that drawn-wire tungsten filament lamps were now available in commercial quantities. Possibly a similar announcement and demonstration has been made on your side by the British-Thomson-Houston Company's parent, the General Electric Company.*

*As is well known to our readers, the new drawn-wire tungsten lamp is the outcome of a long series of researches on processes for producing ductile tungsten, carried out at the Research Laboratory of the General Electric Company, at Schenectady, N. Y., under the direction of Dr. W. R. Whitney. The successful work was the result of the efforts of a group of operators and research men, foremost of whom were Dr. C. G. Fink and Dr. W. D. Coolidge.—Editor.

One saw much that was interesting—the new lamps will stand an enormous amount of over-running. It was distinctly novel after one's close acquaintance in the past with carbon filaments, or more recently with squirted tungsten filaments, to see bobbins of tungsten wire from which requisite lengths are cut off as readily as is double cotton-covered wire for the use of armature winders. This is not the place to discuss small structural improvements which, apart from the filament, distinguish this lamp from its predecessors. Neither, and this is the more disappointing, can your correspondent say anything about processes conducted behind locked doors whereby tungsten in its powdered form is converted into a drawn wire. It is a triumph in science, lying on the borderland between chemistry and metallurgy, of great commercial value and more scientific interest. In course of time information, at first no doubt more or less erroneous, must leak out. Meanwhile one can only speculate as to how this has been effected.

A Month of Industrial Unrest.

Early in August the stress of a political crisis masked the symptoms of the labor situation. Unrest and discontent had long been prevalent in South Wales, there had been strikes in the seafaring trade, and employers of labor had recognized that the present trade expansion was liable to be throttled by labor disputes. Just as the Parliamentary situation was clear of all save the recrimination over the *fait accompli*, the trade of London, Liverpool and Leith was paralyzed by strikes of dockers and carmen. On top of this followed a national railway strike, with extensive rioting in South Wales and destruction of property in the Midlands. Considering all the facts of the suddenness of the calamity, the forces of organized civilization in the shape of constabulary and soldiers proved surprisingly adequate. Concessions of increased pay to dock laborers, increased pay and shorter hours for carters and lightermen (certainly justified in these cases) together with the appointment of a Royal Commission to go into the question of the Railway Conciliation Boards have calmed down the situation. The industrial machine therefore is getting into its stride again.

Short though the trouble has been, the loss has been very serious, and will be reflected in balance sheets and trade returns at a later date. Cotton mills and engineering works have been stopped for raw material, contracts have been lost, and the general dislocation will take a lot of adjustment. Of course, the effects of increased wages will lead to a redistribution of the charges incurred thereby; and we shall, unless the index-numbers of the world's food prices take a downward movement, encounter further demands.

The immediate economic questions sink into insignificance compared with the greater sociological questions now partly unveiled to the gaze of the man in the street. To the individualist it is an unwelcome fact that the power of the organized proletariat, by means of a general strike, to attempt to force say state ownership of mines or railways upon the general community brings the climax to the coming industrial struggle thirty years nearer than was anticipated thirty days ago.

The Formation of Sludge in Oil-Cooled Transformers.

An article in the *Times* of the 9th of Aug., by an engineering correspondent, discusses the general aspects of the problem presented to users of oil-cooled transformers, and to the manufacturers of oil for insulating purposes by the deposition of sludge, particularly on the windings and cores. The author says:

"Of the hypotheses advanced to account for the trouble one ascribes most of it to the absorption of vegetable acids from varnishes nominally, but not actually, oil resisting, the balance being attributed to the ingress of dust, which is attracted electrostatically to the windings, and to the thickening of the material through chemical action. The other hypothesis is purely a thermal one, and predicates that a fractional distillation of the oil takes place through high temperatures. In investigating the problem in any case when the deposit has reached such a stage as to call for a renewal of the oil, the difficulty is encountered that very often little or nothing is known of the initial qualities and subsequent history of the oil, while not sufficient is known of the temperature ranges in the transformers themselves. Probably there are cases which the first hypothesis meets, but there are undoubtedly others to which it cannot apply, and for which the thermal hypothesis is necessary in order to afford a complete explanation of the phenomena observed."

He then proceeds to outline the changes produced in transformer oil by baking at temperature from 230° F. to 270° F., details of which can be found in a paper by Digby and Mellis, published in the Proceedings of the Institution of Electrical Engineers, 1910. The results then given were considered to be mainly of academic interest, but, in connection with the thermal theory of formation of sludge, those results, together with further investigation, might be of very practical value.

The time which elapses before any noticeable deposit of sludge occurs varies considerably. The colloidal deposit has been observed after only six months running of a transformer; but generally the accumulation of a serious deposit occupies from three to six years. Observations with thermo-couples have shown that at points where the core-plates are burred the temperatures are from 15° F to 25° F. higher than the warmest portions of the oil remote from such positions; and, of course, the deposition of sludge prevents the normal distribution of heat by convection and gives rise to a largely extended area in which the heat is unduly augmented.

Analyses of sludges have yielded some very interesting information as to their various metallic and organic constituents; and the research is being continued in the hope of elucidating the causes of a trouble the importance of which is now recognized.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the seven months ended the 31st of July gives the value of the imports of iron and steel, including manufactured articles, at £6,501,659 and of exports as £25,373,018, and the respective increases over the value for the corresponding period of 1910 are £1,511,050 and £485,396, but in July, 1911, there was a deficiency of £727,055 as compared with July, 1910. For other metals, including manufactured articles, the imports were of the value £16,044,504 and the exports £6,322,193, and the increases as compared with the value for last year are £2,607,777, and £463,622. Imports of electrical goods, exclusive of machinery and line wires, amounted to £795,065, a decrease of £46,026, while exports were £1,542,133, or a decrease of £420,556. The value of imports of machinery was £3,575,125, with exports £17,952,018, showing increases of £956,676 and £1,100,728, respectively. Importations of new ships were put at £48,203, and exports at £3,220,582, the imports having improved by £40,856, and the exports having decreased by £1,636,275.

The British Association.

At the meeting at Portsmouth on the 31st Aug., Professor H. H. Turner in his presidential address to the Mathematical and Physical Science section on "The Characteristics of the Observational Sciences" declaimed against the dangerous—he might have said pernicious—doctrine that work done before the formulation of a law was in any way inferior: and instanced the valuable results of W. W. Campbell's observations of the line of sight velocities of stars at Lick Observatory, Professor Schuster's analysis of facts bearing on the periodicity of sunspots, Groombridge's observations of stars, and M. Teisserene's meteorological observations with balloons.

In so doing the professor was only voicing the opinion of the practical scientist against the tendency only too prevalent at present among some possessing high scientific repute to theorize on any and every subject, formulate a "law" from their questionable speculations, and then cast about for apparent

facts which may by hook or crook be distorted into some semblance of evidence in support of their precious "law." Science is not gaining anything by the substitution of such methods for the true and nature-guided work of men like Davy, Faraday and Tyndal; or we should not find our ears assailed at assemblages of "scientific" men with such onological absurdities as the expression, pretty frequently used of late, "atoms of electricity." A certain person of considerable reputation as a scientist several years ago at an annual meeting of one of the leading London scientific societies uttered the exhortation "therefore, gentlemen, let us DREAM," and it is only too apparent that there are many who do not need such advice to cause them to give preference to methods bordering on the metaphysical.

A Fourth Recalescence Point in Steel.

John O. Arnold (Intern. Zeitsch. Metallog., 1911, 1, pp. 192-203), as a result of comparing cooling curves of steels of varying carbon content with curves of iron containing no carbon, has found that an evolution of heat occurs with steel between the Ar_3 and the Ar_1 points. The greatest disengagement of heat is obtained with steels having a carbon content of about 0.45 per cent., which would consist of approximately equal proportions of pearlite and ferrite. This recalescence the author supposes to be due to constitutional segregation of the solid solution with formation of microscopic distinct masses, beginning at Ar_3 and ending at Ar_1.

Cementation of Chromium Steels.

F. Giolitti and F. Carnevali (Atti. R. Accad. Sci. Torino, 1911, 46 pu. 558-568) have experimented with a chromium steel containing 2.33 per cent. Cr, 0.41 per cent. C, 0.15 per cent. Si, and 1.02 per cent. Mn, by cementation in the same way as that adopted for nickel steel (Journ. Chem. Soc., 1911. ii., p. 609). The results of five hours' treatment in ethylene at 950°C., and at 1050°C., treatment with carbon monoxide for the same time at the same temperatures, and with various mixtures of carbon monoxide and carbon dioxide at 1000° and 1100° indicate that the differences observed in the action of these cementing media on carbon steels are produced similarly in chromium steel. The presence of chromium tends to augment the maximum concentration of carbon in the zone of cementation in comparison with the maximum in carbon steel similarly cemented.

Determination of Chromium in Chrome Iron Ore.

Otto Nydegger (Zeitsch. Angew. Chem., 1911, 24, pp. 1163-1164) takes 0.5 gramme of the powdered ore with 5 grammes of a fused and powdered mixture of two parts of anhydrous sodic carbonate with one part borax glass, and heats the mixed ore and fusion-mixture in a platinum crucible over a bunsen flame until all the ore is taken up—from an hour to two hours being required. When cool the mass is dissolved out with 300 cc. or 400 cc. of water containing one volume per hundred of sulphuric acid. Any residual unoxidized chromium is converted into chromate with 0.2 gramme of potassic persulphate, which precipitates, as peroxide, any manganese that may be present. Excess of persulphate is decomposed by boiling for half an hour or so, the MnO_2 is filtered off, and the chromium is estimated volumetrically by ferrous ammonium sulphate with a potassium ferricyanide indicator.

Market Prices During August, 1911.

Copper has been fairly quiet throughout the month. Opening at £56.7.6 it rose to £57 per ton on the 14th, since dropped to about £56.5.0, and closes at £56.2.6.

Tin dropped smartly away from its opening price until it reached £189.10.0 on the 14th. Had risen again to £191.0.0 by the 18th; since irregular, and closes at £189.15.0.

Lead has been fairly steady, with rise of 5/- on the 18th. Opened at £14.5.0, closes at £14.10.0.

Haematite shows a sharp rise from £3.1.3 on the 10th to £3.3.0 on the 18th. Since fell again and closed at £3.2.9.

Scotch Pig rose in sympathy with iron generally from £2.12.1 to £2.13.8 by the 18th, closing at £2.13.3.

Cleveland opened at £2.6.10, showed a sharp drop on the 16th to £2.6.3, afterwards rising to £2.7.6, and closing at £2.6.11.

Rubber (Parafine) has not exhibited any marked changes, was at 4/6½ on the 16th and 4/9 on the 23d; closed at 4/10.

Alum, lump, loose, per ton	£5.12.6
Antimony, black, sulphide powder, per ton	22. 0.0
Borax, British refined crystal, per ton	16. 0.0
Copper Ore, 10 to 25.2, per unit	9/6 to 10.0
Copper Sulphate, per ton	19. 5.0
Carbolic Acid, liquid 97/99 per cent, per ton	0. 1.6
Creosote, ordinary good liquid, per gal	0. 0.2⅜
Camphor, 1 oz. tablets	0. 1.9½
Caustic Soda, Ash, 48 per cent, ordinary, per ton	5.10.0
Litharge, flake, per ton	16. 0.0
Mica, small slab, original cases, per lb	0. 2.0
Naptha, solvent, 90 per cent, 160° C, per gal	0. 0.8
Petroleum, Russian Spot	0. 0.5½

Newcastle Meeting of the British Institute of Metals.

The autumn meeting of the (British) Institute of Metals was held at Newcastle-on-Tyne on Sept. 20, 21 and 22; that is, practically simultaneously with the Toronto meeting of the American Electrochemical Society.

We reserve an account of the excursions, visits and social functions for our next issue, but give herewith concise abstracts of the papers presented.

This young but exceedingly active society must be congratulated on the high intrinsic value of the papers presented at its meetings. The society continues to live up to the high standard set right at its start and it will be seen that the last meeting was no exception.

The headquarters of the Institute, with the office of its very active secretary, Mr. G. Shaw Scott, are at Caxton House, Westminster, S. W. London.

Alloys of Copper and Tin.

A paper by Mr. J. L. Haughton and Prof. T. Turner dealt with "volume changes in the alloys of copper with tin"

The work of which Mr. Haughton presented an account may be regarded as a continuation of previous researches on the changes in length which occur in a cast bar during and after solidification. To these investigations Picken, Simpson, Murray,

Hague, Ewen and Coe (former research students in the University of Birmingham) have contributed. The method employed has been that of applying an extensometer to one end of a cast bar while the other end was kept fixed. With a single substance, such as a pure metal or a definite compound, the extensometer does not appear to act until immediately after solidification has occurred, and contraction thereafter proceeds regularly. But where internal changes take place due to such causes as the separation of a constituent, or of a eutectic, from the solid matrix, such changes are indicated by changes in length of the bar. The separation of a constituent is generally accompanied by an expansion, while if the interval between the solidus and the liquidus is considerable the expansion of the cast bar is also generally large, and it extends over a considerable interval of time.

The apparatus employed has been modified by the author in order to allow a single operator to observe both pyrometer and extensometer readings at the same instant and to record these results by means of a chronographer on a paper tape. In a few cases tin-copper alloys have been already examined by Ewen and by Wüst, and it is desirable to note that the agreement between the author and these previous workers is generally quite satisfactory.

The paper clearly shows that there are four maxima in the expansion curve and that three of these, with about 10 per cent, 46 per cent and 65 per cent of tin respectively, agree with the "crystallization interval" as determined from the accepted equilibrium diagrams. The maximum observed at 30 per cent of tin is not easy to explain, though it may be pointed out that the equilibrium diagram at this point is exceptionally complicated and that perhaps the "crystallization interval" should extend down to 500° C., in which case the maximum would fall into proper order. Mr. Haughton records the fact that certain of the intermediate alloys of the series are remarkably insoluble in acids and ordinary solvents. Hence the analysis presented unexpected difficulties. These were overcome by the use of bromine and this simple and direct method of solution may be of use to other investigators of the tin-copper series.

Alloys of Aluminium and Zinc.

A paper by Dr. Walter Rosenhain and Mr. S. L. Archbutt, both of the (British) National Physical Laboratory, dealt with "the alloys of aluminium and zinc."

The paper describes a detailed investigation of the constitution of the alloys of aluminium and zinc which was undertaken in connection with an extended research on the light alloys of aluminium—the latter research being carried out by the authors on behalf of the alloys research committee of the Institution of Mechanical Engineers.

The present paper describes the detailed thermal and microscopic study of the alloys. A long series of cooling curves were taken at a very slow rate of cooling, and in many cases the ingots of the alloys were subjected to prolonged annealing before the cooling curves were taken. The microscopic examination of the slowly cooled alloys was supplemented by the study of specimens which had been annealed and quenched at various definite temperatures.

The results are embodied in an equilibrium diagram which differs considerably from the diagram of Shepherd, which has hitherto been accepted; these differences result from the discovery of the existence of the definite compound Al_2Zn_3 which has a stable existence only between 443° C. and 256° C.; in the majority of the alloys this compound is only slowly formed by a reaction between crystals of zinc and an aluminium-rich mother liquor at 443° C. At 256° C., however, the compound again decomposes into practically pure zinc and an aluminium-rich solid solution; this decomposition is, however, of special interest because it produces a finely laminated constituent closely resembling the "pearlite" of carbon steels. The research has been carried out in the metallurgy department of the National Physical Laboratory.

Non-Ferrous Metals in Railway Work.

A paper by Mr. George Hughes dealt with "non-ferrous metals in railway work."

In this paper the author has placed on record some of the methods of working and uses pertaining to the non-ferrous metals in locomotive and carriage construction.

The use of copper is described in the shape of plates, stays and tubes, and analyses, tests, specifications, together with life of material and instances of wear and failure, are described.

Copper fireboxes on the Lancashire & Yorkshire Railway have a life of from 10 to 16½ years, an average mileage for the older engines with 140 lb. pressure being 310,000 miles. Engines with 160 lb. pressure run from 235,000 to 272,000 miles. Individual tube plates show a life of 7¾ years.

Workshop methods, such as patching of copper firebox plates, brazing copper steam pipes, melting and mixtures of brass alloys, are dealt with, with the object of eliciting a practical and scientific discussion.

The molding and coring of an injector casting are referred to.

The author states that brass slide valves of the unbalanced type will run 1000 miles with a wear of 0.035 in. on the face. Balanced valves wear 0.0053 in. per 1000 miles, while even better results are showing from a modified form of valve for superheat designed by the author.

A short account of the bearing metals used under the name of white metals is included, together with a note of non-ferrous metals and alloys used in the railway carriage department.

Corrosion of Brass.

A paper of Mr. Paul T. Bruhl dealt with "the corrosion of brass, with special reference to condenser tubes."

It is urged by the author that so important a subject as the corrosion of brass by sea water, the neglect of which must mean no slight expenditure, should induce steamship companies to keep records bearing on the subject. It has been this lack of data that has hitherto retarded the solution of the corrosion problem. All the companies with whom correspondence was opened possessed "no definite information."

The conclusions arrived at by the author are:

1. That the presence of air or an increase of temperature up to a certain point accelerates corrosion.
2. That iron, nickel and small amounts of lead are injurious; tin up to 1 per cent, large amounts of lead and aluminium are useful in diminishing corrosion.
3. That the inlet pipe and the condenser plates should preferably be made of brass.
4. That the condenser should be protected against stray currents.
5. Protective coatings are not recommended.
6. The importance of "spills" cannot be exaggerated.
7. That the tubes should be flushed with clean water after use.

Hard-Drawn Copper.

A paper by Mr. D. R. Pye discussed "the mechanical properties of hard-drawn copper."

In this paper the lack of any satisfactory definition of standard hard-drawn copper is pointed out. Although the (British) Post Office specification is highly satisfactory for the sizes of wire used in telephone and telegraph construction, it is quite unsuitable for larger sizes. The various definitions adopted from time to time are reviewed, and it is suggested that the one at present adopted by the Engineering Standards Committee, viz.: "The term hard-drawn copper wire shall apply to copper wire which does not elongate more than 4 per cent on a gage length of 10 in. when broken by tension," though not contradictory of the properties of hard-drawn copper, is unsatisfactory since a specification should preferably fix a *minimum* elongation as a safeguard against the wire becoming brittle. An important point is that tensile strength per square inch and elongation at fracture both depend on the diameter of the wire.

Experiments are described confirming a suggestion made by Mr. A. P. Trotter that this tensile strength per square inch diminishes with increase of diameter according to a linear law. It is also shown that the elongation at fracture for similarly manufactured wires depends very much on the diameter, being considerably greater for larger sizes of wire.

In view of these experiments it is suggested that a satisfactory definition of hard-drawn copper wire would fix a minimum tensile strength per square inch given by the formula $T = 30 - 20\ D$ and a minimum elongation per cent at fracture given by the formula $e = 5\ D$ where D = diameter in inches.

This specification would hold good for all sizes up to 0.5 in. diameter. Finally this suggested definition is compared with the specifications of the American Society for the Testing of Materials, and an appendix is added, giving the results of some recent experiments in America showing the effect of hard-drawing upon the electrical properties of copper.

Electric Conductivity and Constitution.

A paper by Dr. W. M. Guertler dealt with "the electric conductivity and constitution of alloys."

The aim of this paper, which is one mainly of theoretical interest, is to call attention to the property of electrical conductivity in its bearing upon the practical determination of the constitution of alloys.

The so-called "equilibrium diagram" for alloys is now almost universally accepted as the basis for any systematic study of the properties of alloys, and hence it is of great importance to be able to construct it accurately, and to have a thorough knowledge of it. The relationship between concentration, temperature and any given property—electrical conductivity, specific volume, magnetism, etc.—is best and most clearly brought out by the employment of a co-ordinate system in those dimensions. Thus taking concentration and temperature as the base, we can erect ordinates from it whose lengths are proportional to the numerical values of the property under consideration, and so obtain a series of intersecting curved surfaces, each of which corresponds to a particular phase-region of the equilibrium diagram.

The converse problem is one of great importance, viz.: that of obtaining the equilibrium diagram (when it is unknown) by projection from these surfaces on to the basal plane.

The best known method, and one which has been hitherto and is still most universally employed for the determination of the equilibrium diagram, is that known by the name of "thermal analysis," in which special account is taken of the variations in the "total heat" of the systems under consideration.

The author discusses at length the limitations of "thermal analysis," and in particular explains why it fails in those cases where, as so often happens in practice, a state of complete stable equilibrium is unattainable within a comparatively short interval of time.

The respective merits of electrical conductivity and of specific resistance measurements are set forth and illustrated by numerous examples from practice.

Solid Solutions.

A paper by Mr. C. A. Edwards gave "further notes on the nature of solid solutions."

The main object of this paper is to deal with a few points of interest and difference raised in the discussion on a previous paper by Mr. Edwards on the same subject, and also to stimulate further discussion on a matter which is not purely of scientific interest. The main conclusion in the previous paper was that "solid solutions of two metals or intermetallic compounds are intimate crystalline mixtures and while the crystals are so small that the mass appears quite homogeneous they are, nevertheless, sufficiently large to retain their identity." The principal objection to this view was that it is opposed to the phase rule. A general review of solutions—gaseous, liquid and solid—is given in the present paper, after which review the author concludes that the above idea does not conflict with the phase rule, and in fact the phase rule was never intended to extend in its application to the internal nature of a constituent.

As regards solutions in general Mr. Edwards holds that gaseous, liquid and solid solutions are members of the same family, the different states of these members being due to differences in their molecular aggregation.

Failure of a Brazed Joint.

A paper by Dr. H. Louis discussed "the failure of a brazed joint."

The paper gives a brief account of the investigation of the cause of a failure in the braze of a steam pipe on a steamer, undertaken at the instance of the (British) Board of Trade. The author shows that the failure was due to corrosion following certain well defined lines in the brass, and he traces the cause of these lines to the presence of small quantities of lead and tin in the original brazing spelter. The lead-tin alloy separating out between the crystals of brass formed planes of weakness that gave access to the corroding solutions, and this brought about the gradual corrosion of the entire brazing material.

SYNOPSIS OF CURRENT LITERATURE.

Iron and Steel.

Electric Steel.—It is not often that the results of experimental work carried out on the scale of that described by A. Müller in *Stahl und Eisen*, July 20, finds its way into print. The work was that carried out by a German steel company on a three-ton Girod furnace preparatory to equipping their plant with electric furnaces. That connections to such a furnace can play such an important part in the life of the lining and the power consumption of it is well emphasized in the changes made by the author in question on his furnace. Where one connection was made to the top electrode and another to the bottom electrode it was found that the arc was thrown strongly against the opposite side of the furnace to the conductors. The top conductor was then split into two and led to the electrode on opposite sides, a single conductor being used on the bottom electrode. With this system the arc was blown toward the line. The final solution of the problem was to split both the conductors, bring them up to the furnace many feet underneath and then rise vertically, a pair on each side of the furnace, carrying the conductors leading to the top and bottom electrodes just as far as possible side by side. To increase this length the bottom electrodes were in electrical connection with the shell of the furnace so that connection with them could be made high up on the side of the furnace. This splitting of the conductors keeps the arc central and saves half the lining and all trouble with blowing out of the arc. Even the shell of the furnace was finally made of steel of low permeability. The energy saving in the conductor system and shell as revised amounted to 10 per cent over the first installation. The flat circular arc now carried on the furnace means an even greater saving of electrode, as previously when it was thrown off to one side it caused very uneven consumption and consequent waste of electrode.

The present system of working is to charge the furnace with about three tons of open-hearth metal and put on a current of 4000 to 6000 amperes. A highly oxidizing slag is formed and all the phosphorus and some of the sulphur is removed during this oxidizing period. The bath is then deoxidized under a new slag formed of lime, sand, ferro-silicon and petroleum coke or scrap electrode ends. This removes sulphur down to 0.01 per cent. On an average five charges are worked

in 12 hours, though this is dependent on the amount of impurities to be removed.

With the original form of two conductor connections where the arc was thrown to one side, the silica roof over that side, even with air cooling, lasted only 20 heats. With the four conductor system the roof now lasts 60 to 70 charges. Experiments are not yet completed as to the economy of using other materials in place of silica for the roof.

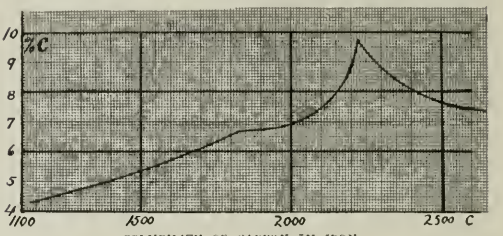
The side walls were first formed by ramming a mixture of magnesia and tar around a core shaped like the inverted frustrum of a pyramid. Such a lining cost $175. It was later determined that dolomite would most economically replace the magnesia so that all linings are now made of this material. They last 120 charges and cost $85. The total cost of lining, including repairs to slag line between heats, amounts to 30 cents per ton of steel. The area of the ends of the steel electrodes in the bottom bears the ratio of 0.05 to 80 to that of the whole bottom.

The bottom electrodes are water cooled in the ends projecting outside of the furnace. The dolomite bottom is rammed in between them with an air tamper, such a bottom lasting 1000 heats in a furnace run very intermittently. A calorimetric determination of the heat carried out in the cooling water of these bottom electrodes gave 10.1 kilowatt-hours for the 130-minute run, or about 1.01 per cent of the total electrical energy supplied, or 2.9 kilowatt-hours per ton of steel produced. The cooling water used in the top electrode carried out 36.7 kilowatt-hours, 3.65 per cent of total energy supplied, or 10.5 kilowatt-hours per ton of steel. The paper contains numerous other determinations of the power lost by stoppage, energy requirements for different weights of charges, etc., most of which are given in the form of charts.

The running of this small experimental furnace has thrown much light on the nature of many reactions in the refining of the steel. In the oxidation period carbon is but slowly removed, manganese more rapidly, phosphorus very rapidly and about 20 to 35 per cent of the sulphur. The sulphur appears to be removed in three ways: In the oxidation period by the action of the iron oxide in the slags; in the deoxidation period by solution in the high lime slags and volatilized as silicon sulphide. It has also been noted that oxides, slag emulsions and gases have a much more important bearing on the physical properties of the finished metal than the sulphur and phosphorus present.

Regenerative Furnaces.—A novel change in the construction of regenerative furnaces and one which has proven successful in practice is described by Fr. Bertiardt in *Stahl und Eisen*, July 3. The flues carrying the gases from the chambers to the furnace ports are led up separately to the furnace, and distinct from each other. The flues resemble flying buttresses so typical of Gothic architecture in the way they stand out distinct from the furnace. The gas is admitted to the hearth of the furnace in a nearly horizontal stream, while the air is brought down vertically through ports in the roof of the furnace. This construction does away with the narrow division wall between the air and gas ports in the usual style furnace, a source of great trouble at all times. A 17-ton furnace which formerly made on an average of 280 to 300 heats before requiring shutting down for repairs when provided with this new construction ran 630 heats. In a 40-ton furnace the new gas and air flues lasted 1500 to 1800 heats. The ports averaged 280 to 330 charges before requiring any repairs, and after that time the roof was in 50 per cent better condition than that of a similar furnace provided with the old-style ports.

Solubility of Carbon in Iron.—A new determination at high temperatures by Ruff and Goecke appears in *Metallurgie*, July 22. Iron was heated in a carbon crucible in a carbon resistance furnace. After standing at various temperatures for some time it was dropped into ice water and the carbon content determined. Temperatures were measured by the Wanner pyrometer. The results are shown in the accompanying curve, the per cent of dissolved carbon forming



SOLUBILITY OF CARBON IN IRON.

the ordinates and the temperature in centigrade degrees the abscissas. The change in direction at 1837° corresponds to the formula Fe_2C, the maximum at 2220° to the formula Fe_2C.

Copper.

Leady Copper Matte.—The treatment of leady copper mattes has always presented a serious problem to the metallurgist. Some new experiments which have led to the introduction of a new process are described by Robert Hesse in the June numbers of *Metallurgie*. The author started on the assumption that by smelting a leady matte with oxides of copper, lead and iron the lead could be removed in the metallic state, leaving the copper in the form of an enriched matte, the reactions involved being similar to those in the roast-reaction processes in use in lead and copper metallurgy. Numerous experiments proved the fallacy of this line of work as the only results were the production of a lead-copper alloy, and even that only when the amount of oxide present was very greatly in excess. However, when silica was added to the mixture of matte and oxides, or of roasted matte, black copper containing little lead could be produced and the larger part of the lead and iron slags off as a silicate. Even when an insufficient amount of oxide is present black copper will be produced together with an enriched matte containing but little lead. Low-grade mattes must be concentrated before the process is applicable, the author having great success with Octavi matte containing 40 per cent copper, 24 per cent lead and 11 per cent iron.

As the method does not require resmelting of anything but the lead silicate slag, which can be done in a blast furnace, it represents a saving of 60 per cent of the present cost of treatment as carried out at Altenau. An interesting conclusion drawn from his work is that with electric energy at a cost of $24 per kw-year the process of fusion can be more cheaply carried out in an electric furnace in Germany than in a reverberatory. The stages of the process recommended for the treatment of the Octavi matte are as follows: Pulverization to 2 mm, roasting to 4 per cent sulphur, fusion with silica. The black copper is refined, the leady slag going to the lead smelter with the silicate slag formed in the first fusion.

Chloridizing Roasting.—The chloridizing roasting of sulphide ores forms the basis of an extended study by Von Kothny in *Metallurgie* for July 8. He observed that when pyrite was heated in a stream of indifferent gas sulphur was first evolved at 200° C. and at 700° the pyrite had been transformed over into simple sulphide of iron. When heated in a current of air it started to transform itself to $FeSO_4$ at 250°, this being the only reaction taking place up to 200°. At higher temperatures it oxidized mainly to Fe_2O_3, though the reaction took place very slowly at temperatures below 500°. Any $FeSO_4$ formed was transformed by the oxygen to basic ferric sulphate which at 530° was decomposed into iron oxide and sulphur trioxide.

By the oxidizing roasting of copper sulphide mixed with iron

oxide and sodium choride practically all the sulphur goes into sulphate and about half the copper is transformed into chloride. Anhydrous cupric chloride mixed with sodium chloride and heated in a current of air to 250° gives off chlorine. The decomposition of copper sulphate by sodium chloride begins at 280°.

In a study of the reactions involved in chloridizing the author finds that the Hargreaves process by which hydrochloric acid is formed plays no part in converting cupric oxide into chloride. Neither does the direct action of chlorine on cuprous sulphide. Ferric chloride converts copper oxide into chloride very rapidly at temperatures around 500-600°. The formation of copper sulphate by roasting pyrite with copper oxide in the presence of sodium chloride plays no part. At temperatures of 300-600° ferric sulphate converts copper oxide slowly into sulphate. The author concludes that the mechanism of the chloridizing of a pyrite cinder containing a small amount of copper and sulphur is as follows: The copper is present largely as sulphide, which by an oxidizing roasting is converted into sulphate and oxide. Sodium chloride acts directly on the sulphate and ferric chloride on the oxide.

To insure chloridizing of such a material it must be finely ground; a large amount of air must be admitted in the oxidizing roasting period and stirring must be resorted to to insure contact with this oxygen; sufficient pyrite must be present to furnish the required amount of ferric chloride and is best added in a weathered form; for 4 per cent copper content at least 7.5 per cent salt must be added; the process should be carried out at temperatures between 500 and 600°.

Gold and Silver

Amalgamation Practise on the Rand.—In our issue for July, 1911, page 322, we gave a review of the proposals of W. R. Dowling regarding amalgamation of banket ore. These involved the removal of the plates from in front of the stamps and a large reduction of plate area used following tube milling. A further suggestion was that all amalgamation be carried on in a special plate house and that shaking plates be abandoned in favor of stationary plates. The reasons for Mr. Dowling's proposed changes were fully given in his paper.

In the June, 1911, issue of the *Journal* of the Chemical, Metallurgical and Mineral Society of South Africa, Mr. James E. Thomas contributes to the discussion of Mr. Dowling's paper and gives some data based on conditions before and after adopting Mr. Dowling's suggestions. These are conveniently tabulated in the following tables and present obvious conclusions.

Under the old system of plates in front of mortar boxes and shaking plates following tube mills the following results were obtained:

Average number of stamps running	235
Average aperture of mill screen	0.0461 in.
Average ratio of water to ore in mill	5.75 to 1
Average duty per stamp per 24 hours	9.459 tons
Average number of tube mills (22 ft. x 5 ft. 6 in.)	7
Average amalgamating plate area in use	5276 sq. ft.

The plates in front of mortar boxes accounted for 3351 sq. ft. of the total, and the shaking plates for the balance. The latter had a grade of 10 per cent and the pulp flowing over them a consistency of 2 to 1. The extraction by amalgamation was 56.8 per cent of the gold in the ore sent to the mill and by cyaniding 84.67 per cent of the gold in the cyanide pulp. The total extraction on the ore was 93.38 per cent.

During January and February of this year the plates were removed from the stamp mills and the shaking plates in the tube mill circuit were replaced by stationary plates. Comparative results follow:

Average number of stamps running	220
Average aperture of mill screen	0.0685 in.
Average ratio of water to ore in mill	5.17 to 1
Average duty per stamp per 24 hours	10.834 tons
Average number of tube mills (22 ft. x 5 ft. 6 in.)	10
Average amalgamating plate area in use	1700 sq. ft.

The plate area consists of three stationary plates per tube mill with a grade of 18 per cent; ratio of liquid to solid in pulp flowing over plates was about 1.1 to 1. The extraction by amalgamation was 55.52 per cent of the gold in the ore, by cyaniding 87.03 per cent of the gold in the cyanide pulp, and the total extraction was 94.23 per cent of the gold in the ore.

Cyaniding Pyritic Concentrate.—The concentration of black sand on amalgamated plates presents a special problem for the recovery of the gold which it contains, usually as particles of metallic gold attached to particles of pyrite. In the July, 1911, issue of the *Journal* of the Chemical, Metallurgical and Mineral Society of South Africa, Mr. R. Lindsay describes the method of treatment followed at the Geldenhuis Deep, Ltd. The concentrate treated results from the daily scrape from the mills and the barrel residue. The material is ground in barrels for four or five hours and then cleaned in the usual way over stationary copper plates. The flow from the plates is roughly divided in a settling tank into coarse and fine pulp, the former grading about 45 per cent — 200 and the later 98 per cent — 200. The former amounts to about 250 lb. daily, assaying about 30 oz. gold per ton. This is ground in a small tube mill to minus 200-mesh and passed into a batea containing a bath of 250 oz. mercury. The batea in this instance is used in place of an amalgamated plate and serves as a good amalgamator besides recovering some amalgam and mercury which escaped the first copper plate. From the batea the pulp flows to a tank where it is combined with the portion which was already as fine as minus 200-mesh.

The concentrate from the mill barrels is similarly first run over a plate and then divided into coarse and fine portions. The coarse is tube milled, combined with the fine, forming a pulp which is about minus 200-mesh in grade.

The combined fine pulps of pyritic concentrate from the plates and barrels is then ready for cyanide treatment. For this work an agitating and decanting tank designed by Andrew F. Crosse is used. This tank and a description of its use and operation were noted in this journal, February, 1910, page 72. The tank is conical, 7 ft. 6 in. in diameter and 8 ft. 4 in. deep, and has a content of 122 cu. ft. It has a capacity of 1800 lb. dry weight of material and there is no difficulty in obtaining a clear solution for decanting while air agitation is in progress.

In the present instance the practice is to agitate the charge with air for 12 hours before beginning to wash with weak cyanide solution. The gold goes into solution rapidly on account of the fine state of subdivision of the material, a charge assaying 250 dwt. gold per ton being reduced to less than 30 dwt. after one hour's agitation. At the end of 12 hours the undissolved gold in the concentrate is down to 6 dwt. per ton and the cyanide solution has a gold value of 56 dwt. per ton. Washing then proceeds at the rate of ½ ton solution per hour, agitation going on meanwhile. The quantity of solution required for washing the charge of 1800 lb. is six tons, and at the end of this operation the concentrate residue assays 4 dwt. per ton and the solution 0.08 dwt. per ton. This is about the economic limit to which solution and washing can be carried. The cyanide consumption is 2.75 lb. of 120 per cent KCN. Agitation requires 7 cu. ft. free air per minute.

Treatment of Old Slime by Air Agitation.—It is well known that accumulated slime which has become acid by reason of the oxidation of sulphur to sulphuric acid is not readily treated by the cyanide process on account of the heavy consumption of cyanide and the relatively large quantity of gold left in the residues. With a view to determining the best conditions under which such material could be treated, Mr. J. E. R. Adendorff made a number of experiments which are recorded in the July, 1911, issue of the *Journal* of the Chemical, Metallurgical and Mineral Society of South Africa. The material treated was accumulated slime containing 22.7 per cent

moisture, 0.024 per cent acidity as H_2SO_4, 2.31 dwt. gold per ton. The solution used was precipitated slime solution containing 0.017 per cent free KCN, 0.024 per cent total KCN and 0.02 per cent CaO.

Bottle tests were first made and these demonstrated certain facts, viz., the addition of lead acetate was beneficial in raising extraction; the free cyanide was well protected by the lime present; high residues pointed to a lack of oxygen.

Tests were then made on 100-lb. lots in a small Pachuca agitator. The reactions seemed to be most active within the first hour of treatment, during which the alkalinity and percentage of free cyanide dropped rapidly and had to be increased. About 50 per cent of the gold dissolved went into solution in the first hour and the economic limit of treatment seemed to be eight hours. In one test the original slime assayed 2.53 dwt. gold per ton, and at the end of eight hours' agitation the residue contained 20 dwt. undissolved gold per ton. This test seemed to show that success depended on maintaining a high alkalinity during the first three hours of treatment and that lime should be added to the slime before treating with KCN solution. The beneficial effect of lead acetate also was noted in the agitation experiments.

The author makes no mention of preliminary aeration of the slime in alkaline water before the addition of cyanide, which is a condition of success that other experimenters have laid down with reference to the treatment of acid slime for the purpose of oxidizing the reducers present.

Australian Ball Mill Practice.—Pulverizers other than stamps are meeting with success in various parts of the world, and engineers are showing a commendable tendency to investigate the merits of the newer machines. The mills of Kalgoorlie, Australia, have for some time been using ball mills in dry crushing and with considerable success, as is shown by Mr. M. W. von Bernewitz in a contribution to the *Mining Magazine* (London) for August, 1911.

It is doubtful if the ball mill is operated anywhere with greater efficiency and less cost than at Kalgoorlie. The ore ground averages 60 per cent silica and is considered hard to grind. It is dry enough for milling, containing from 0.5 per cent to 1 per cent moisture. Anything above this figure retards the crushing action. The best foundation for these mills has been found to be reinforced concrete blocks, as no other structure has given the required freedom from vibration. Two sizes of Krupp mills are used in Australia having the following dimensions:

	No. 5 Inches	No. 8 Inches
Diameter	80	106
Width	46	54
Outside screen area	46 x 26	54 x 24

Approximately the net screening surface in each mill is 70 sq. ft. and 100 sq. ft. respectively. From 24 r.p.m. to 26 r.p.m. is the correct speed for the No. 5, and from 21 r.p.m. to 24 r.p.m. for the No. 8 mill. They are loaded with from one to two tons of 5-in. steel balls, according to the size and hardness of the ore to be ground. There is no advantage in feeding several sizes of balls. The No. 5 mill takes from 18 hp to 23 hp when in average working condition and the No. 8 consumes 50 hp to 60 hp. Where motor driven the ammeters register 60 amp to 65 amp at 550 volts.

The balls are fed either through the manhole or hopper, and ore is added until the balls are well mixed with it. A mill should not be started without ore and the mass of ore and balls should be evenly distributed with no bare balls showing.

The efficiency of the ball mill over some other forms of grinders, notably stamps, lies in the fact that as soon as the ore is ground fine enough it must pass out of the mill. The ore crushed by the balls passes through the perforated grinding plates and is screened by the inside or coarse screen, the oversize being returned to the mill for further grinding. That part which passes the inside screen is further screened by the outside screen and the oversize returned to the mill.

Mr. von Bernewitz calls attention to the fact that the grinding of a ball mill generally has been supposed to be due to impact, but from observation he is convinced that this is not so and that the grinding is due to rolling and abrasion. The balls are lifted only to about the height of the mill axle and then roll back, rubbing and grinding the ore. This belief is confirmed by a microscopic examination of particles of various sizes taken from a mill. The larger ones, say plus 30-mesh, are shown to be rounded, while the finer grains, say plus 120-mesh, are angular.

The average consumption of balls is about 0.55 lb. per ton, and the grinding plates last about 190 days. A No. 5 ball mill will crush ordinary sulphide ore up to 43 tons daily and the No. 8 up to 100 tons. Dividing this by the horse-power consumed we get 2.1 tons and 1.6 tons per horse-power respectively. In a small plant of 100 tons daily capacity the No. 5 is a useful unit, but in larger plants the No. 8 is preferable. On quartz the capacity of the No. 5 mill is about 30 tons per day. The capacity of the mills is greatest with a feed of 3-in. material. The cost of ball milling is given by the author for several mills in Kalgoorlie. Depending on the ore treated, this varies about 35 cents to 65 cents per ton.

Wet Method for Making Gold Assays in the Field.—In a paper read before the Institution of Mining and Metallurgy, London, May 31, 1911, Mr. G. M. Austin gave his experience with a method of assaying for gold ores by a wet process suitable for use in the field where the usual facilities are not at hand. In brief the method is as follows: 1 A. T. of pulverized ore is treated with 50 c.c. of a solution containing 2 parts of iodine and 4 parts of potassium iodide in 100 parts of water. The mixture is ground in a mortar, and if necessary more iodine is added. The color of the mixture should remain brown. After 10 minutes' grinding and one hour standing the mixture is filtered and the solution agitated in a bottle with 3 g. of pure mercury. The color will disappear and the gold will be reduced and collected in the mercury.

The mercury is then separated from the solution and treated in a dish with 10 c.c. of nitric acid. The mercury will dissolve and leave the gold in a compact form ready to be annealed and weighed, or fused into a button and measured, or compared with standard beads mounted on a card.

Mr. Austin's experience with this method on a variety of ores gave the following results. Oxidized ores containing only a trace of gold showed this trace quite plainly. Low results were obtained in every case with basic ores containing manganese. Iron pyritic ores gave rather low results and copper pyritic ores containing as high as 34 dwt. gave no gold even after roasting. Telluride ores gave fair results, but the consumption of iodine was high. Ores containing blende and mispickle gave only about 75 per cent of their gold content.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Desulphurizing and Nodulizing Iron Ores.—For the utilization of pyritic cinder and other finely divided iron ores which are not fit for use in making iron, Mr. Tom C. King, of Marion, Ala., has invented a desulphurizing and nodulizing kiln which reduces the sulphur content to substantially nothing and discharges a sintered and agglomerated product suitable for blast furnaces. As shown in Fig. 1, the device consists of a rotating kiln suitably mounted and driven, having a hood 8 mounted on a carriage 9, with a fuel and supply pipe 11 projecting through the hood. The upper end of the kiln projects into a boiler setting, this end also being in connection with a feed chute 14. The heated gases issuing from the kiln are used to generate steam in the boiler 15. The inventor claims that he has found by practice that a temperature of 1200° Fahr. to

1500° Fahr. is sufficient to drive off the sulphur contained in the material and that a further temperature of 2000° Fahr. is required to sinter and nodulize the ore. The presence of moisture facilitates the operation, but no other binders or fluxes are used. (995,542, June 20, 1911.)

Gold and Silver.

Regeneration of Cyanide Solutions.—The recovery of the cyanogen present in solution in combination with the various metals it may have dissolved during the treatment of an ore is the object of a process patented by Mr. Raymond P. Wheelock, of Searchlight, Nev. Generally speaking the results of the process are first the precipitation and removal of such base metals as copper, lead and zinc which may have been dissolved during the treatment of the ore; second, the precipitation of any gold and silver which has escaped regular precipitation by the regular methods; third, the recovery of the cyanogen which was combined with these metals as soluble compounds.

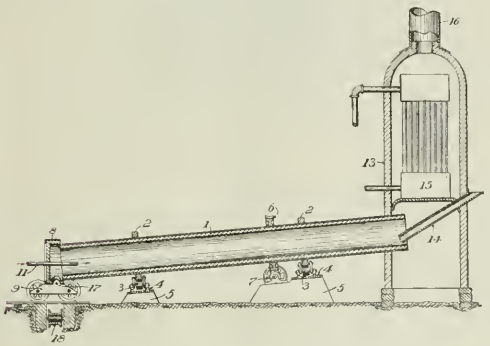


FIG. 1.—DESULPHURIZING AND NODULIZING KILN

The first step is to add sufficient sulphuric acid to the spent solution to precipitate as simple cyanides the metals held in solution as double cyanides of the metals and the alkali or alkaline earths present. This will liberate one-half of the cyanogen combined as double cyanides, which will be held in solution as hydrocyanic acid if care is taken not to agitate the solution. Taking copper as a typical case the following equation will show the reaction: $H_2SO_4 + K_2Cu_2(CN)_4 = K_2SO_4 + 2HCN + 2CuCN$. The precipitate is removed and the solution is rendered alkaline by the addition of a soluble alkali or alkaline earth, such as calcium hydrate, thus regenerating potassium cyanide as follows: $K_2SO_4 + 2HCN + Ca(OH)_2 = CaSO_4 + 2KCN + 2H_2O$. The precipitate resulting from this step is filtered off and the resulting clear solution used again as a solvent for gold and silver.

The precipitate resulting from the addition of sulphuric acid may be further treated with acid and heated to evolve hydrocyanic acid which can be combined with a solution of an alkali for further use. The metals remaining from this treatment can be recovered if their value warrants the operation. (996,179, June 27, 1911.)

Improved Cyanide Process.—Mr. John C. Clancy, of New York, whose inventions relating to cyanidation have been repeatedly noted in these columns, has patented another procedure based on his discovery that when pulverized ore is treated with a solution of a thiocyanate containing a halogen salt, and electrolyzed, the precious metals only will be dissolved to the exclusion of the baser metals, and that the process may be applied successfully to either rebellious or non-rebellious ores without preliminary roasting.

The following example is given: 2000 lb. of pulverized ore are suspended in a solution of 2 lb. of thiocyanate, 2 lb. of caustic soda or lime, 1 lb. of potassium iodide, the mixture being in the proportion of two parts of solution to one of ore. This mixture is continuously circulated for a period of eight hours through an electrolyzer having a current density of about 50 amp per square foot of anode surface. About from 90 amp to 100 amp are used per ton of ore. The function of the current is simply to produce nascent oxygen or liberate iodine from the salt. The same solution can be used repeatedly by keeping up the requisite strength of thiocyanate, but no further addition of iodide is required except to compensate for mechanical losses. The reason for using thiocyanate alone or in conjunction with simple cyanide solution in preference to the ordinary alkaline cyanide solution is that, if cyanide solution be used without containing thiocyanate or the addition thereof, the nascent oxygen produced by the current destroys the cyanide by converting it into a cyanate which is not a gold solvent. The following equations represent the reactions which occur: (1) $KCNS + H_2O + 3O = KCN + H_2SO_4$. (2) $KCNS + KI + 4O = ICN + K_2SO_4$. (908,749, July 25, 1911.)

Refining Gold and Silver by Distillation in Vacuum.—The present methods of refining gold and silver bullion consist in electrolyzing their solutions. Mr. William C. Arsem, of Schenectady, N. Y., proposes to effect a separation and refinement by distillation at proper temperatures in vacuum. He finds that silver can be completely distilled from an alloy by heating it to a temperature of about 1300° C. in a nearly complete vacuum. Subsequently the gold can be separated from any remaining refractory metals such as platinum by raising the temperature to about 1500° C.

The furnace in which Mr. Arsem carries out his distillation is shown in sectional elevation in Fig. 2. The main envelope

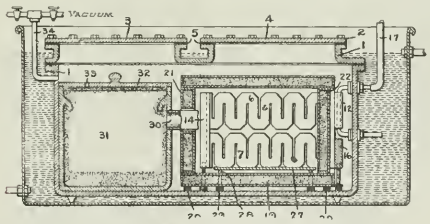

FIG. 2.—SILVER DISTILLATION FURNACE

of the furnace is a rectangular box 1 with a cover 2 bolted to it. The heating element consists of four graphite grids 6, 7, 8, 9, which attain a uniform incandescence when the current passes through them. Current is supplied by way of water-cooled copper tubes passing through the envelope. The heating element is properly insulated by double graphite walls with a

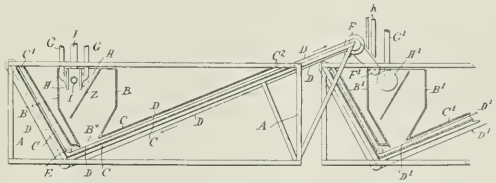

FIG. 3.—APPARATUS FOR SEPARATING CYANIDE SOLUTION FROM ORE PULP

packing of graphite. A crucible of suitable form containing the charge of bullion is placed in the heating space and connected with the condensing chamber 31 by a tubular outlet 30. The condensing chamber is of earthenware or iron of proper size to insure condensation, and properly water-cooled. The vacuum pump is connected with the pipe 34 and is kept in continuous operation throughout the distillation. The distillate can be re-

ceived in a container which can be removed from the chamber when the operation of distillation is completed. (998,665, July 25, 1911.)

Separating Solution from Ore Pulp.—A machine designed to afford a simple and inexpensive means of recovering the valuable cyanide solution from treated ore pulp has been patented by Horace G. Nichols, of Ymir, B. C. One of the difficulties of such separation which the machine is designed to overcome is that of causing the settlement of the finely divided pulp held in suspension in the fluid mass. This is accomplished by steadily and continuously withdrawing the solid matter as it settles from the deepest part of the machine by means of an endless moving belt traveling near the bottom of the tank. As shown in Fig. 3, the device consists of a supporting framework *A* in which is mounted a settling tank *B* converging to a bottom opening *Bx*. An endless traveling belt *D* moves along the bottom of the tank, finally emerging with a layer of settled solids and returning to the tank as shown in the drawing. The angle of inclination of the belt is from 20° to 25° with the horizontal. As pulp is fed into the receiving tank *B*, solids settle to the deepest part and are removed continuously by the belt. Valuable solution is withdrawn by means of suction applied through the pipes *G* to the surfaces *H*, the latter being covered with suitable filtering medium. The filtration may be stopped and the accumulated slime blown from the filters by means of a current of any fluid applied in the reverse direction to that of filtration.

The inventor claims that this procedure will remove the solids with a content of 22.5 per cent moisture, and if desired these solids may be similarly treated in a second tank with washing solution for the removal of the contained value. In practice the inventor finds that three of these tanks in succession are sufficient for complete washing. (996,877, July 4, 1911.)

Sand and Slime Classifier.—An improvement in a former machine of the inventor, John V. N. Dorr, of Denver, Col., has been devised for the purpose of more completely eliminating moisture or solution from the classified sand. The form of the improved machine is not greatly different from that

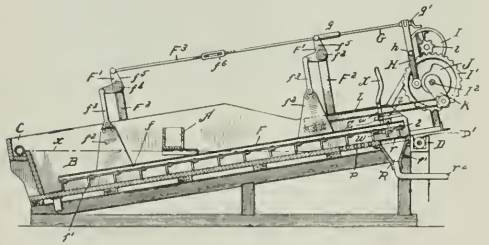

FIG. 4.—SAND AND SLIME CLASSIFIER

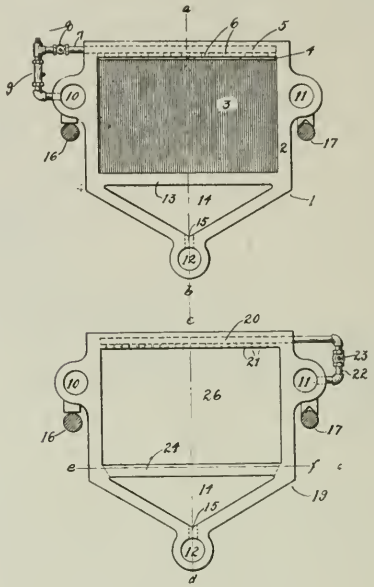
of the older, and is shown in Fig. 4. It consists of an inclined settling box B, which is fed with the ore pulp through a launder A. The liquid level in the box is indicated by the line *x*. Moving within the settling trough is a reciprocating rake which moves settled sand up the inclined bottom of the trough on its forward movement and rises above the sand on its return. The sand is thus continuously removed from the slime which overflows at the launder C. Ordinarily in the use of this classifier the sand is removed with about 26 per cent moisture, but it frequently is desirable to deliver drier sand, and it is the purpose of the present improvement to accomplish this end.

Near the point of discharge of the sand, above the level of the liquid in the settling box, will be seen a suction box R which is used for the removal of moisture. The suction box is connected with an exhaust pump by pipe r^2. The arrangement and shape of the rakes is such that an even layer of sand is steadily moved onto the surface of the suction box so that the moisture may be withdrawn uniformly. In this way the sand may be withdrawn with 9 to 10 per cent moisture. If it is desired to wash the sand at the time of discharge this may be accomplished by means of a spray pipe W, carried by the rake and arranged to deliver a spray of water on the sand during the upward stroke of the rake. (996,624, July 4, 1911.)

Filter Press.—In Metallurgical and Chemical Engineering for January, 1910, p. 52, there appeared a description of



FIGS. 5 AND 6.—FILTER PRESS

the filter pressing of slime by means of the Sweetland press. The inventor of the press, Ernest J. Sweetland, of Los Angeles, Cal., has recently patented a form of press differing in some features from that described last year. The principle on which the press works can be understood by reference to Figs. 5 and 6, which show respectively a filter frame or drainage unit and a distance frame unit of the press.

The cycle of operations in the press, viz., filling and forming the cake, washing and discharging the same, can be performed without opening or breaking the press. Each of the frames making up the press has three openings at 10, 11 and 12, which register exactly when the frames are locked in the press and form a continuous channel connecting with pipes at the ends of the press. The drainage frame has a rectangular corrugated part 3, connecting with an upper groove 4 and channel 5. The latter is further connected by suitable pipes and fittings 7, 8 and 9, with the opening 10. The part 9 is a glass tube through which the filtrate can be seen as it comes from the unit. The distance frame corresponds in outline with the drainage frame, but is open in the rectangular portion. The opening 11 is connected by suitable pipes and fittings 22, 23, with a channel 20, which has passageways 21 communicating with the rectangular space 26. In both drainage and distance frames the triangular space 14 is open and connected by a passage 15 with the opening 12.

The frames described are placed alternately in a press, and a filter cloth is placed over each side of the drainage unit. The press is filled through the channel 12 at the bottom of the press. The filtered liquid passes through the cloths on the drainage unit, upward through the corrugations 3 to the groove 4 and thence by 5, 6, 7, 8 and 9 to the conduit 10, which has a pipe connection carrying the fluid to the desired place. When

the cake has formed to a sufficient thickness the excess pulp is withdrawn through the conduit 12 and wash water or solution forced in through the same opening. When the pressure is withdrawn from the cakes they are held onto the filter by vacuum applied through conduit 10. In discharging the cakes from the filters, compressed air or water is forced through conduit 10, whereupon the cakes drop into the triangular space 14 and are flushed from the press by means of water jets at one end. At the same time the filter cloths are washed clean by means of jets of water forced through the conduit 11 and openings 21.

A further claim of the inventor is that the triangular space 14 serves as a storage of filtered pulp. In some cases only thin cakes can be formed on the cloths, and then it is more convenient to drop those cakes off into the space 14 and continue filtering without flushing the cakes out of the press. This he claims is possible because the plastic mass of discharged cake does not disintegrate under the action of the inflowing pulp. (996,537, June 27, 1911.)

Copper.

Smelting and Converting.—Mr. George Mitchell, of Los Angeles, Cal., proposes to construct a furnace in which reverberatory smelting and converting operations shall be carried on in the same furnace structure, and the heat evolved in the converting process utilized on the smelting hearths. His patent papers show various combinations of hearths and converters, the latter being arranged intermediate the former and adapted to receive matte from hearths by gravity. (997,405, July 11.)

Arsenic.

Recovery of Arsenic from Ores.—An improvement in handling arsenical vapors is claimed in a patent recently granted to Ira F. Peck, of Providence, R. I. The arsenic-bearing material is roasted in a revolving drum and the vapors issuing therefrom are conducted through a series of tanks which contain a thick creamy mixture of lime and water. A vacuum

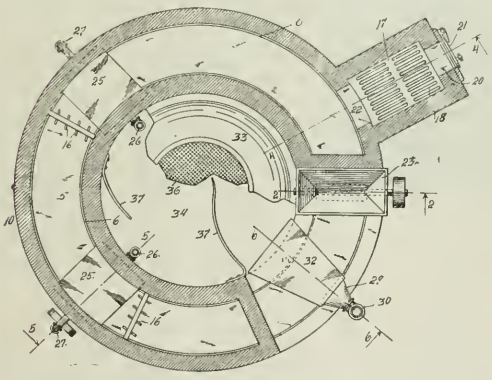


FIG. 7.—MAGNETIC ROASTER

applied at the last tank assists in causing the gas to flow through the lime mixture where the arsenic is absorbed. When the mixture in any tank has taken up as much arsenic as possible it is withdrawn and replaced with a new mixture. The composition of the lime mixture is about 25 lb. lime per 100 gallons of water. The recovered arsenic can be used in the manufacture of insecticides. (996,516, June 27, 1911.)

Magnetic Roasting.

Wilfley Roasting Furnace.—In the issue of this journal for April, 1910, page 171, mention was made of a new furnace designed especially for magnetic roasting of ores. A patent on this furnace has recently been issued to Arthur R. Wilfley, of Denver, Col. A plan view of the furnace is shown in Fig. 7. It consists of a roasting chamber 5 within which is an endless traveling annular hearth. Ore is fed onto the hearth from a hopper 23 having a distributing roll beneath its discharge opening. Heat is supplied to the roasting chamber from a furnace 17 by way of an opening 22. Stationary rabbles 16 are disposed above the hearth at intervals as shown, although if the ore bed is shallow they may not be needed. Receptacles 25 are placed above the hearth as shown, adapted to receive cooling water and thereby regulate the temperature of the hearth at these points. The roasted ore is removed from the hearth by means of a jet of steam delivered through a nozzle 29, this procedure being designed to cool the ore at the time of its removal and thereby prevent further oxidation of the sulphur. The ore thus blown from the hearth passes into the chamber 34, where it is distributed uniformly by the deflectors 37. It is then removed from the chamber in any suitable manner. (996,548, June 27, 1911.)

Aluminum.

The electric reduction of aluminum from its sulphide or a double sulphide of aluminium and another metal is the basis of a patent recently granted to Lucius R. Keogh, of Ottawa, Ontario, Canada. The process consists essentially of causing a reaction between a mass composed of sodium chloride or similar substance and anhydrous aluminium sulphate and carbonaceous matter. Intermediate reactions between these will form aluminium sulphide, thus:

$$6\,NaCl + Al_2(SO_4)_3 = 3\,Na_2SO_4 + 2\,AlCl_3.$$
$$3\,Na_2SO_4 + 6C = 3\,Na_2S + 6\,CO_2.$$
$$3\,Na_2S + 2\,AlCl_3 = 6\,NaCl + Al_2S_3.$$

The mass is fused by the application of heat, as by electricity, and the reduction of aluminium will follow. The process can be varied by withholding the carbonaceous material, in which case only aluminium chloride will be formed, which may be distilled away and collected. For the formation of aluminium sulphide and reduction to aluminium the anhydrous sulphate of aluminium is mixed with carbonaceous matter in equivalent proportions, finely ground, mixed with water to form a paste, dried and again finely pulverized. It is then fed into an electric furnace containing a fused bath of the sodium chloride or other selected reagent. The specific gravity of the bath must not be greater than 2.54 in order that the reduced aluminium can sink below it and be tapped from the furnace. The presence of fluorides in the bath contributes to fluidity and salts of lithium decrease the specific gravity of the bath. By regulating the current voltage so as to overcome the resistance of the circuit and just dissociate the aluminium sulphide, no other metal need be deposited, and the aluminium will be obtained free from any appreciable quantity of other metals. (996,094, June 27, 1911.)

Manufacture of Aluminum Nitride.—Ottokar Serpek of Paris, France, has patented a process for producing aluminium nitride from bauxite which he has assigned to Société Generale des Nitrures, of Paris. The general process is as follows: Ground bauxite is calcined, mixed with carbon and heated in an electrical resistance furnace through which is passed a stream of nitrogen generated for the purpose. The apparatus used is designed to afford a methodical heating of the substances with as complete recovery of the heat as possible. Reference to the complete specifications is necessary for a detailed explanation. (996,032, June 20.)

An improved aluminium alloy has been patented in the United States by Conrad H. H. Claessen, of Berlin, Germany. He makes use of magnesium and copper, the former in quantities not exceeding 2 per cent and the latter in quantities not exceeding 5 per cent. He has obtained particularly good results with an alloy consisting substantially of 99.5 to 99.75 per cent Al, 0.25 to 0.5 per cent Mg and 4 per cent Cu. The alloy is claimed to be light, and at the same time stronger and of better quality than either aluminum or the present alloys of that metal. (995,113, June 13, 1911.)

Toronto Meeting of the American Electrochemical Society

The twentieth general meeting of the American Electrochemical Society was held from September 21 to 23 (Thursday to Saturday), at Toronto, Ontario, Canada.

The number of members and guests registered was 125. The attendance was thus somewhat smaller than at most of the recent meetings of the Society, but this was hardly a drawback, as it gave a distinct homelike character to the affair. It was a very congenial gathering and the hospitality of Toronto was unbounded.

There were three professional sessions for the reading and discussion of papers, two on the morning and afternoon of Thursday in the Chemistry and Mining Building of the University of Toronto, and a third at the clubhouse of the Lambdon Golf and Country Club on Friday morning. In the whole nineteen papers were presented and discussed, and one more was released and distributed on the train on Saturday morning; printed advance copies were on hand of sixteen papers. In some cases a lively and interesting discussion ensued. A full account of the professional sessions with abstracts of the papers and discussions will be found below.

Smoker.

On the evening of Wednesday a very enjoyable smoker was given to the Society in the West Hall of the Main Building of the University. This will long be remembered for its main features as well as for the quaint arrangement of the whole, with the piper, the torchlight parade, and the song of Auld Lang Syne.

The main entertainment features were a remarkable exhibition of glass-blowing by Prof. E. B. Kenrick and an equally remarkable play by Section Q. Prof. Kenrick showed in the most skillful and entertaining manner the development of three embryos (glass bulbs) into a rooster, a cat, and a human being.

W. R. WHITNEY, PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY

The play by Section Q was entitled "The Electro-Comical Lab," and the playwright actors were Messrs. Lidbury, FitzGerald, Bennie, Saunders, Carveth, Hooker and Dushman. It was an electric-furnace farce, full of bright lines and clever fun.

The rise of the curtain showed an electric furnace room with three assistants getting up things. One has just graduated from a correspondence electric furnace engineering course of three weeks. Instruments are gathered together—an electrode indicator ("going, going, gone") an effishy-ometer (reading up to 250 per cent efficiency), also samples of electrochemical products. "Priceless" ferrotitanium, for instance (the only ferroalloy Mr. Price does not make). Everything is ready, when the doctor enters with a party of visitors to demonstrate the furnace.

To "graphitize our amorphous ideas" a little text of Browning for Section Q is quoted (back to his studies, fresher than at first, fierce as a dragon, he, soul-hydropic with a sacred thirst, sucked at the flagon).

The demonstration of the furnace begins. Not starting at first it is lubricated with jagdag. The furnace works and the visitors and the doctor talk. A phonograph also talks—an auto-starter, guaranteed to start discussion on any subject at any time. It is a pity that all the talk cannot be reproduced.

Dr. Zinc O'Chink, the efficiency engineer, is called in, explains water-cooling, sprays the electrode, the electrode breaks and the efficiency rises to 110 per cent. The furnace works now as an induction furnace. Just when the doctor has explained that the furnace is always working very smoothly, there is an explosion. An officer appears and arrests the furnace man—the "pinch effect," also demonstrating "the conductivity of the copper." Mr. Lidbury sings a clever song on making the punishment fit the crime.

The furnace has made graphite. Ferro-alloys are not attempted, since they are all patented several times each, though they are mentioned in the Old Testament. (Didn't Pharaoh's daughter discover Pharao Moses in the bull rushes?) So a steel mixture is tried. Fractional distillation of impurities begins, driving off nitrogen and oxides. When the furnace is to be tapped, there is trouble and resort is had to the latest remedy in treatment cases of electrothermic constipation, the squirt effect.

Three ingots of steel are tapped Owing to the high efficiency of the furnace, the metal is tapped at room temperature, while by watching the stack the visitors see that the furnace is now giving off solid CO_2. The ingots are taken to the rolling mill. The rail is tested, succumbs to the drop test, and is shipped. The demonstration is over. A song on Dr. Heroult is the finale.

It is impossible to do justice to the play in a brief review. But those who had the privilege of seeing it acted, enjoyed it immensely.

Before the smoker an exhibition was given in the basement of the Chemistry Building of the Evans-Stansfield electric furnace for producing titanium steel direct from ore. A feature of the furnace design is the arrangement of the electrodes, several sets being provided for starting and running.

Excursions and Banquet.

Friday was devoted to a trip to the Lambton Golf and Country Club. The professional session of the morning was held at the club house, while after lunch those who wanted to play golf did so on the beautiful grounds. Ideal weather contributed to the enjoyment.

In the evening of Friday a subscription dinner was held at McConkey's restaurant. Prof. Ellis acted as toastmaster with great success. Three toasts were drunk, to the President, to the King, to the Society.

Speeches were made by the president of the Society, Dr. Whitney, by the secretary, Dr. Richards, by the chief engineer of the Hydro-Electric Power Commission of Ontario, Mr. Sothman, by Dr. Baekeland, and by Mr. Cohoe. The two last named speakers called attention to the eminent importance of next year's Congress of Applied Chemistry—the first to be held in this country.

The third day of the meeting was given over to a highly interesting visit to Hamilton, Ontario, and its vicinity. Over forty members and guests participated. The first plant inspected was the large, and rapidly growing, plant of the Canadian Westinghouse Company. The one hour available in this

plant passed all too quickly, among the multitude of interesting and instructive apparatus and operations.

The party then proceeded to the plant of the Steel Company of Canada. Here were two blast furnaces, and numerous basic open-hearth steel furnaces, mixer, etc. The attraction commanding chief attention, however, was the Gayley refrigerating plant for drying the air for the two blast furnaces. These furnaces each require some 20,000 cubic feet of air per minute, which is cooled to 14 deg. F (—10 deg. C.). The moisture content of 6 to 7 grains per cubic foot is thus reduced to 0.5 grain. The output of the two furnaces has been increased from 200 and 300 tons per day to 225 to 350 tons, respectively, while the coke consumption has been considerably reduced, being now 2200 lb. per 2240 lb. of pig iron. The *net* saving over all in the production of the iron is given as 75 cents per long ton of pig iron. The refrigerating plant contains 48 miles of pipes, and cost $500,000. The party was divided into groups, and conducted through the refrigerators into the coldest chamber—a unique and long-to-be-remembered experience.

The basic open-hearth steel plant for the inspection of which very little time only was available, contains four furnaces, two of 50 tons each and two of 25 tons. It is fired by natural gas.

The transformer station of the Canadian Hydro-Electric Commission was visited in the afternoon after lunch had been taken at the Waldorf hotel in Hamilton. A spick-and-span new plant is this transformer station, receiving power at 110,000 volts from Niagara and reducing the voltage to 13,200 volts for the local Hamilton service. It is also a switching station for all the territory supplied to the north, up to Toronto. It is equipped to handle 70,000 kilowatts, but only 12,000 kw go through it at present. The line loss from Niagara is given as under 5 per cent. Many obscure phenomena have occurred in the handling of this 110,000-volt current; one being a jump of the current *several feet* to another crossing line, during a thunderstorm, when either a lightning flash started the current across, or else a condition of unusual atmospheric electric tension superimposed on the 110,000 volts did the mischief.

The party returned to Hamilton, where it broke up and the members went off by train in different directions.

Professional Sessions.

The first professional session was called to order by the president, Dr. W. R. WHITNEY, on Thursday morning. Since the secretary, Dr. J. W. Richards, had not yet returned from Europe, Mr. Carl Hering was elected active secretary for the first sessions. Dr. Richards arrived on Friday morning.

The first paper of the meeting was presented by Mr. Robertson.

Electric Iron Smelting in Sweden.

A paper by Mr. THOMAS DUNCAN ROBERTSON, of the Canadian Böving, Co., Ltd., of Toronto, Ont., gave an account of "recent progress in electrical iron smelting in Sweden."

The author referred to Dr. E. Haanel's well-known reports on the work of the three Swedish engineers, Assar Grönwall, Axel Lindblad, and Otto Stalhane in the electro-metallurgy of iron and steel, their first 700-hp electric iron ore reduction furnace at Domnarfvet, and their later 2500-hp furnace at Trollhättan, erected by the Jernkontoret (the association of Swedish Iron Masters).

All these developments have been fully covered in this journal (concerning the design of the Trollhättan furnace and the results obtained at Trollhättan see especially the three articles in our issues of July and September and elsewhere in the present issue).

It may therefore be merely stated here that charcoal is used as fuel and that an important feature of the furnace is the provision made for the circulation of the gases produced by the reduction of the iron ore. The gas is drawn from the cool upper part of the furnace by means of a fan, and blown under the hot roof of the crucible, serving the double purpose of prolonging the life of the roof, and at the same time giving up its heat to, and helping in the reduction of, the charge.

During a large portion of the time the charge has been high in iron and the quantity of slag correspondingly small, so that the iron and slag have been tapped out together, and by means of a small dam the slag has been allowed to run off down a sand trench.

Table I given in Mr. Robertson's paper, is interesting, as it gives a very concise and yet full summary of the working results at Trollhättan.

The thermal efficiency of the furnace was carefully worked out, when it had been running for five months, after which time the lining had worn rather thin, so that radiation losses were probably higher than normal. However, 80 percent (the figure obtained) compares favorably with 82 percent for the efficiency of the Swedish charcoal blast furnace, and with the 70 percent of the English blast furnace.

As the volume of the furnace and gas piping is constant an excess of gas is being continually produced, proportional to the amount of ore reduced. This gas is allowed to burn into the air at present at Trollhättan, but in the newer plants arrangements are to be made for using it for calcining purposes. About 550 cubic meters of gas are produced per ton of pig iron, and each cubic meter will develop 2,100 to 2,500 Calories, as the gas averages about 80 per cent of combustibles.

When calculating the various charges the quantity of charcoal is kept constant at 6½ hectolitres and the amounts of ore and limestone are varied to produce the desired grade of iron, a typical charge at the time when the author was present at

the furnace being 266 kilograms of magnetite, 133 kilograms of concentrates, and 11 kilograms mill cinder, the total of these three constituents being 410 kilograms.

To this were added 32 kilograms of limestone and 6½ hectoliters or 100 kilograms of charcoal.

This is dropped into the furnace at one raising of the bell and tappings are made every 18 charges, or about once every six hours.

The conditions governing the grade of iron produced are similar to those in the ordinary blast furnace except that the irregular influence of the air blast is absent. The furnace gives the maximum output when making white iron, as the making of grey iron requires a rather higher temperature and consequently a greater power consumption. By increasing the

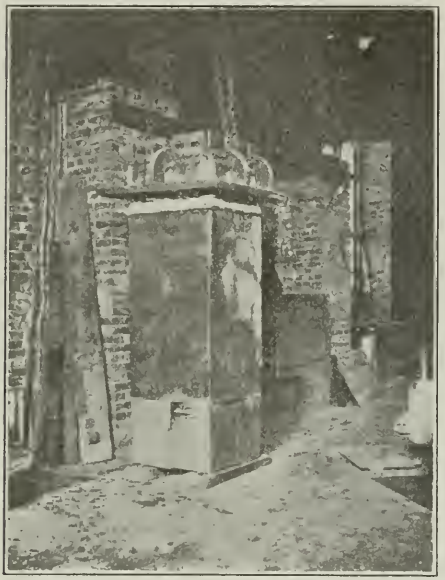

FIG. 1.—NEW ELECTRODE, EQUIPPED WITH IRON SHEATH AND CONTACT FRAME

amount of ore in the charge when the furnace is making white iron, a low-carbon iron with very little silicon is produced, a typical analysis of which is as follows:

	C.	Si.	Mn.	S.	P.
Percentages	2.60	0.10	0.11	0.02	0.01

This iron naturally is full of holes, but instead of these having colored oxidized surfaces, they are silvery white; the absence of oxygen from the furnace atmosphere accounting for the production of this grade of iron free from oxides.

The results of making steel from this iron are given in the second part of the paper.

The tension employed varies greatly and depends mainly on the resistance of the charge. This broadly speaking increases with the amount of slag produced and with the wear of the electrodes, but decreases as the amount of charcoal in the charge becomes greater. The maximum power allowed is 1,900 kw. and to avoid overheating the electrodes the current must not exceed 17,000 amperes, so that the voltage has to be regulated accordingly.

The wearing of the electrodes has given rise to some curious and interesting results. In Fig. 1 is shown a new electrode with its iron sheath and contact frame. When this is placed in the furnace, the bottom end projects into the actual charge and is gradually abraded and consumed. Between the stock line and the roof is a space filled with furnace gases which contain about 15 per cent CO_2, so that the portion of the electrode exposed to them is very gradually oxidized.

The result of this is shown in Fig. 2 where the half-con-

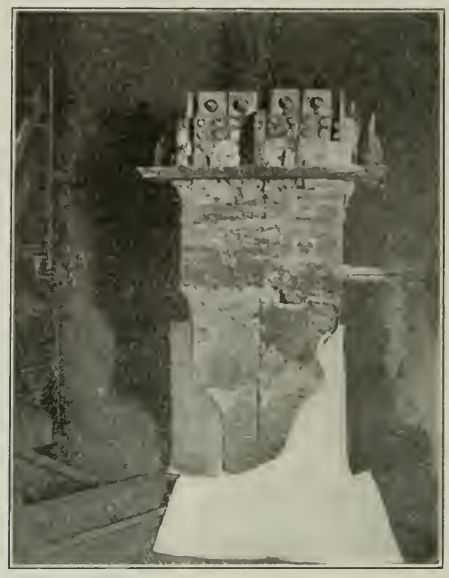

FIG. 2.—HALF-CONSUMED ELECTRODE

sumed electrode was removed for inspection, the line of the

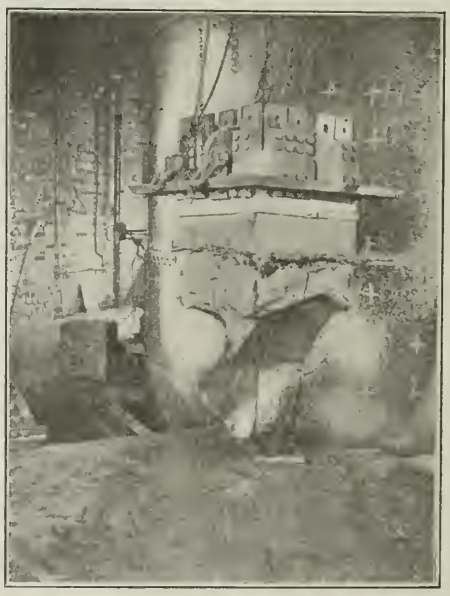

FIG. 3.—STUMP END OF ELECTRODE

surface of the charge being clearly visible in the picture. Fig. 3 shows the stump end of an electrode which had been

lowered as far as possible into the furnace and kept there until unfit for further use. It will be seen that two of the four carbons which compose it have been burnt through to the center.

About three weeks is taken to burn through an electrode above the stock line, so that in practice each electrode is

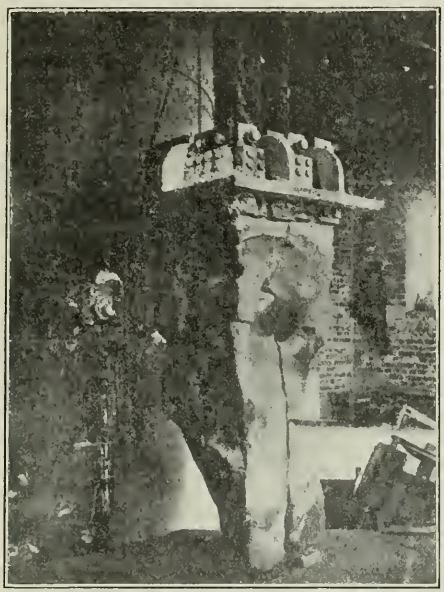

FIG. 4.—EFFECT OF CARBON DIOXIDE ON ELECTRODES

lowered once every two weeks, to ensure regular working without risk of fracture, which would result in a lump of electrode being left in the charge.

With the object of cooling the roof immediately behind the electrodes, gas was blown in beneath the water jackets during a portion of the time. The effect is shown in Fig. 4, the CO_2 in the stream of gas having burnt a hole in the electrode, causing this practice to be discontinued.

A point of interest from a Canadian point of view is the success met with in smelting magnetic concentrates at Trollhättan. The design of shaft in this particular case is not considered suitable for the purpose, being too narrow, but in spite of this, 65 per cent of finely divided concentrates caused no inconvenience in working. The inventors of the furnace are of the opinion that, with a specially designed shaft, charges of all fine concentrates could be smelted.

Canada is rich in deposits of iron sands and lean magnetites, which are easily concentrated, but which are expensive to nodulize or briquette into a form suitable for blast furnace smelting, so that where these are within easy reach of water powers, there seems to be a good field open for electric smelting.

Titaniferous iron ores were found to present no difficulty, although no ores were used with more than 0.8 TiO_2. Nor does high sulphur content prove objectionable, as there can be little doubt that the electric furnace with its reducing atmosphere and basic lining of the hearth, permitting as it does of the use of a slag very rich in lime, offers the best method of producing sulphur-free pig iron from ores containing that unwelcome element.

The pig iron produced by the furnace was sent to various Swedish iron works for conversion into steel in open-hearth furnaces. The characteristic feature of electric pig iron is its freedom from oxides; and in consequence electric pig iron of normal silicon content (say, 1 per cent and over) takes a longer time and more ore to convert into steel than ordinary blast-furnace grey iron.

Low-carbon electric pig iron, however, is found to give surprising results, charges made up of 50 per cent of this iron and 50 per cent of scrap producing hot fluid steel with considerable saving of time over ordinary practice.

As was to be expected, the open-hearth furnace managers looked somewhat askance at this iron at first, as they knew the disastrous effect of using low-carbon iron full of holes from the blast furnace; however, after giving it a trial, the workmen asked for more, as they said that the furnace worked better and more rapidly with the new pig iron.

Fortunately for the electric furnace in Sweden, it is more economical to make the white iron, that the steelmakers prefer, than to make high-silicon grey iron. Thus it may be maintained, on the strength of the experience gained, that for the open-hearth process, high-silicon contents are detrimental rather than advantageous, while in the blast furnace pig iron a certain quantity is necessary to neutralize the defects of a reduction process less perfect and ideal than that employed in the electric furnace.

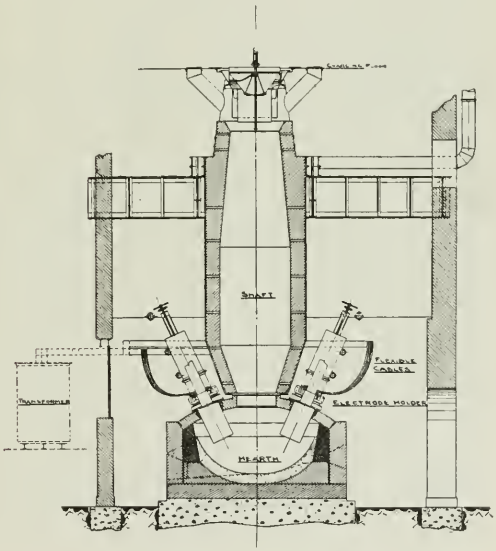

FIG. 5.—DESIGN OF NEW 3000-HP FURNACE

The quality of the steel produced has been thoroughly tested by making it up into various products and comparing it with steel made from Swedish charcoal blast furnace iron. In no case was the new steel inferior, and, from the most recent reports to hand, it was in several cases decidedly superior.

The Trollhättan furnace was shut down at the end of May of this year in order to make certain alterations suggested by the results of its six months' campaign. Two of these deserve mention.

1. Since the furnace was designed, the manufacture of large carbon electrodes, of high conductivity, has made great progress. It is now possible to obtain cylindrical electrodes of 600 mm. diameter, fitted with screw joints. These have recently been installed at Trollhättan, and result in two considerable improvements, the first one being that the loss due to stump ends is done away with, as when an electrode becomes too short, a new one can be screwed on above it. The second

one is that the electrical contact can be made at the point where the electrode enters the roof, in this way saving about 40 kw., which with the old arrangement was lost, due to the resistance of the whole length of the electrode through which the current had to pass. This new arrangement will permit of the furnace taking 3,000 hp. instead of 2,500 hp., and is shown in Fig. 5.

2. The other important alteration is in the gas-circulating arrangement, the new form of which is seen in Fig. 6. The old dust-catcher was not very effective, as only very fine dust is expelled from the furnace. The result was that the dust

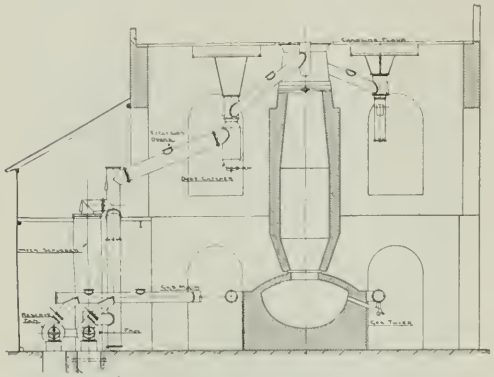

FIG. 6.—NEW GAS-CIRCULATION ARRANGEMENT

collected in the centrifugal fan, and had it not been that this was kept fairly clear by a jet of water, would have choked up the blades in a few hours; as it was the fan had to be stopped and cleaned every week. Now a water-scrubber takes the place of the dust-catcher, and a fan on the ground floor blows the cleaned gas into the furnace, the other fan shown being held in reserve.

Rather more than three metric tons of pig iron are produced by the electric furnace per electrical hp. year, using one ton of charcoal for the reduction of the ore. The blast furnace uses about three times this amount of fuel per ton of iron, so that in Sweden, where, owing to the demand of wood for the pulp industry, the price of charcoal is yearly advancing, there is a great field open for electrical smelting on account of the saving in fuel.

The furnaces in Norway have a somewhat different form of shaft, as coke is the fuel employed for smelting. The volume of the shaft is smaller, but its diameter is greater, than the corresponding shaft of a charcoal furnace. The coke in the charge gives a greater conductivity, so that a lower tension has to be used.

Mr. Robertson summed up as follows:

1. Electric smelting of iron ores is no longer in the experimental stage, but in Sweden is thoroughly established on a commercial scale.

2. The smooth and regular working of the furnace at Trollhättan has been a marked feature, probably less trouble being experienced than would have been the case with a blast furnace doing similar work.

3. The quality of iron produced for steel-making purposes has been shown to be equal and in some cases superior to that of Swedish blast furnace pig iron.

4. The comparative costs of electric and blast furnace smelting depend in general on the cost of suitable fuel and electrical energy, as the electric furnace simply substitutes one electrical hp. year for two metric tons of blast furnace fuel. In Sweden there is do doubt that the electric furnace has come to stay on account of cheaper production.

5. The electric furnace is specially adapted to the smelting of finely divided ores or concentrates.

6. Electric smelting in Sweden has a national value as its adoption will result in the development of water powers which could not in many cases be profitably utilized for any other purpose.

The paper elicited an extended discussion in which Dr. Brady, Dr. Whitney, Mr. Louis Simpson, Mr. Kohn, Mr. Hering, and Mr. Lidbury participated.

Mr. Simpson referred to the troubles due to the dust in the gas and asked whether there was any necessity for using the gas for cooling the roof. This necessity might be questioned since this method is not employed at the Noble electric iron furnace plant in Heroult, California. Another difference from the California practice is that while the electrodes reach deeper into the charge in California, they are free burning in Sweden. Mr. Simpson also questioned whether any reduction of ore was accomplished by the gas in the shaft in view of its relatively low temperature. Finally he stated, that English buyers of electric pig iron had found it irregular; while electric pig iron had always been claimed to be of higher quality than ordinary pig iron, it would be most unfortunate if it should turn out to be irregular.

Mr. Robertson replied that the trouble with the dust in the gases existed, even with the new washing arrangement, yet they were continually making progress and improvements and were sure that the problem would soon be solved. As to the use of the furnace gas for cooling the roof, this is considered by the inventors of the Trollhättan furnace to be one of the essential and most important points of their design. While the temperature of the gases in the stack is relatively low, it is in general still sufficiently high for reduction of magnetite. Finally as to the alleged irregularity of the electric pig iron sold in England, Mr. Robertson stated that most of the pig iron made in Trollhättan in the electric furnace was used by the Swedish iron masters themselves, who had supplied the iron ore. None of the Trollhättan electric pig iron was sold in England. Probably the pig iron sold in England to which reference had been made by Mr. Simpson had been made in small electric furnaces, hence the possibility of irregularity. With the new large electric furnace no such difficulty as to irregularity is experienced.

In reply to another question Mr. Robertson stated that at Trollhättan all kinds of electric pig iron are made, low or high in carbon. There is no more difficulty in making high-carbon pig than low-carbon pig in the electric furnace.

In reply to a question of Mr. Hering, how the 80 per cent efficiency of the furnace had been calculated, Mr. Robertson said that he had not the exact method of calculation at hand, but he knew it had been carefully calculated and the three comparative efficiencies of the Swedish electric furnace, the Swedish charcoal blast furnace, and the English blast furnace had been calculated by the same method. Mr. Lidbury remarked that Table I (given above) was so complete as to exact statements of facts that it enabled anyone to calculate any efficiency desired to suit his idiosyncrasies.

Heat Losses of Electric Furnaces.

A paper by Mr. Francis A. J. FitzGerald, of Niagara Falls, N. Y., is entitled a "note of an unsuccessful furnace experiment." It refers to experiments with various furnaces of the type in which the heat is obtained by downward radiation from electrically heated resistors arranged near the top of the furnace chamber, as described in our vol. VIII, pp. 289 and 317, and vol. IX, p. 259.

Various furnaces of this type have since been built and tested, but the results have been disappointing in one respect. For, while the working of the furnace, so far as its electric properties were concerned, was most satisfactory, the efficiency was very low, owing to excessive heat losses.

The table below gives certain data in reference to five fur-

naces constructed on this principle, the furnace number appearing in the first column. In the second column the nominal electric capacity is given; in the third column the temperature of the hearth at which experiments were made; in the fourth the heat losses in kilowatts, determined by holding the furnace for a long period at a constant temperature and measuring the rate of generation of energy necessary to maintain that temperature constant; the fifth column gives the percentage loss referred to the electric capacity of the furnace. The columns headed "A" and "B" give certain ratios which will be explained later.

Furnace No.	Capacity, Kw.	Temperature Cent.	Losses, Kw.	Losses, Per Cent.	A.	B.
1	40	1300	18	45	0.20	1.1
2	40	1240	15	38	0.20	1.1
3	150	1250	33	22	0.29	1.0
3	150	1450	42	28	0.29	1.0
4	75	1100	38	51	0.20	2.0
4A	75	1200	35	47	0.22	2.0

Furnace 1 had walls 230 mm. (9 in.) thick. The resistor was "open," that is, it radiated directly on the hearth.

Furnace 2 had walls 345 mm. (13.5 in.) thick, the outer part of the wall being built of hollow bricks. The resistor was "enclosed," that is, there was a septum of refractory material interposed between the resistor and the hearth.

Furnace 3 had walls 345 mm. (13.5 in.) thick, and between these walls and the iron casing of the furnace was a space of 30 mm. (1.2 in.) filled with kieselguhr.

Furnace 4 was of the design described in our vol. IX, p. 259, and had double walls, each 230 mm. (9 in.) thick, separated from one another by an air space 25 mm. (1 in.) wide.

Furnace 4A was the same as Furnace 4, except that part of the walls was covered with a layer of heat insulating bricks 55 mm. (2.2 in.) thick.

Now, since Furnaces 4 and 4A were supposed to be the most improved model of this kind of furnace, the very high heat loss was extremely disappointing. In looking for an explanation of the poor results obtained, the first thing naturally suggested was that the septum between the resistor and the hearth might offer such a high resistance to the flow of heat that the efficiency of the furnace would be low. However, as this hypothesis was formed during the experiment, it was an easy matter to test it by the simple expedient of knocking out the septum. As this produced no appreciable improvement in the working of the furnace, the hypothesis ceased to be useful.

There then seemed to be two other explanations of the phenomenon; either the design of the furnace was radically wrong, or the loss of heat by conduction through the furnace walls was excessive.

The heat energy radiated from the resistor is absorbed by the charge on the hearth of the furnace on the one hand, and by the walls and roof on the other. Now, the heat absorbed by the walls and conducted away to the surroundings of the furnace is lost, and, consequently, other things equal, it is desirable to keep the ratio between the hearth area and the total area receiving heat from the resistor as large as possible. This ratio has been calculated for the various furnaces and is given in the column marked A in the table. It will be observed that the ratio is greatest in the case of Furnace 3, and this is at any rate a partial explanation of this furnace's superiority.

Another important consideration is the ratio between the area of the surface, other than the hearth, receiving the heat radiated from the resistor, and the rate of generation of energy in the resistor. This ratio has been calculated for the various furnaces, and is given in the column marked B. Here it is seen that the ratio for furnace 4 is twice as great as in the case of furnace 3; consequently, other things equal, the heat losses would be twice as great.

It does not follow, however, that, because the ratio B is high, the design of the furnace is faulty, for other considerations may make such a ratio desirable or even necessary. The point that requires close attention is the most perfect heat insulation possible. If the heat insulation is good, then, while there may be a great difference in temperature between the charge on the hearth of the furnace and the resistor, there will be very little difference between the rest of the surface receiving radiation and the resistor. Here was found the great weakness in furnace 4, for the walls, instead of being good insulators, were relatively good conductors of heat. Observation showed that when a balance had been reached, so that the total energy radiated from the outside of the furnace was equal to the energy generated in the resistor, there was a marked difference between the temperature of the resistor and the interior surface of the furnace. There were no means by which these temperatures could be measured, but by the eye it could be seen that the difference amounted to at least 200° C.

A very clear demonstration that was approximately quantitative of the high heat conductivity of the walls was made by comparing furnace 4A with furnace 4. In furnace 4A the side walls were partly covered with bricks having high heat-insulating properties, about 25 per cent of the total exterior surface of the furnace being protected in this way. From the table it is seen that, working with even a higher temperature than in the case of furnace 4, the losses were considerably reduced. It is unfortunate that the determinations were not made at the same temperature, but it is safe to assume that, if furnace 4 had been tested at a temperature of 1200 deg. C., the losses would have amounted to at least 43 kw. Hence by the improved heat insulation the loss was reduced about 19 per cent.

In building furnace 4, a good grade of firebrick, so far as its refractory properties are concerned, was used. It was recognized that silica brick are better heat insulators than fire brick, as may be seen from Wologdine's determinations,* which show that the heat conductivity of silica brick is 0.0020, and of fire brick 0.0042. On account of its high co-efficient of expansion by heat, silica brick is sometimes objectionable, and it was thought that, with a wall of fire brick 460 mm. (18 in.) thick and an air gap, the heat insulation would be amply sufficient. The air gap, however, was useless, for a reason that has been well expressed by Ray and Kreisinger.** The surface of the inner wall forming the air gap reached a temperature of at least 600 deg. C., so that the very device on which dependence was placed to prevent heat losses was worse than useless.

In the discussion of Mr. FitzGerald's paper Dr. Whitney emphasized that the description of unsuccessful experiments should be encouraged for the valuable lessons which they teach.

Mr. Lidbury read a communicated discussion by Mr. John Thomson, who had been Mr. FitzGerald's co-worker in the design of the furnace. He pointed out two special differences in the design of the later and earlier furnaces, which might possibly have contributed to the difference in the results; he also expressed the opinion that the point made with respect to the air gap was not yet fully proven.

Titanium in Iron and Steel

A paper by Mr. Charles V. Slocum, of the Titanium Alloy Manufacturing Company, of Pittsburgh, Pa., refers to the work of Mr. Auguste J. Rossi with titanium continued during 30 years or more of his life, until he produced his "titanium alloy" in the electric furnace in 1903. Since that time the manufacture and consumption of titanium in the steel industry has grown with leaps and bounds.

Metallurgists have practically all agreed that the use of a small percentage of an alloy of titanium is of benefit in both iron and steel, but some question has arisen as to the form which this alloy should take. In a recent publication*** the statement has been made that carbon-free metals dissolve more easily than other metals containing carbon, since the latter

*"Electrochem. and Met. Industry," Vol. VII, (1909), page 383.
**"The Flow of Heat Through Furnace Walls," by Walter T. Ray and Henry Kreisinger; Bulletin 8, Bureau of Mines, Washington, 1911.
***H. Goldschmidt in this journal, July issue, p. 348.

contains carbides. The experience of the present author does not bear out this fact, he having found that a carbon-free alloy was not at all adapted to use in the iron and steel industry, and the manufacturers were obliged to make a product containing from 5 per cent to 8 per cent carbon for such use. His early experience with an alloy of iron and titanium free from carbon, but containing 5 per cent to 10 per cent aluminium, resulted in almost complete failure, as the aluminium when present in any appreciable quantity made the steel brittle and its oxide showed great tendency to remain in the steel.

"Titanium alloy" contains 5 per cent to 8 per cent of carbon, mostly in the form of graphite. Analyses of this material made in the laboratory of Dr. C. F. McKenna show the following proportions of the two forms of carbon:

Sample No.	Graphitic Carbon	Combined Carbon
141	9.601	0.147
162	9.179	0.12
291	7.012	0.13
298	6.234	0.118

From these analyses it appears that titanium acts very much like silicon in that it causes a separation of carbon as graphite.

Dr. G. B. Waterhouse recently cited an interesting experiment to bear out this fact: A ladle of iron for making malleable castings was treated with 10 per cent titanium alloy sufficient to equal 0.1 per cent metallic titanium added to the iron. The original iron gave castings showing a white fracture with a slight graphite in the center. The titanium-treated metal showed a white border between ⅜ and ½ in. (1 to 1.25 cm) deep, and a gray center showing the separation of graphite. Contrary, therefore, to the viewpoint of Dr. Goldschmidt, there need be no fear of the non-solution of the electric-furnace titanium alloy, as it does not contain more than the merest fraction of the unreadily soluble carbide.

The density of ferro-titanium has an important bearing on its incorporation in the molten bath. Careful determinations made on the electric-furnace product containing both 10 and 15 per cent titaniums, show a density of 6.20 to 6.40. The alloy produced by the alumino-thermic process shows a density of between 6.20 and 6.30. The difference between the densities of the two alloys is therefore hardly noticeable.

The alloy is best added to the ladle of steel after tapping from the furnace and before the slag begins to run. For open-hearth steel the supply should be placed convenient to the ladle and shoveled in precisely as so much coal. For soft steel an addition equivalent to 0.03 per cent titanium is sufficient to make the steel more ductile. Larger quantities are of increased benefit, but cannot always be added because of the carbon content and also because of the density imparted to the steel, which increases as the proportion of alloy is increased, and therefore is not always desirable. In high-carbon steels this increased density is desired and more alloy is used. The addition of the alloy permits the use of a considerably higher carbon without increasing the brittleness, and several railroads are now using as much as an equivalent of 0.10 per cent titanium or more in securing tough, durable rails.

In the crucible practice the best results have been obtained by adding the titanium alloy to the pots before they are removed from the furnace, giving more time for washing and deoxidizing before teeming.

Leading authorities seem to agree that titanium achieves its remarkable results through its strong deoxidizing powers, together with its effect of giving the slag formed sufficient fluidity to completely separate it from the metal.

"The presence of titanium oxide lowers the melting point of slags occluded in iron and steel and imparts thereto sufficient fluidity to account for their elimination."[2]

"Titanium . . . has a stronger affinity for oxygen than have the well-known deoxidizers; . . . it probably gives the slag such a consistency that it separates more completely from the molten iron."[3]

"The treatment of all steels with ferro-titanium for the purpose of purifying the metal is strongly recommended, the presence of nitrogen to the extent of 0.02 to 0.035 or 0.045 in certain steels being enough to cause the metal to break asunder, destroying all elongation and reduction of area."[4]

"The great affinity of oxygen and titanium is an absolutely sure means of completely deoxidizing the steel, the advantages of which need no further elaboration. It has been proved that an ingot of steel containing a very small quantity of titanium would show practically no segregation."[5]

The cost of treatment with titanium varies from a minimum of 25 cents to a maximum of $2 per ton of metal treated. It is the cheapest deoxidizer above the grade of manganese or silicon, and a far greater purifier than any other alloy. The amount to be used is very small, and should be proportioned according to the carbon content of the steel and to the amount of impurities present. To the electrometallurgist it is a triumph worthy of record that Rossi should take an element like titanium, so long considered useless, and make out of it so wonderful a servant in the iron and steel industry.

Mr. Slocum's paper brought forward a lively discussion.

A communicated discussion by Dr. Richard Moldenke, Secretary of the American Foundrymen's Association, was read by Mr. Lidbury. It referred especially to the use of titanium in foundry practice. Dr. Moldenke attributes the success of titanium treatment to its action as a deoxidizer. It removes the oxidation effects which are due not only to remelting under oxidizing conditions (cupola) but can also be traced directly to the blast furnace. The removal of this oxidation, which is small, is important and this is what titanium does.

Because the oxidation is small Dr. Moldenke points out that only a small amount of titanium is needed and useful. If more is added, it makes apparently no difference. This would mean that titanium acts simply as a deoxidizer, not as an alloying element. A practical conclusion from this is that the titanium treatment of metal should be adjusted to the amount of oxidation present.

Mr. Wm. C. Cuntz, general manager of the Goldschmidt Thermit Co., then read a communicated discussion of Dr. Hans Goldschmidt who first replied to Mr. Slocum's claim that a carbon-free ferrotitanium was not adapted to the use in the iron and steel industry and emphasized that this claim was refuted by the undisputed practical results of a large number of prominent metallurgical works which use continually carbon-free ferrotitanium made by the aluminothermic process.

Dr. Goldschmidt does not claim that ferrotitanium containing carbon is unsuitable or useless. But he claims that the carbon-free ferrotitanium, containing aluminium, is a more effective reagent. His first reason is that ferrotitanium which contains little or no aluminium, alloys with steel only with difficulty. When Dr. Goldschmidt had placed on the market in 1897 a 35 to 40 per cent. ferrotitanium containing very little aluminium, an open-hearth steel plant to which he had furnished an alloy of especially high percentage, inquired whether he could not make the product at very low cost, since they were inclined to use this ferrotitanium as an open-hearth furnace lining; so little was it affected by the molten steel. Dr. Goldschmidt could satisfy his steel customers only after he added aluminium to the alloy so that it contained 1 part of aluminium to 3 or 4 parts of titanium.

Dr. Goldschmidt pointed out that the addition of aluminium to the alloy had a threefold purpose. First, it caused the alloy to be embedded and dissolved more easily and intimately in the steel.

Secondly, titanic acid (the product resulting from the titanium reaction in the steel bath) is very difficult to fuse.

Also alumina (the product resulting from the aluminium reaction in the steel bath) is very difficult to fuse. Hence, if either titanium or aluminium alone are used as deoxidizers, the products of the reaction—titanic acid or alumina, respectively—are liable to remain as suspended particles in the steel, as can be shown by microphotographic methods. But if titanium and aluminium are used together simultaneously, the product of the reaction is titanate of aluminium, which is much more easily fusible than titanic acid or alumina alone. Hence the titanate of aluminium will separate out of the steel bath and pass into the slag much more easily.

Dr. Goldschmidt's third reason for adding aluminium to his ferrotitanium is that when the aluminium serves its purpose of cleaning and deoxidizing it enables the titanium to manifest more strongly its own specific effectiveness.

Dr. Goldschmidt denies that titanium is a stronger deoxidizing agent than aluminium and points out as proof that aluminium reduces titanic acid, but titanium does not reduce alumina. But he agrees that titanium is a good purifier and stands in the first rank as an agent for the production of a dense, non-porous steel. Besides acting as a deoxidizer and for removing nitrogen the titanium itself has some beneficial effect on steel and cast iron.

In the cleansing of the metal bath the great affinity of the added metal for oxygen and its speed of reaction are important, but Dr. Goldschmidt emphasizes that it is undoubtedly the specific properties of the added metal itself which give the result. For example, metallic calcium has a greater affinity for oxygen than aluminium, but in spite of this, though many attempts have been made, calcium is not generally used in steel making. The alloy of calcium and silicon which he has produced by his process as a substitute for aluminium and has put on the market has not shown the results expected and hoped for in spite of the fact that this alloy is decidedly a good deoxidizer. Practical results have not equalled what aluminium alone and what to a far greater extent the aluminium-titanium alloy has accomplished.

Dr. Goldschmidt stated that he had always followed with great interest Mr. Rossi's work in the titanium field. "Mr. Rossi has worked hard to get on the market a high-per cent. ferro-titanium. He had finally to choose a product running 10 to 16% titanium with a high carbon content, in order to make its introduction into steel possible. It is perfectly apparent that a low-percentage alloy, over-ballasted as it is, is not as desirable as a high-percentage alloy. But I do not wish to minimize in any way the services of Mr. Rossi as I appreciate all the difficulties he has overcome in producing the results he has produced."

Dr. Goldschmidt finally referred to the successful use of titanium thermit for the introduction of small quantities of titanium into cast iron and steel, as proof that he has also devoted himself to the metallurgy of titanium for some years and has produced results. Titanium thermit is a thermit which when introduced into iron or steel liberates a fluid alloy of ferrotitanium, while the slag rises to the surface. This has a double effect, an addition of a small amount of titanium to the bath and a violent stirring up with a slight rise of temperature. The quality of cast iron is thereby decidedly improved.

The discussion was continued by Mr. F. A. J. FitzGerald, who thought that the claimed presence of carbides in ferrotitanium containing carbon was not proven and that the reasons for the claim were weak. He asked: If titanium has really such a tendency to form carbides, why should not carbides be formed if carbon-free ferrotitanium is added to molten steel?

Dr. Waterhouse, of the Lackawanna Steel Company, remarked that the claim as to the carbides had apparently been withdrawn by Dr. Goldschmidt as it was not mentioned in his reply. (To this Mr. Cuntz replied afterwards that Dr. Goldschmidt had further investigations on titanium in hand and would give his results on a later occasion.)

While Mr. Slocum recommends that the alloy is best added to the ladle of steel *after* tapping from the furnace and before the slag begins to run, Dr. Waterhouse thinks it is best added *during* tapping.

An important point, according to Dr. Waterhouse, is that time must be allowed for the reactions to go on and for the products of the reactions to separate out.

In his final reply, Mr. Slocum referred to early experiments of Mr. Rossi in the reduction of titaniferous iron ores. He thought that if aluminium is beneficial in the titanium raaction it could be added separately. He finally gave figures on the rapid increase in the production of ferrotitanium at the Niagara Works and its consumption in the steel industry.

Niagara Transforming Stations.

A paper by Mr. A. J. Jones, of Niagara Falls, gives a review of the "transforming stations of Niagara electrochemical and electrometallurgical industries."

Grouped around Niagara Falls are seven hydro-electric generating stations, four of which are on the Canadian side. From these seven stations energy is being used at the rate of 128,000 hp for electrochemical purposes, 56,000 hp for railway service, 36,000 hp for lighting, and 55,000 hp for various industrial services, the total being 275,000 hp or about 5.5 per cent of the available power of the cataract. Of this total amount 146,000 hp is employed locally in industries that have been attracted to Niagara Falls by reason of the generating stations located there, electrochemical processes forming 87 per cent of this amount and 46 per cent of the total amount utilized.

The paper is essentially a catalog of the equipment of the transforming stations of the following companies, with an account of the more salient features of the equipment: International Acheson Graphite Company, Aluminium Company of America, Carborundum Company, Niagara Lead Company, Castner Electrolytic Alkali Company, Norton Company, Union Carbide Company, Niagara Alkali Company, Hooker Electrochemical Company, Niagara Electro-Chemical Company, United States Light and Heating Company, and Electro Metals.

In the discussion which followed, Mr. Fitzgerald pointed out that electrochemical newcomers to Niagara are often astonished at the amount of apparatus they have to put in. The plants at Niagara often have a cramped appearance. Usually not enough space is allowed. This is an important matter.

Dr. Northrup referred to a mercury ammeter, based on the pinch effect and being in use at the Aluminium Company's plant at Massena; it measures 14,000 amp regularly; the capacity being 16,500 amp. The instrument is in continuous operation, no failure having ever occurred.

Production of Molybdenum Steel in the Electric Furnace.

A paper by Messrs. E. T. Dittus and R. G. Bowman gave an account of an investigation carried out in the Colorado School of Mines.

The use of a sulphide ore of so active a metal as molybdenum in connection with the manufacture of steel presents a number of problems. Foremost among these are the complete reduction of the molybdenum without serious loss, the diffusion of the molybdenum through the steel to form a homogenous product and the elimination of the sulphur from the steel. The process employed was one based on a reaction described by Mr. F. M. Becket in U. S. Patent 855157, and is believed to be new.

In the production of steel direct from ore in the electric furnace the removal of certain impurities, particularly sulphur, offers difficulties. For the reduction of molybdenite in the presence of molten iron it is necessary to have present some substance which has a greater affinity for sulphur than either molybdenum or iron. The compound formed by the desulphurizing agent and the sulphur must either pass into the

slag or be volatilized as soon as formed. The two metals which seem best adapted for use as desulphurizers, under these conditions, are manganese and silicon.

Manganese in the form of metal, or as the ferroalloy, reacts with sulphides at high temperatures according to the following reaction:

$$2\,Mn + RS = R + 2MnS.$$

The manganese sulphide forms a slag resembling iron sulphide. If the above reaction takes place in a bath of molten steel or iron the resulting metal is apt to contain small included masses of manganese sulphide. Sulphur in this form has little effect on the properties of steel. This reaction might be applied to the production of alloy steels, such as molybdenum

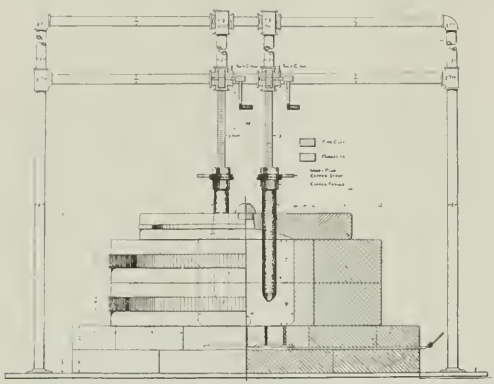

FIG. 1.—LABORATORY FURNACE FOR PRODUCTION OF MOLYBDENUM STEEL

steel, by adding a mixture of molybdenite and ferromanganese to the bath of molten steel just before tapping. This would result in the formation of ferromolybdenum and manganese sulphide; the former alloying with the steel and the latter passing into the slag.

Silicon reacts with sulphides to form silicon sulphide SiS_2 and liberates the metal of the original sulphide. This is the reaction described by Becket.[1] The reaction has been investigated by Fielding[2] who produced a yellow powder which sublimed at 1500° C and which decomposed water with the formation of H_2S and silicic acid. This compound did not correspond to the formula SiS_2. Sabatier[3] describes a somewhat similar compound and suggests the formula Si_2S_6. The heat of formation of SiS_2 is given by Sabatier[3] as + 40.4.

This reaction might be applied to the production of molybdenum steel in the same manner as the manganese reaction described above. The silicon, in the form of ferrosilicon, and the molybdenite should be reduced to powder, intimately mixed in the proper proportion to produce the reaction and added to the steel in the furnace before tapping. The mixture might be added in a soft iron tube or in small briquets made up with a binder of sodium silicate. Addition to the ladle during tapping would probably result in raising the sulphur content of the metal on account of the absence of slag, which in the furnace would remove small amounts of sulphur which might tend to pass into the steel.

The experimental work was done in an electric furnace which could be operated either as a Heroult furnace (two arcs in series on the top) or as a Girod furnace (two arcs in parallel on the top and a metallic electrode in the hearth).

The crucible is elliptical in cross section and measures 6 in. x 9 in. x 9 in. (15 x 23 x 20 cm.) deep. The total volume of the crucible is about 360 cu. in. (5.5 litres), the volume of the smelting zone is about 90 cu. in. (1.4 litres). The walls have a slight bosh to effect a concentration of heat at the base of the crucible. The crucible lining is of burned magnesite obtained by crushing magnesite brick to pass 10 mesh (2.5 mm.) The magnesite was mixed with tar to form a paste and rammed in hot around a central wooden form. The tar was burned out in the heating up of the furnace.

The walls are built up of eight fire-brick sections of special design, luted together with fire-clay and encircled by steel bands. These rest on a foundation made up of two courses of standard fire-brick, with the joints filled with fire-clay.

The cover for the crucible is a solid elliptical fire-brick section 17 in. x 20 in. and 2½ in. (43 x 50 x 53 cm.) thick, encircled by a steel band. The electrodes enter through the slot in the center of the cover. This slot admits of considerable lateral or angular movement of the electrodes. The under side of the cover is slightly concave. An asbestos gasket is placed under the cover where it rests on the top of the furnace, and small asbestos washers encircle the electrodes where they pass through the cover. The tap-hole is 1¼ in. (3 cm.) in diameter, and is well rounded at its point of entrance to the crucible.

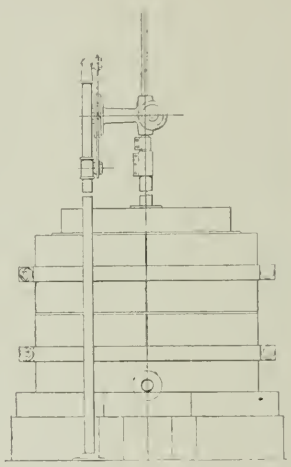

FIG. 2.—MODIFICATION OF FURNACE DESIGN, SHOWING ELECTRODE SUPPORT

The hearth electrode consists of six ½-in. (1.3 cm.) rods of Swedish iron screwed into a ⅜-in. (0.9 cm.) plate of the same material. The plate is embedded in the lining of the bottom of the crucible in such a position that the upper ends of the rods are flush with the inner surface. A copper strap 3-16 in. (0.5 cm.) thick and 1.5 in. (4 cm.) wide, bolted to the plate, extends outside the furnace for connection to the source of current.

The two movable electrodes are supported on a frame above the furnace. The supporting frame is entirely independent of the furnace proper and is therefore unaffected by expansion or contraction of the walls. The electrodes are cylindrical graphite rods 1.25 in. (3 cm.) in diameter and 11 in. (28 cm.) long. Each electrode is attached to a brass rod by means of a collar clamp and cotter pin. The rod carries a rack which meshes with a pinion mounted on the electrode support. The electrode supports are mounted to slide from right to left on the supporting frame. This facilitates adjustment of the electrodes while the surface is in operation and also allows the electrodes to be pushed back out of the way when relining the crucible. The support is so constructed that the electrode may be swung about it as a center and inclined at any angle. Ordinary pipe fittings were used as much as possible in the construction of the frame and supports since these give a light, strong construction, and require no special castings or forgings. An electrode support built entirely of pipe and fittings is illustrated in Fig. 2.

The furnace illustrated in Figs. 2 and 3 differs from that described above in having a crucible of double the depth de-

[1] Elec. Chem. & Met. Industry, Vol. V., p. 237 (1907.)
[2] Bul. de Soc. Chem., Paris 2, 38, 152.
Comptes Rendus, 90, 819.

scribed, i.e., 16 in. (40 cm.), and a different arrangement of the rods in the bottom of the crucible. This furnace was designed to operate continuously with a column of cold charge resting on the molten material, as in a shaft furnace.

This type of furnace may be operated as a Girod steel furnace by connecting the two movable electrodes in parallel with one side of the circuit and the hearth electrode with the opposite side. The movable electrodes may then be placed parallel vertically, thus forming two arcs, or set to converge to a single central point forming but one arc. To operate the furnace as a Heroult steel furnace, the points of the rods in the hearth electrode are covered with a layer of magnesite, and the two movable electrodes are connected in series with the circuit. The magnesite covering for the hearth electrode need not be of any great thickness, since there is but a slight tendency for the current to cross through the iron plate after the charge becomes molten.

The furnace is charged at the beginning of a run by removing the cover and distributing the charge with a trough or funnel. Additional material may be added through the opening in the cover while the furnace is running.

The small amount of coke in the charge used was found

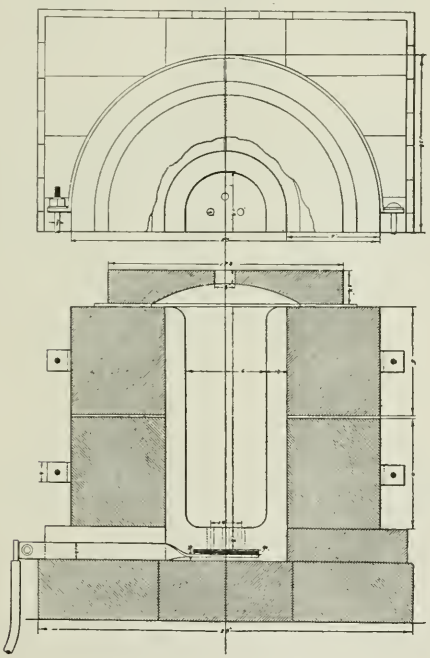

FIG. 3.—MODIFIED FURNACE DESIGN

to be sufficient to make the cold charge slightly conducting, the resistance rapidly decreases with rise of temperature, and the furnace may thus be readily started on a cold storage charge, providing the walls of the crucible are hot. The electrodes are forced down through the charge to within a short distance of the bottom of the crucible at starting. As the charge becomes hot, the electrodes are gradually raised until the charge is reduced and the arcs play between the ends of the electrodes and the surface of the slag. With the current available it was found impossible to maintain arcs below both electrodes simultaneously for any length of time. The best results were obtained by raising and lowering the electrodes alternately at intervals of two or three minutes, which caused the arcs to alternate from one electrode to the other electrode.

The capacity of the furnace as described is about 1,000 gm of metal per charge, or approximately 2,000 gm. of raw charge.

Single-phase alternating current at 60 cycles, 25 volts, was used, with an average amperage of 250.

The iron ore employed was a good grade of hematite from the mines of the Colorado Fuel and Iron Co. at Sunrise, Wyoming, the analysis being 66.06 per cent Fe., 1.52 Al_2O_3, 4.12 SiO_2, 0.04 P and 0.04 S. The ore was crushed to pass eight mesh (3mm.) and the fines were retained. A quantity of molybdenite from Yorkes Peninsula, Australia, was used, being practically pure MoS_2 with only a trace of impurity in the form of copper sulphide.

Ferrosilicon was used with an analysis of 49.7 per cent Fe, 50 Si, 0.005 S, 0.20 C.

The ferrosilicon and molybdenite were ground to pass thirty mesh (0.85 mm.) and intimately mixed in the proper proportions to bring about the reaction:

$$MoS_2 + Si = Mo + SiS_2.$$

The proper amount of this mixture to give the desired molybdenum content in the steel was enclosed in a small paper tube and added to the bath of metal just before reduction was complete.

Analysis of the coke and lime (ordinary builders' lime) are also given. Both were crushed to pass eight mesh (3 mm.) and the fines retained.

Six furnace runs are given in the paper. There was considerable trouble in tapping, as generally the metal would not flow. Only one of the runs is here given.

The charge consisted of 3025 grams iron ore, 660 coke, and 412 lime, the calculated iron content being 2000 grams.

The length of the run was 1 hour, 30 minutes, the mean amperes 200, mean volts 25, power 5 kw.

1,700 grams of metal were obtained. The calculated molybdenum content was 2.5 per cent. The run is described as follows:

Iron turnings were spread over the bottom of the crucible and covered by a layer of coke, lime and silica to form slag and protect the iron. The metal melted in 25 minutes but was kept molten in the furnace for 15 minutes after fusion in order to burn out the tar from new portions of the lining. This metal was tapped cleanly and a charge sufficient for 500 gm. of metal was added. This reduced in 20 minutes. Molybdenite-ferrosilicon mixture sufficient to give a content of 5 per cent. Mo in the metal was added in a paper tube just before reduction was complete. The tap hole was opened but the metal was level with the tap and only slag flowed out. The tap hole was again plugged and a charge sufficient to give 1,000 gm. of metal was charged.

Reduction was rapid and the charge was entirely reduced in 30 minutes. Molybdenite mixture sufficient to give a molybdenum content of 2.5 per cent. in the metal was added just before final reduction of the charge. Since the bottom of the crucible appeared to be sinking constantly, another charge equivalent to 500 gm. of metal was added and reduced in 15 minutes. This gave a total of 2,000 gm. of metal (calculated) in the furnace, with sufficient molybdenum to yield 2.5 per cent. in the total.

The tap hole was opened and slag flowed out freely but no metal was obtained. The current was shut off and the furnace allowed to cool. A solid mass of metal level with the tap hole was found in the bottom of the crucible.

The furnace was taken down and the entire lining and bottom electrode removed. A solid mass of metal weighing 1,700 gm. was obtained. The metal was malleable and tough, and was broken with great difficulty. When broken across the center the fracture was very fine grained and dense at the center of the mass and coarsely crystalline and full of small blow holes at its outer edges.

A section of the central portion of the mass, polished and etched with picric acid showed a network of a bright white

constituent, probably a double carbide of molybdenum and iron. A section in the coarsely crystalline portion of the mass showed a coarsely granular structure.

The analysis of the metal showed 0.62 per cent. C, 0.91 Si, 1.15 Mo, 0.08 P, 0.37 S.

In one of the later runs molybdenite concentrates from Woods flotation process were used. Most of the tests were qualitative rather than quantitative, so that further experiments would be necessary in order to determine the loss and distribution of molybdenum.

Since no analyses were made upon the slag, it is impossible to determine what proportions of the sulphur were removed by the ferrosilicon and the slag.

The following final conclusions are drawn:

(1) Molybdenum steel can be made in the electric furnace by the direct reduction of iron ore and the addition of molybdenum in the form of molybdenite, MoS_2.

(2) Molybdenum steel of low sulphur content can be produced from molybdenite by the use of ferrosilicon as a desulphurizer.

(3) Molybdenum steel of low sulphur content can be produced from molybdenite in the form of low grade concentrates by the use of ferrosilicon as a desulphurizer.

With regard to the design of a furnace for small scale operations, the experiments seemed to indicate that:

(1) The Girod principle as used was superior to the Heroult.

(2) A tilting furnace would be more effective than a stationary furnace.

(3) The tap hole on a stationary furnace should be made short, with a steep inclination. Ample provision for heating the tap hole should be made.

(4) Tar does not make a satisfactory binding material for crushed magnesite.

In discussing this paper Mr. FitzGerald pointed out there was danger in drawing conclusions from such small-scale experiments. He objected to the use of the names of Heroult and Girod for designating the two respective types of electric furnaces.

Mr. Hansen thought that the use of the two names was useful as a brief name for the two furnace designs, but Mr. FitzGerald objected to it as "electrochemical mythology."

Dr. Whitney liked the paper as coming from two young enthusiastic students. Such work should be encouraged.

Design of a 30-Ton Electric Induction Furnace

A paper by Mr. Albert Hiorth, of Kristiania, Norway, describes the design of a 30-ton induction furnace based upon the data and results obtained with the author's original 5-ton induction furnace in Jossingford, Norway.

The two most important things to be determined in the design were the power factor and the energy required to keep the charge at the working temperature.

The power factor of the furnace depends essentially on the ratio of the resistance to the reactance (inductance). The effective resistance consists of three parts, as is indicated by the fact that the power consumption in the furnace consists of three items, two representing the losses, namely, the loss due to the resistance of the primary coils and the hysteresis and eddy-current loss in the iron core; while the third item is the production of useful heat from electrical energy in the (secondary) bath; the secondary resistance may therefore be termed the useful resistance. The useful resistance depends essentially on the conductivity of the iron at the working temperature of the furnace and on the dimensions of the bath.

The author takes from his records figures for the volts, amperes and watts of his 5-ton furnace and calculates the total resistance. From this he deducts the resistance of the primary coils and the resistance corresponding to the losses in the iron core. He thus obtains the equivalent useful resistance of the bath. Figures are given for this useful resistance for different charges in the bath (that is, for different cross-sections of the molten metal). The resistance should be proportional to the cross-section.

This is indeed approximately fulfilled and from his figures he obtains a specific resistance of the molten iron equal to 1.4 ohms per sq. mm. cross-section and m. length. In handbooks the value given is somewhat higher, and even as high as 1.7. The discrepancy may be due to inaccuracies, which are quite unavoidable, considering the difficult nature of the measurements, or may be due to the fact that in the present case the section of the bath is not absolutely uniform and that, for instance, the central portion of the bath, where the two rings meet, represents a somewhat lower equivalent resistance than the rest. The value 1.40, it must be remembered, includes all the irregularities in the shape of the bath, and also the skin effect, as far as this influences the resistance. It can only be used for figuring the resistance of furnaces of similar shape and disposition of the bath.

The reactance (or inductance) of a given furnace and for a given frequency is independent of the weight of the charge and remains constant all the time.

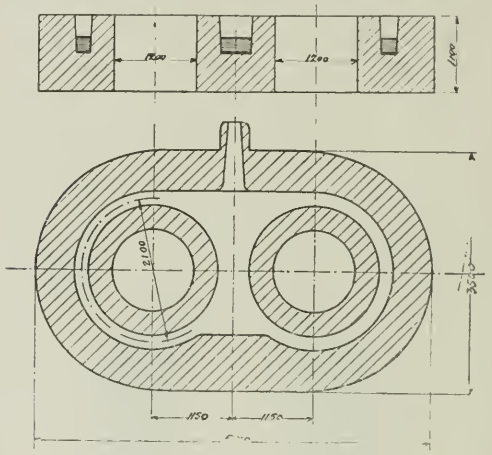

FIG. 1.—DESIGN OF 5-TON FURNACE.

Using the figures thus found for the resistance and inductance of his 5-ton furnace, he figures out theoretically the power-factor of the 5-ton furnace with different charges, and obtains the following table:

With	3 tons	Cos. ϕ	$=0.81$.
"	4 "	"	$=0.73$.
"	5 "	"	$=0.65$.
"	6 "	"	$=0.60$.

These figures correspond very well with the actual figures.

With regards to the design of a 30-ton furnace the first condition, of course, is that the space for the charge must be large enough to hold 30 tons, but the actual dimensions and shape of the bath must be such as to give the best possible power-factor.

In order to increase the capacity of the furnace, it is necessary to increase the sectional area of the bath more than the length, as otherwise the diameter of the bath, and consquently the dimensions of the furnace, would become too large. The resistance of the bath will thus be considerably decreased and at the same time the inductance will be increased, owing to the large diameter, which increases the area of the space between the primary and the secondary windings (hence the magnetic leakage).

The power-factor will thus in any case be reduced with the increased capacity, and the author has figured that a 30-ton furnace built on the same line as the 5-ton one, for single-

phase current, with a two-leg magnet and a current supply with 25 alternations, would show a power-factor equal to 0.25, and that the power-factor even with 15 alternations per second would still be only 0.38.

It was therefore decided by the author that the 30-ton furnace should be built on the three-phase principle instead of the single-phase. In this case the weight of the charge per ring is only 10 tons instead of 15 tons with a single-phase furnace and the reduction of the power-factor is not nearly so great.

In order to facilitate the tilting of the furnace, the three rings were disposed in one row.

After having finally chosen the dimensions for his new 30-ton furnace, he calculates the resistance and inductance and finds from these the power-factor which comes out as 0.34, which is still too low.

In order to increase the power-factor, it is necessary to further decrease the inductance by using a lower periodicity. What can be obtained in this way is shown in the following table:

Periodicity	Power-factor
25 alts.	0.34
20 "	0.41
16 "	0.50
10 "	0.67

From this table he selects a periodicity of 16 alternations per second. To decrease the periodicity further still will hardly

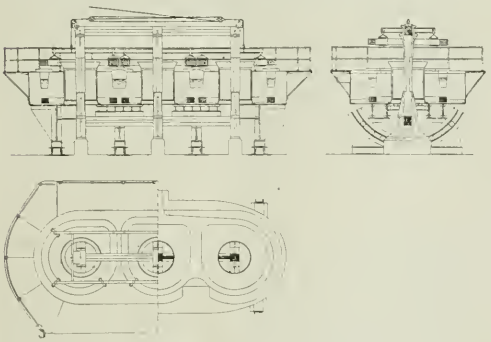

FIG. 2.—DESIGN OF 30-TON FURNACE

pay, seeing that the cost of the generator will thus be further increased, even if the output is reduced on account of the power-factor being improved.

It remains to figure out the necessary energy required for the furnace, the dimensions of the iron-core and the number of primary turns, together with the sectional area of these.

As the furnace will be used with a liquid charge, and no melting-down will take place, the amount of energy required is only the amount necessary to keep the bath at the required temperature. Apart from the small losses in the primary coil and the iron core, all the energy is converted into heat in the charge itself, and, as soon as a constant temperature is reached finally conducted to the surface of the furnace and given out from this by radiation, conduction and through the cooling arrangements. If water cooling is arranged in the same way and the same amount of water increased correspondingly, it may therefore be assumed that the loss of heat, and consequently the energy required to keep the charge hot, will be in proportion to the surface of the furnace.

According to the dimensions of the two furnaces the surface of the new furnace is between two and two and a half times as large as the old one. The amount of energy required in the old one to keep the charge in a molten condition during the night was approximately 180 kw., and during the refining the energy varied between 250 kw. and 350 kw. The minimum energy required for the new furnace should consequently be $2 \times 180 = 360$, and the maximum, $2.5 \times 350 = 875$. He assumes 700 kw., but at the same time the generator should be constructed in such a way that, by merely altering the voltage it can give anything between 400 and 1,000 kw. With 700 kw the current per ring becomes approximately 46,000 amperes, and the current density in the bath will be about 0.34 ampere per sq. mm.

The further figures are then easily calculated.

The table below shows the principal data for the old furnace and the new one:

	Old Furnace.	New Furnace
Total capacity	5 tons	30 tons
Capacity per leg	2.5tons	10 tons
Diameter of bath	2.1 m.	3m.
Width of bath	20 cm.	30 cm.
Depth of bath	27 cm.	45 cm.
Total surface of masonry	55 sq. m.	110 sq. m.
Total length of platform	8¼ m.	13 m.
Total width of platform	5¼ m.	6.5 m.
Sectional area of core per leg	1800 sq. cm.	1200 sq. cm.
Weight of core	15 tons	23 tons
Number of primary turns per leg	15	13
Sect'nal area of primary windings	1000 sq. mm.	4000 sq. mm.
Weight of copper per leg	0.875 tons	*ca.* 4.5 tons
Total weight of copper	1.75 tons	*ca.* 13.5 tons
Energy used	250 kw.	700 kw.
Copper losses	12.3 kw.	40 kw.
Iron losses	18 kw.	18 kw.
Power-factor	0.65	0.50
Voltage	250	230
Periodicity (½ alternations per second)	12½	8
Amperes per phase	1400	3540
Kind of current	1 phase	3 phase.

The number of primary turns of the new furnace is given above as 13, but in order to be able to run the furnace at full charge, even if the inductance and resistance should prove to be somewhat different from the values given, two turns should be added per leg, making the number of turns in the upper coils 8. The last three turns in each of these coils should be provided with terminals, enabling one to use at will 12, 13, 14 or 15 turns per leg.

The generator should, according to the foregoing, be designed for a normal output of 700 kw., 8 periods (corresponding to 16 alterations) per second, 230 volts, 3,540 amperes, and a power-factor of 0.5. At the same time it must be able to give 400 kw. at 165 volts, and 1,000 kw. at 275 volts, with the same power-factor, and 290 and 125 kw., respectively, with a power-factor of 0.362. The maximum current will thus be 4,300 amperes.

The engine or turbine driving this generator should be for a maximum output of 1,550 effective h. p., and run at a practically constant speed at all loads between 600 h. p. and 1,550 h. p.

This plant should be quite sufficient to supply energy to the 30-ton furnace, even if the constants of this should vary considerably from the figures given above. In order to study this, he has figured out what would happen, and the maximum and minimum energy which could be supplied to the furnace, in case either the resistance or the inductance or both should vary 25 per cent from the assumed value, either up or down. The results are given in this paper in form of a table.

Fig. 1 gives the designs of the old 5-ton furnace, Fig. 2 the design of the new furnaces.

In a communicated discussion Mr. Unger, of the General Electric Company, emphasized that the power installation as proposed in Mr. Hiorth's paper would be very costly on account of the use of so low a frequency as 8. He thought it would be cheaper to combine a number of smaller units in one furnace. In such a way it would be possible to build up an induction furnace of any size for commercial frequencies.

Dr. Waterhouse asked whether there would be any advantage of such a 30-ton pure induction furnace over a Roechling-Rodenhauser furnace or over an arc furnace of the same size.

Mr. FitzGerald replied to this question that the Roechling-Rodenhauser furnace for such sizes would be found greatly superior to other forms of induction furnaces, but made no comparison with any arc furnace.

Mr. Carl Hering referred to some calculations which he had made concerning the possibility of reducing heat losses on the basis of Mr. Hiorth's figures. The final conclusions will be published in an article in this journal. This was the last paper of the morning session.

An enjoyable lunch was then served in one of the halls of the University, and shortly afterward the second session began, being held as in the morning in the lecture room of the Chemistry and Mining Building.

Mineral Resources of Ontario.

The first paper was presented by Mr. T. B. Gibson, Director of Bureau of Mines of Ontario, on the mineral resources of Ontario. With the aid of a map the author sketched the situation and geology of the different portions of Ontario and gave an account of the mineral resources which have been found or may be expected to be found in these different portions. In Eastern Ontario there are a great variety of ores, but northern Ontario is the real home of the metallic deposits.

Mr. Gibson discussed at some length the production of silver, nickel, and gold in Ontario. There have been two eras of silver production in Ontario; the present one began with the opening of the Cobalt mines in 1904.

The nickel industry depends on the nickel-copper ores in the Sudbury district.

The gold industry is at present widely scattered and while it is not yet very successful it may be expected to become of great importance in the future.

Mr. Gibson concluded by suggesting two problems of importance which might be solved by electrochemical means. The first has to do with corundum which is practically pure alumina and is used at present mainly as an abrasive. But it is a richer ore of aluminium than bauxite and a process of making aluminium from corundum would be very profitable.

The second problem is the possible recovery of potash. There are deposits of feldspar in Ontario containing 13 to 14 per cent of potash. If the potash could be gotten out of it we would be able to get independent of Germany which has at present the monopoly in potash salts.

In the discusion Dr. Whitney remarked that another problem which might be worked out profitably is a process for the complex cobalt silver ores.

Addition Agents in Electrolytic Copper Deposition from Solutions Containing Arsenic.

A paper by Dr. Ching Yu Wen and Dr. Edward F. Kern gives an extensive account of an investigation carried out at the School of Mines of Columbia University on "the effect of organic and inorganic addition agents upon the electrodeposition of copper from electrolytes containing arsenic."

Since the object of this investigation and the results obtained were already discussed at some length in our June issue, page 318, it will suffice here to give the chief final conclusion. The combined "addition-agents" of gelatine and sodium chloride, and of glue and sodium chloride, when present in small amounts, are the most suitable and most satisfactory "addition-agents" for copper sulphate electrolytes, especially such as contain a high proportion of arsenic, as with these the deposited copper possesses the greatest ductility and the highest purity. But the combined "addition-agent" of gelatine and sodium chloride (say 0.01 to 0.02 per cent. gelatine and 0.01 per cent. Cl as NaCl) seems to be a little better than sodium chloride and glue, for it gave smoother deposits. In the case of glue and inorganic compounds, the use of cuprous chloride, cupric chloride or hydrochloric acid is just as effective as sodium chloride; but for economic reasons sodium chloride is to be preferred.

In a communicated discussion by Mr. W. L. Spaulding, of the Buffalo Smelting Works, reference was made to experiments on the addition of NaCl to copper refining solutions. In one case the addition of the salt had been found to have deleterious effects, causing a slimy layer on the anode.

Conductivity of Mixtures of Copper Sulphate and Sulphuric Acid.

A paper by Prof. H. K. Richardson and Mr. F. D. Taylor of the Pennsylvania State College gave an account of a series of measurements of the conductivity of mixtures of copper sulphate and sulphuric acid.

In the absence of the authors it was presented in abstract by Mr. Lidbury.

To obtain figures for calculating the voltage drop due to electrolytic resistance in a copper refining tank knowledge is necessary of the conductivity of sulphuric acid and copper sulphate mixture. This was measured by the authors in different proportions at two different temperatures, namely, 25 deg. C. and 45 deg. C.

CONDUCTIVITY IN RECIPROCAL OHMS PER CM.

Grams H_2SO_4 per 100 c.c.	$CuSO_4.5H_2O$	25° C.				45° C.			
		0	5	10	15	20	0	5	10	15	20
Grams per 100 c.c	0	....	0.208	0.410	0.565	0.683	....	0.246	0.492	0.683	0.839
	5	0.953	0.204	0.388	0.531	0.646	0.0205	0.242	0.461	0.643	0.791
	10	0.0221	0.195	0.350	0.500	0.600	0.0294	0.222	0.422	0.606	0.738
	15	0.0343	0.189	0.338	0.458	0.558	0.0468	0.217	0.381	0.545	0.690
	20	0.0423	0.182	0.319	0.433	....	0.0574	0.212	0.378	0.521	0.643

In practical work most all strengths of solution are given in terms of percentages. To convert the values in the above table to these units the following table may be used.

Percentage-			Grams per 100 c.c.			Gram Equivalent per 1000 c.c
Copper	$CuSO_4$	$CuSO_4.5H_2O$	Copper	$CuSO_4$	$CuSO_4.5H_2O$	
1.00	2.5	3.91	1.04	2.56	4.0	0.321
2.00	5.0	7.82	2.09	5.25	8.2	0.658
3.99	10.0	15.64	4.41	11.05	17.4	1.387
5.99	15.0	23.46	6.97	17.50	27.4	2.194
6.98	17.5	27.37	8.37	22.00	32.9	2.631

% H_2SO_4	Grams per 100 c.c.	Grams Equivalent per 1000 c.c.
5	5.15	1.05
10	10.7	2.18
15	16.5	3.38
20	22.8	4.66

Measurements were also made of the temperature coefficient of the conductivity.

Of the general conclusions of the authors these are the most important:

Addition of copper sulphate to solutions of sulphuric acid increases the conductivity of the mixture if the sulphuric acid is less than 3 grams per 100 cc. On the other hand, it decreases the conductivity if the sulphuric acid is over 3 grams per 100 cc. If the sulphuric acid is just 3 grams per 100 cc. the addition of a little copper sulphate to the solution of sulphuric acid has no effect on the conductivity of the mixture.

The temperature coefficient of mixtures of equal parts of copper and sulphuric acid appears to be that of the sulphuric acid alone.

Transformation of Other Forms of Carbon into Graphite.

A paper by Mr. W. C. Arsem, of the Research Laboratory of the General Electric Company, Schenectady, N. Y., discusses the conditions under which "amorphous carbon" is transformed into graphite. These conditions have been the subject of much discussion, and many statements have found their way into literature which are not supported by experimental evidence.

The following theories are commonly held:

1. A high temperature alone will convert "amorphous carbon" into graphite (Moissan).

2. Pure carbon is not converted to graphite by heat alone (Berthelot).

3. Graphite is the result of intermediate formation and decomposition of carbides, due to the presence of mineral matter as an original constituent, or purposely added (Acheson). For instance, in one of Dr. Acheson's patents (617,979, Jan. 17, 1899)

it is mentioned that a mixture of 97 parts coke or charcoal and 3 per cent iron oxide can be changed to a greater or less extent into graphite by varying the time and temperature of heating. As the iron is insufficient to convert all the carbon to carbide, it is assumed to have a catalytic effect, first forming a carbide which decomposes, yielding graphite and setting free iron, which again forms carbide, and the cycle is repeated.

The present author has collected all available references relating to the problem. These are summed up in the paper.

He also emphasizes the ambiguity in the use of the term "graphite." The Brodie test is thought not to be decisive. The most characteristic property seems to be specific gravity. Mr. Arsem therefore proposes the following definition:

Graphite is that allotropic form of carbon having a specific gravity of 2.25 to 2.26.

Those varieties of carbon which have some of the physical properties of graphite, such as color, softness and streak, but a lower specific gravity, may perhaps be regarded as impure graphites; that is to say, mixtures of graphite with other forms of carbon.

Mr. Arsem then gives an account of an experimental investigation the object of which was to clear up these two points at issue:

1. Can a pure form of carbon be transformed into graphite by simply heating it to a high temperature?

2. If this is not the case, is it possible to cause this transformation to occur by heating the carbon, well mixed with a quantity of mineral matter, insufficient to form carbides with all the carbon present?

There are two ways of attacking the problem.

(a) To determine the effect of heating various forms of pure carbon alone and with small amounts of added mineral matter.

(b) To remove the mineral matter from certain varieties of impure carbon which ordinarily change to graphite when heated and see if the change will still occur.

Both methods were tried and the following results were obtained:

All the pure forms of carbon which have been tested, when fired above 3000°, reach a limiting density which is not appreciably raised by the addition of small amounts of mineral matter. The end product is graphite in some cases and not in others. Pure petroleum coke, heated without addition of mineral matter, is converted into graphite of excellent quality, while lampblack, although it increases in density, does not reach the value corresponding to graphite, nor acquire any of its other physical properties, even when heated with various oxides.

The impure carbons show a similar behavior. The properties of these carbons after firing are characteristic for each variety of carbon and independent of the amount of ash present.

Anthracite coal is only imperfectly graphitized by heating. The specific gravity of the fired material was approximately the same for three samples having a range of ash content. Moreover, coal from which most of the ash has been previously removed graphitizes better than the crude material.

Bituminous coal coke, which graphitizes fairly well, yields an even better product if a part of its ash has been removed before firing.

It must, therefore, be concluded that a small amount of mineral matter exercises no beneficial effect in the manufacture of graphite by the heating of carbon, and that the quality of the product cannot be improved in this way. As to the effect of mineral matter on the rate of conversion, no data are yet available, although some experimental work along this line has been started. At 3000° the maximum density is reached in less than 15 minutes for any variety of carbon.

Some theory of the nature of graphite and of amorphous carbon is needed which will permit a rational explanation of the changes which occur on heating. Mr. Arsem offers the following discussion as a tentative step in this direction:

Graphite, in the most restricted sense of the term, is an allotropic form of carbon having a definite and not very complex molecular configuration. The molecule might, for example, be regarded as two benzene rings side by side and joined at all six angles, the extra bonds being satisfied as in the usual centric formula. Such a formula might be used to explain the formation of mellitic acid and graphitic acid by oxidation of graphite.

Amorphous Carbon. When an organic compound is decomposed, there results a mixture of substances constantly increasing in complexity until finally carbon is obtained. This carbon need not be regarded as a simple substance, but may be considered to be a mixture of many varieties of carbon, each with a different number and arrangement of atoms in the molecule. According to this view, it seems better not to regard "amorphous carbon" as the name of a distinct allotropic form, but rather as a general term covering all varieties of carbon except graphite and diamond.

In speaking of amorphous carbon, therefore, the source of each sample should be stated.

The Mode of Transformation. In a given sample of amorphous carbon, some of the molecules will be capable of easily undergoing rearrangement under the influence of heat to form graphite molecules, while others will not, and the proportion of molecules capable of such change will determine the character of the final product.

Petroleum coke would therefore consist almost wholly of graphitizable molecules, while anthracite coal contains a smaller proportion.

Mr. Arsem's paper which had been read in the absence of the author by Mr. Hansen was briefly discussed by Mr. Lidbury and Mr. Hansen.

Electric Laboratory Furnace with Resistor of Ductile Tungsten or Molybdenum.

A paper by Messrs R. Winne and C. Dantsizen of the Research Laboratory of the General Electric Company, of Schenectady, N. Y., describes two simple electric furnaces for laboratory work with resistors of ductile tungsten or molybdenum wire or ribbon. On account of their very high melting points and relatively low cost these metals are well adapted for that purpose.

The first type is a **crucible furnace** and consists of a helix of ductile tungsten or molybdenum, supported by an alundum tube and protected from oxidation by a hydrogen atmosphere.

Fig. 1 shows the furnace in vertical section. The heating wire, of ductile tungsten or molybdenum, is wound on *G*, an alundum cylinder which is molded plain inside and with a helical groove on its outer surface. *A* is a Battersea crucible; *B* is an inverted Battersea of which the bottom has been cut off; *C* is the crucible bottom, used as a cover. The bottom of *A*, as well as the space between *A* and *B*, is filled with powdered silica. Hydrogen is constantly supplied to the furnace through the pipe *D*, and burns as it escapes from the top of *B*. This gives a protecting atmosphere for both the tungsten or molybdenum winding and the object to be heated. Current is supplied to the winding through two large copper connectors *E*.

An object to be merely heated, as for annealing, may be inserted directly into the alundum cylinder. Material to be melted is placed in a small crucible, preferably made of pure alumina, and this is let down into the alundum cylinder.

In the apparatus shown in Fig. 1, the Battersea crucibles *A* and *B* are sizes *O* and *J* respectively. The alundum body *G* (made by the Norton Company, of Worcester, Mass.) consists of two cylinders placed end to end. Each is 7.6 cm. high and 5.1 cm. inside diameter, while the distance from one convolution of the helix to the next is .95 cm. The winding consists of 260 cm. of square molybdenum wire, 1.27 mm. on a side. This wire is first wound on a mandrel 3.8 cm. in diameter, and wire and mandrel are then heated up to about 800 deg. C. Upon then releasing the coil, it expands to the diameter of the alundum body, on which it can then be screwed. The copper connectors

E are 0.8 cm. in diameter, and the ends of the coil are simply clamped in with set-screws. The copper connectors and the hydrogen inlet tube are held in place in the crucible wall by a mixture of powdered silica and water glass, which at the same time prevents loss of hydrogen.

This furnace can be safely run up to 1700 deg. C. At this temperature it calls for 25 volts and 45 amp.

Pure iron can be melted and ferro alloys and other alloys can be produced in this furnace.

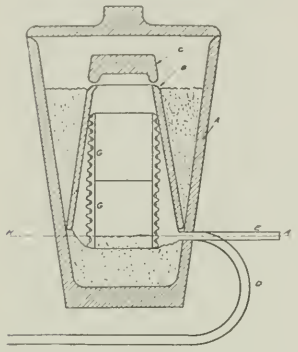

FIG. 1.—CRUCIBLE FURNACE WITH TUNGSTEN WIRE RESISTOR.

The second type is a **tube furnace** and consists of a porcelain or alundum tube, wound with tungsten or molybdenum foil. Around the tube is a tight metal casing filled with powdered silica, and, to prevent oxidation of the winding, a hydrogen atmosphere is maintained in the casing. Fig. 2 shows the furnace in vertical length section. *A* is an alundum tube, 2.3 cm. inside diameter and 46 cm. long. The casing *D* is made of thin sheet iron and is oxy-acetylene welded. The winding *B* is a molybdenum ribbon, 0.184 mm. thick, 2.54 mm. wide and 445 cm. long. *I*, *I* are heavy copper leads, fastened to the ends of the coil by twisting the latter about them. *C* is the powdered silica packing, *F*, *F* is some asbestos wool, used to prevent the escape of hydrogen at the ends of the casing.

H and *G* are the hydrogen inlet and outlet tubes respectively, *E* is a rubber stopper.

With this furnace a temperature of 1600 deg. C is readily attained. At this temperature it calls for 80 volts and 14.3 amp. The two furnaces described are adapted to heating the charge in an atmosphere of hydrogen. In case it were desirable to heat

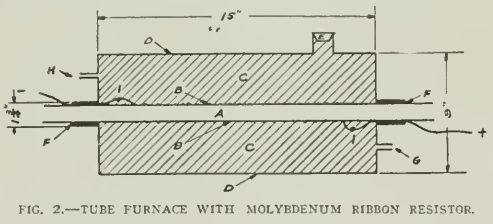

FIG. 2.—TUBE FURNACE WITH MOLYBDENUM RIBBON RESISTOR.

in an oxidizing atmosphere, it would be necessary to replace the very porous alundum by porcelain, as otherwise the furnace winding would become oxidized.

In the discussion of the paper of Messrs. Winne and Dantsizan in which various speakers participated, Mr. Saunders suggested that the porosity of alundum tubes could be overcome and that their field of application could thereby be extended by providing a glazed inner surface. The melting point is high enough.

Electric Properties of Sodium, Potassium and Their Alloy

A paper by Dr. Edwin F. Northrup, of Princeton University, gives new data on some electrical properties of sodium, potassium, and their alloy. The author intends to determine the electric resistivities and temperature coefficients of as many metals as possible at higher temperatures. To carry out the investigation in a systematic manner, he will take up the elements in the order of Mendelseff's table. The investigation began with soduim and potassium, which fall in the first group. In view of their low melting points it seemed sufficient to limit the investigation to the temperature range between 0 deg. and 150 deg. C.

A glass tube, supplied with platinum potential and current terminals, was first filled with pure mercury, and the resistance of this, throughout the range of temperature employed, was determined between potential points. The same tube was then filled with the metal, in a molten state, which was to be measured. Its resistance, between the same potential points, was then measured at various temperatures as the metal cooled, from the highest to the lowest temperature. From the data so obtained the specific resistances and temperature coefficients were determined.

The methods of measurements are described in some detail.

For the resistance of the mercury in the interval from 20 to 110 deg. C the following relation giving the relation between resistance and temperature was found.

$$Rt = 0.02889\ (1 + 0.0010036t)$$

where t is degrees C above zero.

Substance	Spec. Res. at 20° C. $10^{-9}\times$	Spec. Res. at 100° $10^{-9}\times$	Temp. Coef. Low Range	Temp Coef. High Range	Density at 0°
Mercury	95,810	103350	0.001003 (20° to 100°)		13.595
Sodium	4,875	9,705	0.0053 + (20° to 80°)	0.00494 + (100° to 140°)	0.978
Potassium	7,118	15,275	0.0058 (20° to 50°)	0.00507 + (66° to 120°)	0.87
Alloy, K + Na	33,800	37,795		0.00147 [46° to 125°)	0.92
Copper	1,721	2,266	0.00387 +		8.89

Spec. res. of Na at 20° C. = 0.05088 × Spec. res. of Hg at 20° C.
" " " Na " 100° C. = 0.09390 × " " " " " 100° C.
" " " K " 20° C. = 0.07429 × " " " " " 20° C.
" " " K " 100° C. = 0.1478 × " " " " " 100° C.
" " " Na + K " 20° C. = 0.3528 × " " " " " 20° C.
" " " Na + K " 100° C. = 0.3657 × " " " " " 100° C.

Some figures in this table are interesting. First the very high coefficient of potassium in the range 20 deg to 50 deg. of 0.0058 and the slightly smaller coefficient of sodium in the range 20 deg to 80 deg. of 0.0053. Potassium is thus probably unique in possessing the highest coefficient of any pure metal in this range that has been observed. It should be noted that the coefficient of the alloy of potassium and sodium, instead of being approximately the mean of the coefficients of sodium and potassium when liquid, is only between a third and a fourth of the mean value of the coefficients of its constituents in the same temperature range.

The mean specific resistance at 100 deg. of sodium and potassium is $12{,}490 \times 10^{-9}$, while the specific resistance of the alloy, in equal proportions by volume, is $37{,}795 \times 10^{-9}$, or slightly over three times as great as the mean specific resistance of its constituents. This is an interesting physical fact which may help to throw light upon the theory of conduction in metals.

In this connection we may note that alloying metals generally, if not always, increases their specific resistance and lowers their melting point.

The abrupt increase in resistance of the metals experimented with, expressed in percentage, is as follows:

Sodium, in passing from the solid state at 93.5 deg. to the liquid state at 96.3 deg., increased 44.8 per cent.

Potassium, in passing from the solid state at 60.4 deg. to the liquid state at 63.2 deg., increased 52.2 per cent.

The alloy of sodium and potassium, in passing from 2.8 deg., at which temperature it may probably be considered as completely solid, to 20 deg. C., at which temperature it may probably be considered as completely liquid, increased in resistance 48.5 per cent.

The ratio of the resistivity at 20 deg. C. of sodium to copper is 3.058, but the density of copper is almost exactly nine times that of sodium, which, in round numbers, makes sodium three times as good a conductor per unit of weight as copper. Hence it could compete with copper as a conveyor of electric power if it cost anything less than 3 times as much as copper per pound, provided, of course, current-carrying capacity were the only consideration. It has been suggested before now that sodium might be used in iron pipes in a practical way for carrying electric power. Dr. Northrup suggests that inasmuch as electrochemical processes often necessitate the carrying over short distances of enormous currents, the consideration of the proposal might be with advantage taken up afresh.

The paper was discussed by Messrs. Morrison, Whitney, Hering, and Lloyd. Reference was made to the considerable change in electric conductivity of steel at the melting point.

Electric Resistivity of Iron Alloys.

A paper by Prof. Chas. F. Burgess and Mr. James Aston, of the University of Wisconsin, discusses the electric resistivity of various iron alloys. In the design of electrical machinery, the electrical resistivity of the iron used for electromagnets is of an importance second only to the magnetic permeability, particularly for alternating-current working. A high resistance is desired, since it will reduce to a minimum the eddy currents sets up by the reversals of the magnetic flux. It is

TABLE I.—HIGH ELECTRICAL RESISTANCE. RELATIVE ABOVE 5.

also of interest to know the conductivity of the various iron alloys, regardless of their magnetic properties, because of their possible utility in rheostats, resistance heating wires and the like.

In connection with the series of tests which the authors carried out on the various properties of electrolytic iron and its alloys, they determined the electrical resistance of the numerous bars used in the magnetic tests. They started with electrolytic iron as base material (the resistivity of which is taken as unity) and made up the various alloys by addition of the other elements.

It appears as a result of these tests that all three of the elements of arsenic, silicon, and tin, which are beneficial to the magnetic properties of iron, have the desirable accompaniment of high electrical resistivity.

Among the materials adapted for high resistances, various combinations of iron with nickel, chromium, and silicon are most suitable.

The change of resistance due to heat treatment in general follows the changes of physical hardness due to the treatment. Annealing usually results in a decrease of resistance. Quenching is uncertain in its effect; usually there is an increase of resistance with physical hardening of the bar.

There are grouped in Table I, in the order of their relative resistances, all those iron alloys tested which showed a relative value as compared with the electrolytic iron of *five or upwards*. (The electric resistivity of pure electrolytic iron being taken as unity.) The highest resistance recorded is 8.50, reached by a bar with 10 per cent Cr, 5 per cent Si. Examination of the table shows 43 bars listed, all of which contain chromium, nickel or silicon, either alone or in various combinations.

The paper was briefly discussed by Messrs. Hansen, Lloyd, Northrup, and Watts. It was stated that the determinations of resistivities had been made at ordinary temperatures.

Before the conclusion of the Thursday afternoon session Mr. F. A. J. FitzGerald read the report of a special committee which had been appointed by the president to consider the possibility of setting a higher standard for the papers published in the Transactions of the Society. The report had been very carefully prepared and contained a series of valuable suggestions which had been approved by the meeting of the Board of Directors the night before. A committee was appointed to carry the suggestions of the report into effect.

Mr. Edward R. Taylor read a set of recommendations on principles of water conservation which he suggested to present at the coming National Conservation Congress in behalf of the Society. These recommendations were approved and endorsed.

Electrochemical and Electrometallurgical Developments in Canada.

The first paper of the Friday session was presented by Dr. S. Dushman, of the University of Toronto.

He first gave a review of the electrochemical plants at present in operation throughout the Dominion of Canada. Their number is at present not very large.

In the extreme west in the Province of British Columbia, there is in Trail the electrolytic lead refining plant (using the Betts process) of the Consolidated Mining and Smelting Company of Canada.

The oldest electrochemical industry in Ontario is the manufacture of calcium carbide at the plant of the Willson Carbide Company at Merriton. Carbide is also made by the Ottawa Carbide Company on Victoria Island, in that section of Ottawa known as the Chaudière.

In the old Heroult electric furnace plant at Sault Ste. Marie, in which Dr. Haanel made his well known tests for the Government on the reduction of iron ore in the electric furnace, and which was later taken over by the Lake Superior Power Company for the manufacture of nickel pig from pyrrhotite, the company is now making ferrosilicon for its own consumption.

Ferrosilicon is also made by the Electro Metals Company, at Welland.

On the Canadian side of Niagara Falls there are plants for making cyanamide, graphite, and carborundum. The American Cyanamide Company commenced operations in January, 1910, with a 10,000-ton plant and is at present producing to its full capacity. The whole output is shipped to the United States.

The Norton Company has a plant at Chippewa for the manufacture of crystolon—another trade name for carborundum or silicon carbide. The raw materials used are two different

grades of coke (a metallurgical coke with 92 per cent or more fixed carbon and 5 per cent ash, and a petroleum coke, containing about 91 per cent fixed carbon with less than 1 per cent ash), a very pure silica sand, and sawdust. Two grades of product are manufactured, green and steel gray. At present 2000 hp are employed. The whole output of the plant, which is 5 tons per day, is shipped to the company's main works at Worcester, Mass., where it is used for the manufacture of different abrasive articles.

The International Acheson Graphite Company has also established a plant near Niagara Falls, Canada. Its output in 1909 was 513,430 pounds of artificial graphite.

No electrolytic alkali plant is at present in operation in Canada. The old Rhodian mercury-cell plant at Sault Ste Marie was discontinued years ago and has not been opened again.

At the present time the Canadian Salt Company, of Windsor, Ont., is erecting a plant at Sandwich for the manufacture of caustic soda electrolytically, the Gibbs cell being used. It is expected that this plant will begin operations very shortly.

There is an electrolytic gold and silver parting plant at the Royal Mint in Ottawa. The gold bullion (after being assayed) is melted with silver in such proportion as to form an alloy containing 40 per cent gold, 56 per cent silver, and 4 per cent base metals. The alloy is cast into anode plates and used in a dilute solution of silver nitrate and a little nitric acid, and the silver deposited out. When nearly all the silver is removed a spongy mass of gold of the original shape of the anode plate is left. This is washed and re-melted and treated as anodes by the Wohlwill gold refining process.

Most of the electrochemical industries of Quebec are situated around Shawinigan Falls. The Northern Aluminum Company, a branch of the Aluminum Company of America, produces aluminium by the Hall process. The total capacity of the works is 25 tons of aluminium per day, about 500 men being employed when the plant is running at full capacity. The output in 1909 was over 3100 tons.

Carbide is made by the Shawinigan Carbide Company, by a continuous process.

The Electro Reduction Company, at Buckingham, manufactures phosphorus and ferro-phosphorus from apatite.

In the second part of his paper Dr. Dushman gave an account of the possibilities of future electrochemical and electrometallurgical developments in Canada, discussing the available raw materials, water powers, and transportation facilities.

As to mineral resources the greater portion of Canada is as yet unprospected, about one-third lies within the prospected area and two-thirds without, and the mineral resources have been developed (leaving out the Yukon) practically only in the territory lying fairly near the southern boundary. Even the portions of the country represented as being within the prospected territory must not be considered more than partially explored for minerals, as new discoveries are continuously being made within the supposed prospected areas.

At the present time the mining industry of Canada is second only to agriculture. In 1886 the total mineral production was slightly over $10,000,000; in 1909 it had grown to $92,000,000 and in 1910 to over $105,000,000. In 1909 the total mineral production of Canada had a value of $105,000,000. Of this $40,000,000 was the value of the metallic products including $17,000,000 for silver, $11,000,000 for nickel, $10,000,000 for gold and $7,000,000 for copper. Among the non-metallic products coal leads with $30,000,000.

The gold resources of Canada have only been skimmed so far. About 90 per cent of the silver produced in Canada in 1910 was derived from the rich silver deposits of Cobalt.

The ores of the Cobalt district are extremely complex, and the problem of treating these ores economically is still awaiting a solution. Under present conditions one of the pressing needs for the further promoting of mining and metallurgical activity in Northern Ontario is the devising of suitable methods for the treatment of the Cobalt silver ores. Only about 30 per cent of the ore shipped from Cobalt in 1909 was treated in metallurgical works in Canada, most of this being high-grade silver ores, and the rest was shipped to a number of large companies operating in the United States. With respect to the content of nickel, cobalt and arsenic in the ores, the mining companies are paid only for a small portion of the cobalt content, and nothing for the nickel and arsenic, in fact, in certain cases the latter two are penalized.

Another interesting problem in connection with the cobalt silver ores, is what to do with the cobalt.

In the solution of these problems there is undoubtedly a field for the electrochemist.

With respect to iron much attention has been paid in Canada to the possibility of using electric furnace processes since Canada has immense iron ore deposits and water powers. What has held back this development in the past is the very large capital investment which would be necessary.

Electric furnace experiments have also been made on a larger scale with respect to zinc in Canada, but have not led to commercial operation.

As to water powers in Canada, the total amount of power already developed and in process of development in British Columbia is 75,000 hp. The numerous powers off the coast would aggregate another 50,000 hp.

In Ontario the sources of water power are almost innumerable.

The Ottawa River alone would be capable of supplying over 300,000 hp, while the numerous falls on the Gatineau can supply over 200,000 hp.

In the province of Quebec the numerous tributaries of the St. Lawrence present remarkable power possibilities.

In New Brunswick only the St. John river has been exploited.

The Grand Forks Power Company is building a plant at that place to develop 80,000 hp.

With respect to transportation facilities, Canada in 1867, had 2278 miles of railroad, while it has at present close to 25,000 miles. The Canadian Pacific Railway was only completed in 1886, while there are now two other transcontinental railways in Canada.

The author concluded with the remark that in the great evolution which Canada is to undergo during this century the electrochemical engineer will be called upon to solve some of the most important problems.

Metallic Cerium.

A long paper by Dr. Alcan Hirsch on "The Preparation and Properties of Metallic Cerium" gives an account of a very extended and elaborate investigation which required over three years' work at the University of Wisconsin.

The investigation was undertaken with a two-fold purpose. First, starting from as pure cerium salts as it was possible to obtain, it was desired to prepare the metal in quantities sufficiently large that its physical and chemical properties could be studied and a large number of alloys could be made. Second, by preparing metal from the unpurified rare-earth residues from monazite sand, obtained as a by-product in the incandescent gas mantle industry, it was hoped that alloys of commercial value could be obtained. In other words, whereas the application of these residues as oxalates or oxides is very limited to-day, their value might possibly be increased materially if a useful metallic or alloyed product be prepared from them.

A historical review is given of former work done on metallic cerium and then the methods developed for the preparation of the starting material are discussed in some detail. The general scheme followed was to use the mixed rare-earth oxides for experimenting on the exact conditions required for the preparation of the desired salt, and after the proper con-

ditions of the process had been determined, to prepare the pure cerium salt. Oxalates of the rare-earths, a by-product of the commercial extraction of thorium and cerium from monazite sand, were employed for these experiments. The oxides prepared by calcining the oxalates at a temperature of 750-800 deg. C. in a gas muffle furnace, analyzed 97.8 per cent. rare-earth oxides, of which approximately 49 per cent. was cerium dioxide.

The first salts required were the **anhydrous chlorides** (composition RCl_3). There are several hydrated chlorides of cerium known. The chief difficulty is in their dehydration since cerium chloride is similar to magnesium chloride in that when its solution is evaporated to dryness and calcined, HCl is evolved with partial decomposition of the chloride to oxychloride and oxide.

The author discusses a good many methods for the dehydration of chlorides of cerium. One method of obviating the difficulty would be to use a non-aqueous solvent. The carbide RC_2 may be prepared by heating the mixed oxides with powdered graphite in an arc furnace. Alcoholic HCl, made by passing dry HCl gas into cooled absolute alcohol, acts readily on the carbides. But the solution of the chlorides prepared by this method always contains more or less graphite, and is very difficult to filter because of its viscosity. The method is in general unsuitable for large-scale operation.

Resort was, therefore, again made to dehydration methods. It was found that by treating the mixed oxides with concentrated HCl, evaporating to dryness, adding more HCl and repeating the process a number of times, a product was obtained corresponding to one of the lower hydrates of the chlorides. But the difficulty is to get rid of the last molecule of water. In this process certain chlorides of the metalloids, especially those of phosphorus and sulphur, can be used as catalysers in the dehydration of hydrated chlorides. Experiments in this direction are described and finally a method of dehydration which may be carried out by HCl gas alone (without phosphorus and sulphur chlorides) was evolved which was used in the research. This is as follows.

The double cerium-ammonium nitrate from the fractionating vats, where it has been purified and separated from the other rare-earths by fractional crystallization, was used. The absorption spectrum of a concentrated solution of the nitrates showed only the faintest traces of the neodymium and praseodymium bands. The contents of a large bottle containing five kilograms of the double nitrates was divided into four portions and placed in fourteen-inch (35 cm.) porcelain evaporating dishes. The dishes were filled with concentrated HCl and placed on steam-heated sand-baths. Each dish was suitably protected from drippings from the hood by wooden covers raised a few inches above the tops of the dishes and supported on silicia bricks.

Fresh acid was added daily as required and the evaporation continued for about three weeks, at the end of which time the nitrates had been completely converted into chlorides and all the ammonium salts had been expelled. The white solid was broken into lumps and heated on an asbestos-covered hot plate to convert it to the monohydrated chloride.

The final dehydration was carried out as follows (see Fig. 1). About 400-500 grams were placed in a ten-inch porcelain evaporating dish. A short-stem funnel about nine inches in diameter was inverted and placed over the salt. A layer of asbestos fiber was packed tightly around the outside edge of the funnel and plaster of paris set over this. A glass tube passing through the steam of the funnel and reaching to just above the layer of chloride conducted in the dry HCl gas, which was passed at a rapid rate over the heated chloride. The salt was stirred around from time to time by means of a long, thick glass rod. The heating was done gradually, and the progress of the dehydration could be watched through the glass funnel and its completion checked nicely.

The anhydrous chloride was placed, while still warm, in dry glass vessels, and the corks paraffined in to exclude moisture from the extremely hygroscopic product.

The chloride prepared by this method melts to a clear, limpid liquid, and is suitable for electrolysis.

It was observed that the anhydrous rare-earth chlorides may be partially converted into oxides or oxychlorides if they were carelessly heated in the presence of air. The best method of melting the anhydrous chlorides without decomposition was found to be by heating a small portion in a covered crucible until a clear melt was obtained, and then introducing successive small portions of the chlorides to the melted portion. In this manner circulation of air is avoided, as the crucible is kept covered. A good way is to first melt sodium or potassium chlorides, or a mixture of these, and then to add small amounts of the rare-earth chlorides, keeping the crucible covered as much as possible. A small amount of oxide or oxychloride will "gum up" the entire melt, and for electrolysis this condition must be carefully guarded against.

Another salt required in large amounts was the **anhydrous mixed fluorides**, RF_3. Lead lined apparatus are needed in the preparation.

After discussing several methods and their preparation the following method is given as the most satisfactory: About a kilogram of the mixed oxides was placed in a large porcelain evaporating dish and digested in a steam closet with concentrated HCl until a clear concentrated solution of the chlorides was obtained. The hot solution, containing only a slight excess of hydrochloric acid, was transferred to a five-gallon lead jar and concentrated HF added to complete precipitation. The fluorides were allowed to settle somewhat, as much of liquid syphoned off as was possible, and washed twice with hot water and several times with 95 per cent. alcohol. Only a few minutes' time was allowed after each washing for the precipitate to settle.

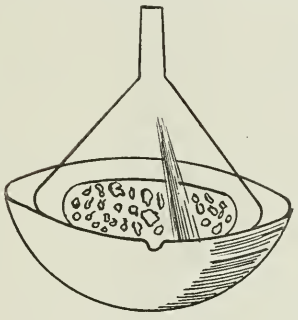

FIG. 1—APPARATUS FOR FINAL DEHYDRATION.

The fluorides were then placed in a lead-lined cage-centrifuge, and most of the remaining alcohol removed in this manner. Absolute alcohol was added and the solution evaporated to dryness without decanting. The absolute alcohol dehydrates the centrifuged fluorides very well. They were then dried at 100°, and the temperature raised to 200° at the end. About six kilograms of the fluorides were prepared in this manner.

Preparation of Metallic Cerium.—Two methods were tried: first thermal reductions and second electrolysis.

Thermal Reductions.—Magnesium and calcium shavings and aluminum powder were used as reducing agents on the mixed oxides. These experiments were conducted in electrically-baked magnesia linings placed in graphite containers. Carbon and silicon were also used to reduce the oxides, but external heat was applied to give the high temperature required. No metal was formed in these last instances but the carbides and silicides respectively. The carbide RC_2 is pyrophoric, but the silicide RSi_2 is not. Reductions using magnesium and calcium in excess gave alloys, many of which were pyrophoric.

In the case of these thermal reductions, either an alloy, a compound or a lower oxide of the rare-earths was obtained. Owing to the high heat of formation of these oxides, the failure of alumino-thermics in the production of metals was only to be expected. The author believes that a study of the

equilibrium conditions of these reactions would form an interesting and valuable research and might result in the discovery of lower rare-earth oxides.

Preparation of Cerium of Electrolysis.—Electrolysis of the anhydrous chlorides was first tried but was found to involve a great number of difficulties which are recorded in some detail.

Electrolysis of anhydrous fluorides was then taken up. The anhydrous mixed fluorides melt at a temperature of a little over 900 deg. C, and dissolve the mixed oxides with avidity. The electrical conductivity of the molten fluorides is low, but increases rapidly with addition of oxides. The solution containing about 20 per cent. of oxides conducts very well.

Several runs of electrolysis are described. The principal difficulties encountered in the electrolysis of the oxides dissolved in the fused fluorides were:

1. Oxides must be added to the fluoride to make a sufficiently conductive solution, and the melting-point of the bath is very high.

2. At the high temperature of the bath, rare-earth metal and graphite combine to form carbide.

One of the principal difficulties in all previous electrolyses was the formation of carbides, which made the bath viscous and unfit for electrolysis. It was thought that if a non-carbon cell was used, the formation of carbide would be less likely to occur, as the only carbon in the cell would be the anode. On account of their corrosive action and high melting point the fluorides could not well be used in other than carbon vessels. It was, therefore, decided to try the electrolysis in a wrought-iron vessel.

Several experiments are described which show (1) that rare-earth metal could be produced by electrolysis of the chlorides in iron vessels; (2) that the use of an insulated cathode of graphite gave a lower current efficiency and resulted in some of the metal being converted to carbide; (3) that it was necessary to regulate the temperature of the bath so as to have the electrolyte well fused and yet well below the alloying temperature of iron and rare-earth metal; and (4) that control of the electrolysis could be maintained by judicious addition of small amounts of potassium fluoride, sodium chloride, and barium chloride.

The experiments in which the anhydrous mixed chlorides were used, were so successful that the method of electrolysis was applied to pure anhydrous cerous chloride. An account is given of several runs made in this way. A difficulty encountered was the removal of the material and electrolyte at the end of the run. This difficulty was overcome by using a vessel of the following construction. (Fig. 2.)

It consisted of a 3-in. (8 cm.) iron pipe screwed tightly into a 5-in. (13 cm.) iron flange, to which a bottom plate was attached by means of four large bolts and nuts. The electrolyte was cerous chloride containing a small percentage of sodium chloride, to which very small amounts of potassium fluoride and potassium fluoride-barium chloride mixture were added when required (about every half hour or so). The function of these additional salts has already been explained in detail.

The voltage was kept at its proper value, which should not be greater than 15 volts. The average current used was 200 amperes, for three hours. The electrolysis required attention about every twenty minutes; that is, the anode needed slight adjusting or the temperature had to be corrected. An ingot weighing 380 grams was obtained. The number of ampere hours was 600, and the ampere efficiency 36.5 per cent.

The electrolyte remained liquid during the entire course of the electrolysis. About 1½ kilograms of cerous chloride was used. The cell held perfectly, and at the end of the run the electrolyte and metal were easily removed. This type of electrolytic vessel is highly recommended for similar work. Care should be taken that the flange and bottom plate are well faced and that the lap is wide enough (at least 1½ in. (4 cm.))

Two methods of analysis of cerium are then described, one being gravimetric, the other volumetric.

The chief impurities of cerium (amounting in the aggregate to about two per cent.) obtained by the method previously described consisted of iron, cerium oxide and cerium carbide, of which over one per cent. was iron.

The best method of **purification of cerium** consists in preparing cerium amalgams. The amalgams are prepared by boiling mercury with cerium in a long iron pipe arranged with a condensing tube at the top. Solid amalgams are easily obtained by this method. The iron and impurities float to the top and may be skimmed off. The amalgams carefully prepared give only a very slight test for iron. The cerium and mercury may be separated by distilling the latter, but this must be done in a high vacuum to prevent oxidation of the cerium. A high temperature is required to drive off all the mercury. The amalgam should be placed in a magnesia vessel, and this in turn heated in an evacuated quartz vessel. The high temperature required would cause the collapse of an evacuated glass vessel.

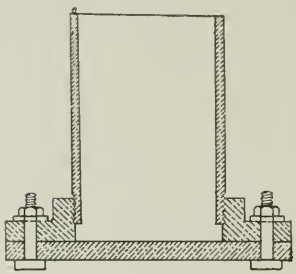

FIG. 2.—ELECTROLYTIC CELL.

Physical Properties of Metallic Cerium.—In the determinations of the physical properties, metal of approximately 98 per cent. of cerium was used, unless otherwise stated.

Atomic weight 140.25.

Specific gravity 6.92 at 25 deg. C.

Hardness. For the determination of hardness, the scleroscope was used. The hardness of cerium varies, depending upon whether the surface of the metal is rolled, freshly cut, or old. The average value of the hardness for rolled surface was 25.9. The average for freshly cut surface was 9.5. The reading 100 is the hardness of the standard steel test plate.

Tenacity. Cerium is malleable and highly ductile. A strip of cerium was rolled to a thin sheet of a thickness of 0.015 mm. Cerium metal can easily be cut with a knife or scissors, and can be machined fairly well, although there is some tendency for the metal to buckle, as does lead.

The specific electric resistance of a sample containing 93.6 per cent. cerium and 4.5 iron was 71.6 microhms per cm. cube.

Magnetic properties. Pure cerium is weakly but definitely paramagnetic.

Melting point 635 deg. C.

The ultimate strength was determined in an Olsen testing machine. The average diameter of the test bars was 0.212 in. (0.55 cm.) There was no elongation with constant load at 350 pounds (159 kg.) The test bar broke with a snap (like cast iron) at 495 pounds (225 kg.). The ultimate strength is equal to 12,900 pounds per square in. (9 kg. per sq. mm.).

The specific heat of cerium (20 to 100° C.) was found to be 0.0524. The specific heating of copper is 0.0925.

The heat conductivity seems to be fairly high and, if so, cerium is probably one of the exceptional metals which has a low electrical conductivity and high thermal conductivity.

The latent heat of fusion seems to be fairly high.

Heat of oxidation. The average value of the heat of oxidation was 1,740 calories per gram, or 60,900 calories per gram equivalent ($CeO_2 = 243.600$).

Single potential. As the single potential of cerium could not be measured successfully, it was calculated and the single potential of cerium in normal solution of its chloride measured against the normal calomel electrode was thus found to be − 3.16 volts.

Thermo-electromotive force. With a hot junction at 100° C and a cold junction at 30 deg., the thermo-emf was 0.000250 volt. With the hot junction at 200.5 deg. and the cold junction at 30 deg. C. the thermo-emf was 0.000502 volt. The current flowed at the hot junction from copper to cerium.

Optical properties of magnesium cerium alloys were also determined.

Chemical properties of metallic cerium.—Cerium is very slightly attacked by cold water, but in boiling water a slow evolution of hydrogen gas occurs and the metal is tarnished black. At room temperature the following solvents have no action on cerium: Ethyl alcohol, amyl alcohol, chloroform, carbon tetrachloride, concentrated sulphuric acid, concentrated ammonium hydroxide, concentrated sodium hydroxide. Ethyl ether has a very slight action on the metal, as have also 3 per cent and 30 per cent hydrogen peroxide at room temperature. The action of dilute sulphuric acid, concentrated and dilute hydrochloric acid, concentrated and dilute nitric acid, in the cold, is moderately vigorous. Ammonium chloride and potassium chloride, at room temperature, have moderate action on the metal. This may be explained by the fact that in water a small amount of cerium hydroxide forms which is soluble in potassium chloride and ammonium chloride, thus causing fresh surface of the metal to be exposed and resulting in moderate attack of the metal by the solvent.

At boiling temperature the following solvents did not attack the metal. Chloroform, carbon tetrachloride, concentrated sulphuric acid, concentrated ammonium hydroxide. The metal was only slightly attacked by the following solvents at boiling temperature: Ethyl alcohol, amyl alcohol, ethyl ether and concentrated sodium hydroxide. Dilute nitric acid, ammonium chloride, potassium chloride and 3 per cent. hydrogen peroxide at boiling temperatures gave moderate action. Dilute sulphuric acid, concentrated and dilute hydrochloric acid, concentrated nitric acid and 30 per cent. hydrogen peroxide gave vigorous evolution of gas at boiling temperature.

The action of various gases on cerium was studied. A small amount of cerium filings was placed in a porcelain boat in a hard glass tube. The air was displaced by the gas under test, and the tube heated gently by means of gas burners. The cerium filings heated in chlorine emitted a very bright light at a temperature of 210° to 215° C. The salt formed was tested and found to be anhydrous cerous chloride.

In bromine, cerium burned at a temperature of 215° to 220° C. with emission of less light than in the case of chlorine. The salt formed in solution in water, and was identified as the bromide.

In iodine vapors no light was emitted, although the tube was heated to a temperature of 300° C. On examination of the contents of the tube it was found that some iodide had formed.

Cerium burned with luminescence when heated in air to a temperature of 160° C. If a lump of cerium is sealed in a glass bottle and kept warm for some time, a black powder is seen to form upon the surface of the cerium, and when the bottle is opened this powder ignites at room temperature. This is probably due to the formation of a highly pyrophoric suboxide of cerium.

When cerium filings are heated to 345° in hydrogen gas, the hydride forms without emission of light. The hydride has been described and studied by Muthmann. (*Liebig Ann.*, 325, 281.)

Cerium filings were heated in nitrogen to a temperature of 1000° C. No luminescence was observed, but some nitride was formed. This nitride is a black powder, and has been studied and described by Matignon. (*Comptes Rendus*, 131, (21), 837).

When the nitride is heated in potassium hydroxide solution, evolution of ammonia gas occurs. When exposed to air the nitride gradually changes over to a brown oxide.

Cerium filings were heated in the vapors of sulphur. When the black substance which is formed is treated with dilute sulphuric acid, sulphuretted hydrogen is evolved. Cerium sulphide has also been formerly studied by various investigators.

Cerium filings were heated to a temperature of 500° C. in an atmosphere of carbon monoxide. There was no visible reaction, but part of the filings appeared oxidized.

Alloys.—A number of different alloys of cerium were studied. In most cases the alloys were high in cerium, usually containing about 70 per cent. cerium. Alloys were made with silver, gold, platinum, copper, tin, antimony, arsenic, carbon, silicon, sulphur, selenium, tellurium, lead, calcium, sodium, aluminum, zinc, cadmium, chromium, manganese, iron, nickel, tungsten, mercury and magnesium.

Cerium and silicon form the silicide $CeSi_2$. This compound may be formed by the reduction of the oxide of cerium. Large amounts of the mixed silicides have been prepared by the author. The following mixture is recommended for their preparation:

M_3O_5	1,000	grams
Powdered graphite	200	"
Powdered silicon	450	"

The silicide of cerium is somewhat brittle, and may easily be pulverized to a fine powder. It is a splendid reducing agent. When the silicide is added to cerium so that the silicon content is about 15 per cent., a good pyrophoric alloy is obtained.

The iron-cerium alloys are very interesting, as they were the first pyrophoric alloys known, and were discovered by Dr. Auer von Welsbach. The alloys of about 70 per cent. cerium content are fairly hard and somewhat brittle. The microstructure of one of these alloys is shown in Fig. 11. It is seen that the structure is heterogeneous, probably consisting in part of a cerium-iron compound. These alloys have been the subject of some discussion in the literature,[53] as have the reasons for the pyrophoric properties.[54] The writer believes that the question of the pyrophority depends upon the following factors: Cerium alone is soft and malleable, and when scratched with a file, small particles are not broken off. However, when the alloy is hard and brittle, small particles are easily detached from the mass, and the friction is sufficient to raise the temperature of these small particles to the incandescent point of cerium (160°). As metallic compounds (such as Cu_3Sn) are as a rule hard and brittle, the addition of such compounds to cerium usually assures a pyrophoric alloy. The alloy should be high in cerium, so that ignition occurs at a low temperature, and should contain excess of cerium above that required for the formation of a compound (such as $CeSi_2$) to act as a binder and so prevent the disintegration of the alloy, as in the case of the cerium-aluminum alloy containing about 60 per cent. cerium.

The whole series of magnesium-cerium alloys were prepared and investigated for their optional properties. The alloy containing about 83 per cent cerium is highly pyrophoric. Most of these alloys are brittle and can be easily pulverized. Excellent flashlight powders can be prepared from the ones of higher cerium content. These alloys also form splendid reducing agents, as the combination of cerium and magnesium is an endothermic reaction, and when the alloy is oxidized, more heat is emitted than from an equivalent mechanical mixture of the two constituents. The fact that the alloys of from 60 to 75 per cent. cerium content may be easily pulverized in a mortar to a fineness of 200 should render these alloys valuable for thermal reductions. A small amount of metallic vanadium was prepared by reducing V_2O_5 by this method. The alloys of from 75 to 85 per cent. cerium content can be pulverized, but they are so highly pyrophoric that it is difficult to prevent igniting them.

Dr. Hirsch had quite an interesting series of samples which were passed around. In the discussion of the paper he was highly complimented on his success by Dr. Whitney, Dr. Parsons, and Dr. Northrup.

Dr. Richards spoke briefly on the cause of the sparking of the alloys. The pyrophoric alloys are brittle. When scratched with a knife fine particles are given off which are

heated to incandescence, but with pure cerium which is soft this does not take place. Dr. Hirsch said that to get a pyrophoric alloy there must be enough cerium in it, generally above 70 per cent.

Mr. Hansen thought the scleroscope was a good instrument for testing the hardness of different steels among themselves, but not for comparing the hardness of different metals or alloys with each other.

He thought the scratch test would give better results for comparison.

Thermal Conduction and Convection in Gases at High Temperatures.

A paper by Dr. Irving Langmuir of the Research Laboratory of the General Electric Company, deals with "thermal conduction and convection in gases at extremely high temperatures."

The author first describes a series of experiments on the formation of nitric oxide from air in contact with a glowing Nernst filament. Some theoretically curious results were obtained. They seem to suggest that some new and previously unsuspected phenomenon was taking place. A dissociation of the gas molecules into atoms or an absorption of energy by the emission of ions from the hot surface suggest themselves as possible causes, but this could only be decided by further experimental investigation.

However, the Nernst glower is not suitable for such experiments, because the range of temperature is limited. The author, therefore, continued his experiments with ductile tungsten wire in a hydrogen atmosphere. Some of the results obtained are as follows:

The energy required to heat the wire to a given temperature is very nearly independent of the size of the vessel containing the hydrogen.

The relation between energy consumption and temperature was determined, and the loss of energy was found to increase very rapidly with increasing temperature.

Up to about 1300 deg. K. the energy increases proportional to a power of the temperature between the first and the second, but above that it gradually increases more rapidly until at 3400 deg. K. it is actually increasing with more than the tenth power of the temperature. In a vacuum the energy loss is proportional to the 4.8 power of the temperature, and this exponent is constant over a very wide range. So, for a wire of about 0.045 mm. diameter, heated in hydrogen, the ratio of radiated to total energy reaches a maximum at about 2600 deg. K. At this temperature, however, only about 9 per cent of the total energy is lost by radiation, while 91 per cent is carried away by conduction through the hydrogen. At 1000 deg. K. the proportion of radiated energy is about 0.7 per cent, and at 3400 deg. it is 3.4 per cent of the total energy.

These results with hydrogen strongly confirm the conclusions drawn from the experiments with the Nernst glower. The most reasonable explanation of the very large heat conductivity of these gases at these extremely high temperatures seems to be that the molecules dissociate into atoms close to the filament, thereby absorbing a large amount of heat. The atoms then diffuse away from the wire, and there, because of the lower temperature, recombine and give up the heat that was absorbed from the wire.

Experiments are now in progress to determine the energy loss of a tungsten wire heated in monatomic gases. (From remarks made by Dr. Langmuir during the discussion it would appear that recent investigations of this kind by the author have made the correctness of the above explanation at least questionable, although the results are not yet conclusive.)

In connection with these experiments it should be noted that the candle-power measurments indicate that the melting point of tungsten is at least 3450 deg. K. Pirani had found 3570 deg. by a very unsatisfactory method of extrapolation, but the best value up to that time, and the one that even now seems to be generally accepted, is that of von Wartenberg, who gave 3170 deg. K.

In the course of the discussion in which Dr. Northrup and Dr. Lloyd participated, Dr. Langmuir discussed the discrepancy of a tungsten filament from a thermodynamically black body and the advantages of determining the melting point of tungsten in hydrogen.

Measurement of Small Gas Pressures.

A paper by Dr. C. F. Hale, of the Research Laboratory of the General Electric Company, deals with the "measurement of very small gas pressures." The extension of studies of the phenomena in rarified gases to the region of very low pressures has made increasingly important the development of manometers whose indications of pressure are not dependent upon the use of mercury.

The manometer of Pirani (*Ber.* der Deutsch. Phys. Ges., 1906, p. 686), depends for its ability to measure pressures upon the fact that at low pressures the heat conductivity of gases is a function of the pressure. It is only necessary, therefore, to observe the effects of varying heat dissipation, with pressure changes, upon some source of heat within the vessel undergoing evacuation.

Pirani has accomplished this by connecting to the system an ordinary tantalum lamp. The wire in this lamp was heated by a constant-voltage current. As the pressure in the system was decreased more and more, the heat lost by conduction through the gas was continually decreased; consequently the temperature of the wire mounted steadily, and, with the temperature, the resistance of the wire increased, thereby cutting down the current.

One had then only to calibrate ammeter readings against the indications of some form of manometer.

A better instrument was obtained when the tantalum wire was replaced by platinum, and the wire was clamped tightly to the anchor wires in order to keep constant the heat loss through the supports.

In simplicity both of construction and of operation, involving only current and resistance measurements within the range of instruments readily accessible, the Pirani manometer recommends itself at once.

However, in point of sensitiveness to pressure changes it is somewhat disappointing.

The present author has modified the Pirani manometer so as to increase its sensitiveness quite materially. The construction of the improved manometer is described in great detail and it is found to give reliable measurements of pressure down to 0.00001 mm. of mercury.

A method of calibrating the manometer is also described. Since the heat conductivity varies with the nature of the gas, it is necessary to calibrate the manometer with the same gas with which it is to be employed subsequently. Calibration curves are given for pure dry air and for hydrogen.

The Electrochemical Industries of Norway.

Prof. Jos. W. Richards, of Lehigh University, who had just returned from abroad, gave a description of a number of electrochemical plants in Norway, which he had visited this summer. There are in the whole thirteen electrochemical plants in Norway and he visited nine of them.

First an aluminium plant at Kristiansand was noticed which operates with a capacity of 12,000 hp by the Heroult process, producing 800 to 1000 tons of aluminium per year.

The next plant dealt with was a nickel refinery depending for its ore supply on a copper-nickel ore mine. The ore is smelted by semipyritic smelting near the mine and the nickel-copper matte shipped to the refinery where the nickel and copper are electrolytically separated by the process of Hybinette (our vol. IV, pp. 33 and 34, 1906).

The next plant described was the experimental plant of the Badische Company for the manufacture of sodium nitrite, 2000

hp being used for this purpose. The well known Schoenherr process for burning the atmospheric nitrogen by electric discharges is employed. But the company finds it more profitable to work up the nitrogen oxides into nitrite instead of nitrate. The nitrite is shipped to Germany. The production is 300 to 400 tons per year.

The next plant visited by Dr. Richards was the aluminium plant erected by the British Aluminium Company in 1906, using 2000 kw and producing about 600 tons a year.

Close by is a sodium plant which was started by Mr. Ashcroft. When Dr. Richards visited it it had been closed down, due to lack of water, but when the power supply does not fail, it is in operation. The Castner process for making metallic sodium is used with a few modifications.

At Odda there are two large and interesting plants, one being a carbide plant and the other a cyanamide plant.

The carbide plant contains 12 furnaces of 1500 hp each and one large one of 2000 hp. The factory works very regularly.

An interesting device for protecting the workmen against the heat from the furnaces is used there. It is a double screen of wire, two screens being 1 in. from each other placed before the furnace. The view is not shut off thereby, since one can look through the screen as through a mosquito screen, but it cuts off a great deal of heat.

Twenty thousand hp are utilized at these works, producing 30,000 tons of carbide per year. Of these 10,000 tons (largely fine stuff) are supplied to the cyanamide works. The carbide plant is to be doubled next year and the whole extra production is to be sent to the cyanamide plant.

This indicates that the cyanamide industry is in a good condition, but it is noteworthy that they prefer not to sell cyanamide itself as a fertilizer but to convert it into ammonium sulphate. The cyanamide is first converted into ammonia and then into ammonium sulphate. The sulphuric acid necessary for this process will be supplied from a near-by plant, to be mentioned below.

Four miles north of Odda there is the Tysse water power, where 125,000 hp will be available.

One of the interesting developments there is electric zinc smelting. Mixed Broken Hill concentrates will be used. They will be roasted and the sulphuric acid will be shipped to the cyanamide plant mentioned above. The zinc oxides will be reduced in electric furnaces. The furnace to be used is stated to be a modified De Laval furnace, but is probably a resistance furnace rather than an arc furnace.

Smelting of pig iron in the electric furnace has not yet been started in Norway, but will be started next year at Hardange. The design of the two furnaces, each of 4000 hp, will be based on the experience obtained at Trollhättan. Also, steel furnaces of the Ludvika type are installed there.

At Arendal there is another company which will produce pig iron in two 4000-hp electric furnaces. This is one of the undertakings of Mr. Eyde.

With respect to electric steel the Norwegians are looking now toward the use of steel scrap. At Stavange there is a company which breaks up old ships. The scrap is to be used by the Stavange Electric Steel Works. They estimate they will have a supply of 3000 to 6000 tons of scrap per year. The water-power plant is being built and the steel plant is to be completed by December.

The steel is melted down in a Siemens open-hearth furnace and roughly refined and is then still further refined in a Roechling-Rodenhauser electric furnace. There is also a rolling mill and a foundry.

At Mr. Hiorth's plant the induction furnace is used for melting down high-quality metal and making a high-quality steel, but he also uses an electrode furnace for working up the scrap.

Dr. Richards attended the jubilee of the University of Kristiania, and found that all Norwegians were extremely interested in the electrochemical industry, as they expected that electrochemistry would play an important part in the future development of Norway. Since strong restrictions against foreign capital have been put in force in Norway, Norwegians now are putting their own money into such developments. The King of Norway is much interested in the use of the electric furnace for iron and steel. Similar interest is taken in all these developments in Sweden.

Among the plants which were not visited by Dr. Richards is the large Nottoden plant for making nitrates from air by the Birkeland-Eyde process. It has been found that for large units the Birkeland-Eyde furnace, being compact, is more economical than the Schoenherr furnace, which must be built high up in order to increase its size.

As to the cost of power in Norway, Dr. Richards stated that power could be bought there from a power company for $6.50 per hp-year. This is at a place right at deep water, so that shipping facilities are also provided. The cost of producing power was given as between $4 and $5 per hp-year.

Galvanizing Wire in Zinc Dust.

A paper by Mr. Alfred Sang, of Paris, France, emphasizes that a perfectly clear conception of the forces at work is essential for successfully operating his process of galvanizing steel wire by heating it electrically in zinc oxide or zinc dust.* Once the nature of zinc dust was well understood and the action which different temperatures may have on it was clearly demonstrated, the application of the process was found to be, after all, not nearly as complicated as might have been feared, in fact it was less complicated than the other two processes in general use.

It may be recalled that zinc dust does not melt when heated to the temperature of fusion of zinc, but at higher temperatures reducing agents will "precipitate" the metal, as it were, and it can also be squeezed out under mechanical pressure. This property of resisting fusion is supposed and is probably due to the surface of each particle being formed of zinc oxide or zinc carbonate.

If zinc dust is heated evenly, the temperature is found to rise steadily until around 390° C., when the rise becomes much more rapid, attaining its maximum rate at about 420°, then falling gradually until in the neighborhood of 470° it again becomes normal. When the dust is cooled down an opposite effect is noted between 450° and 260°. If the operations of alternately heating and cooling the same dust are repeated, the exothermic and endothermic effects are manifested each time between the same temperatures, with their apices at about 420° on the rise and about 350° on the fall.

It is noteworthy that the exothermic effect on the rise occurs at the melting point of zinc metal, but when zinc is melted the effect is the very reverse, heat being absorbed at the moment of fusion to the extent of 28 calories per kilogram.

This represents, therefore, an anomalous critical point, and the author considers separately the operations of galvanizing in zinc dust below and above that critical point.

If a clean piece of steel wire is immersed in zinc dust which is heated to a temperature below 420° C., or at what is known as "sherardizing temperatures," a slow cementation takes place and zinc is absorbed from the very moment that the wire reaches the temperature of the dust; there is at the same time a slow sublimation of zinc at the surface increasing with time but sufficient for all practical purposes after a few hours of treatment; in the presence of reducing gases the time of treatment can be considerably lessened, but the penetration of zinc is, of course, less. This process is sherardizing, unsurpassed for many purposes, unsuitable for many others. There are two varieties of sherardized coatings; the gray, porous and brittle variety, mostly composed of zinc carbonate which darkens with age; the other variety has a high metallic luster

*This journal, Vol. VII., p. 532. Concerning sherardizing see this journal, Vol. V., p. 187; Vol. VI., p. 189, and Vol. VII., p. 485.

and is compact and of a finely crystalline structure. If this were the class of sherardizing produced by all existing plants, there would not be much hot-galvanized work produced outside of wire and sheets.

When we work with the dust at a temperature above the critical 420°, results are entirely different; galvanizing is instantaneous, taking place the very instant that the wire reaches the temperature of the dust. There is very little penetration of zinc in the iron; there may be vaporization and condensation of zinc as in sherardizing, although this is doubtful. A wire heated to 800° or 900° in a non-oxidizing flame and quickly thrust into cold zinc dust will condense around itself a considerable thickness of zinc. The best working temperature ranges between 500° C. and 600° C. The galvanizing is bright and more pleasing in appearance than that obtained by any other means.

The author does not go into details of the furnace used, which merely consists of a zinc-dust trough between two sand troughs provided with a set of cast-iron cover-plates over the zinc trough and power-driven rolls. As high a speed as 850 ft. per minute can be used for securing good merchant galvanizing. It is found preferable to run at 35 ft. only, running a large number of strands and attaching the coils end to end.

The process is economical as regards current consumption which outside of zinc and labor, with a very small amount of power for driving the rolls, represents the bulk of direct cost.

The dust very rapidly assumes a fairly constant temperature. When this is the case the consumption of electrical energy in watt-hours is 7/6 times $w\,s\,t$, where w the weight of wire treated (say 1000 kg), s the specific heat of steel=0.18 at 550° C. and t the temperature to be maintained, say 550° C. The calories needed are $w\,s\,t$, hence by conversion into electrical units we get 7/6 $w\,s\,t$ watt-hours.

Figuring 75 per cent efficiency for the dynamo or transformer supplying the current, the above formula gives 154 kw-hours per long ton of wire of any diameter.

While the wire is softened by the process, a full annealing can only be secured by using a higher temperature, the consumption of electrical energy being then increased from 40 per cent to 50 per cent and the sand trough through which the wire passes after leaving the zinc dust must be appreciably lengthened. If a slight scale is to be removed, the high temperature must be used in connection with a reducing agent. Sand must be used with the zinc dust to prevent caking and cavitation in the path of the wire. Aluminium contact rolls and special mercury contacts are the only ones suitable for this kind of plant.

The wire can be brought out into the air immediately after coating, but it is preferable to let it cool by passing it through sand which brightens it at the same time.

The instantaneous galvanizing of steel in zinc dust above 420° is rapidly explained by completing the theory which the author developed as far back as 1907; it is now stated in its complete form as follows:

"Zinc dust is produced by the sudden cooling of the vapor of zinc and the transition from the gaseous to the solid state is so rapid that, for all practical purposes, the liquid state is skipped. The setting of the zinc, brought about by sudden chilling, prevents regular arrangement of the molecules along determined stereochemical lines; it forbids the formation of crystals for which time is required. The heat of solution of matter in an amorphous state is always higher than when in a crystalline state; the same is true of a strained condition which likewise presents an amorphous appearance. At the time of formation considerable heat is retained which would have been radiated by slow cooling. The condition is one of physical instability resulting in readier and, oftentimes, explosive decomposition.

"The physical instability of zinc dust may be explained thus: In the prolongs of zinc furnaces the uncondensed vapor is suddenly chilled and collects in minute drops which are instantly congealed at the surface and oxidized, forming a rigid spherical skin or crust. Within this crust the liquid zinc cools and contracts more slowly but the rigidity of the crust does not permit the drawing in of the surface to form the facets of a crystal and compensate this internal contraction. Thus voids must exist within the crust and we may presume a structure which might be described as 'piped radially' or as negatively crystalline.

"Below the melting point of zinc this condition persists, but affinities and thermal inducements find a readier response from zinc dust than from any other form of zinc, both by reason of the enormous amount of free surface and because of this unstable condition.

"At about 415°, which is the melting point of zinc, the strain within the zinc dust particle is totally or almost totally relieved as indicated by the loss of heat, although some of the latent heat must be retained for fusion.

"At high temperatures zinc dust is pasty, because formed of innumerable little bags of melted zinc, but these will not coalesce on account of their small size and closely packed condition, unless considerable pressure is used. These minute bladders might be compared to soft-shell turtle's eggs; they form a plastic and cellular mass.

"If, however, a reducing agent, say a drop of coal tar, is introduced, reduction of the skin takes place and we get a small mass of more or less spongy metallic zinc. If a metal which is electronegative to zinc, such as iron, is put into contact with these bags of zinc, reduction and an exchange of metals take place, the bag is punctured at the point of contact and the zinc spreads itself on the iron.

"Hence it is that wire can be galvanized in this manner by means of a plant closely resembling a hot galvanizing plant, for the process is, in fact, one of hot galvanizing."

Electric Nickel Smelting.

A paper by Mr. Walter Leonard Morrison, entitled "Electric Furnace Treatment of Nickel Ore and the Development of a Commercial Process" (being a thesis presented to the Case School of Applied Science), gave an account of the work done by the Consolidated Nickel Company, at Webster, N. C., about which an article was already published in this journal, Vol. VIII, p. 277 (May, 1910). This paper was distributed on the train on Saturday.

The nickel deposits are located about one-half mile from Webster, N. C. The analysis of ores from the same cross cut vary greatly in chemical composition and color. The elements which vary most are iron, magnesia, and alumina.

The reddish brown variety of ore carries the greatest amount of iron and alumina, while the green ores carry the greatest amount of magnesia.

A typical analysis of the hard green ore is 1.90 per cent nickel oxide, 34 silica, 48 magnesia, 3.4 alumina, 1 iron oxide, 1.7 chromic oxide, 10 water of crystallization.

A typical analysis of the soft green variety (genthite) is 42 per cent silica, 8.1 nickel oxide, 36.2 magnesia, 2.1 chromic oxide, 1.2 alumina, 1 ferric oxide, 10.8 water of crystallization.

While the quantity of ore running higher than 10 per cent nickel oxide is very small, the available quantity of ore averaging 1.75 per cent nickel oxide is enormous.

The deposit has been known since the latter part of the sixties, but being low-grade ore it has been impossible to work these properties for two reasons: first, because the former owners did not have money enough to develop a low-grade proposition of this magnitude, and second, until recently there was no process that could treat the ore without hand picking.

The nature and extent of the deposit make the mining a very simple matter, since the ore for the most part can be handled with a steam shovel and can be put into cars at a cost not exceeding 11 cents per ton.

The latest attempt to smelt this ore has been by means of the electric furnace, and as most of the nickel is used in the

steel industry, it was decided to make in one step from the ore a nickel silicide which could be sold directly to nickel steel makers.

Various samples of the nickel silicide thus produced analyzed about 10 to 25 per cent nickel, 55 to 50 iron, 30 to 20 silicon, aluminum, magnesium, chromium, etc., 5 per cent. The presence of the silicon aluminum, and magnesium is in no way objectionable in view of the purpose for which the alloy is intended, since they act as purifiers and gas removers in steel refining.

1. An experiment was first made in which it was tried to reduce the ore directly by hot reducing gases (CO) at a high

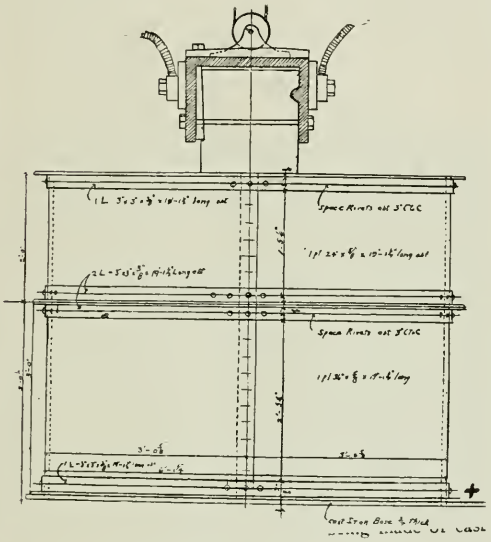

FIG. 1.—SIDE VIEW OF FURNACE.

temperature. The ore mixed with charcoal was placed in a vertical flue and the hot reducing gases passed upward through it. But although the temperature of the ore mass was raised to 1100 deg. C. and held there for an hour, there was absolutely no reduction to metallic nickel. The nickel appears to be held very strongly combined as the double silicate of magnesia and not to be reduced or affected in any way by the hot carbonous oxide gas.

2. About 60 to 75 per cent of the nickel ore runs very high in magnesia (25 to 38 per cent), but low in iron. The fact that the ore is so high in magnesia, makes it a difficult proposition to form a fluid slag, even in the electric furnace, which produces the highest temperature of any present commercial furnace. The idea naturally suggested itself, that the ore could be subjected to a high temperature, in a reducing atmosphere, and intimately mixed with charcoal, and then removed as soon as reduction fusion had taken place. The semi-fused mass could then be crushed and the nickel separated from the slag by a magnetic separator, or on the Wilfley concentrator.

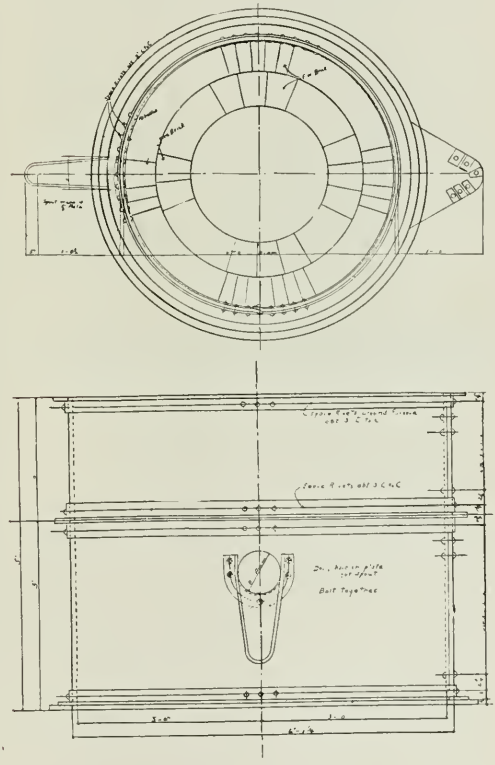
The experiment was carried out in a heating chamber heated by an electric arc, with an inclined bottom, so that the fused mass would flow off in a continuous stream. It was crushed and concentrated on the Wilfley table. The amount of ore treated per kw.-day was very low (14 pounds) compared to the results of a fusion or slag-making electric furnace, which will smelt 23 to 27 pounds of ore per kw.-day. The concentrates from the Wilfley table were high in nickel, but the total extraction of nickel from the ore was about 60 per cent, which is very low.

Further, a furnace of this kind would, after being run for a few hours become so strongly heated that the lining would be in serious danger of falling in from fusion. The experiments along this line were discontinued for they did not appear very promising.

3. Wet processes were then tried. Experiments were made with sulphuric acid, ammonium chloride, sodium chloride, sodium sulphate, and chlorine gas, but neither gave satisfactory results.

4. **Electric Smelting.**—Laboratory experiments were made with a 100-ampere 50-volt Borchers furnace, obtained from Eimer & Amend, with a fixed lower electrode and a movable upper electrode, and also with a larger furnace of the same general type.

The furnace was tapped about every 15 to 20 minutes, giving about 10 lb. (4.5 kg.) of slag and metal, about a quart (liter) in all. The author thinks that with this furnace it is not neces-



FIGS. 2 AND 3.—PLAN AND FRONT ELEVATION OF FURNACE.

sary to tap so often, first because the efficiency of the furnace is increased if the slag is removed as soon as it has become inactive in the reactions within the furnace; second, if the "source of heat" which is near the dividing line of the slag and ore be raised too much above the bottom of the furnace, the metal on the bottom will be cooled to its solidifying point, and the furnace will start to freeze. Further, if the furnace is let run too long between tappings, carbides are formed in the slag, which renders it very infusible and sticky, so that it will not flow.

The capacity of the furnace was limited to the capacity of the gas engine, which gave a maximum of 15 kw. at the switch-

board. The furnace would treat about 100 lb. (45 kg.) of ore in six hours.

Several charges of the green and brown ores were heated with charcoal in graphite crucibles in a gas blast furnace.

The object of this special series of experiments was to get an idea of the self-fluxing qualities of the green and brown ores.

For this purpose the relative weight of brown ore in the mixture was varied from 90 to 10, the corresponding weight of green ore from 10 to 90, a weight 5 of charcoal being added in each case. A mixture of 40 weight of brown ore, 60 of green ore, and 5 of charcoal appeared to give the best slag. Since the greater part of the ore is high in magnesia (the

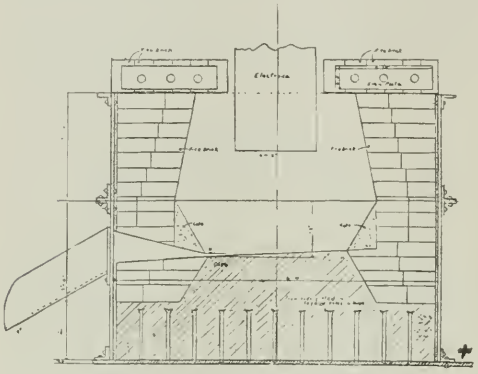


FIG. 4.—SECTION OF FURNACE WITH LINING.

green ore), it is an advantage to be able to use the brown ore as flux instead of barren matter.

Under good working conditions the slags varied about as follows:

Silica	40.00	to 45.00	per cent
Alumina	30.00	to 20.00	"
Ferric oxide	2.00	to 0.50	"
Calcium oxide	3.00	to 10.00	"
Magnesia	20.00	to 15.00	"
Nickel oxide	0.40	to 0.80	"
Alkalies	4.60	to 8.70	"

All the above slags gave little or no trouble in the furnace, flowed freely and allowed the metal to separate and collect in the bottom of the slag pot.

In the smelting of this ore in an open furnace there was considerable loss of nickel by volatilization. The alkalies and magnesia also volatilized to a considerable extent. The loss by volatilization is from 15 to 20 per cent of the weight of ore.

Lime in conjunction with carbon up to certain limits plays a very important part in the amount of silicon reduced. The author thinks that the formation of calcium carbide acts as a very powerful reducing agent and breaks up the silicates, liberating silicon and forming more complex silicates.

The iron aids in the collecting of the metallic nickel, very little iron goes to the slag. At first considerable trouble was experienced with the coke, it would accumulate in the furnace and finally cause it to freeze up. This trouble was practically eliminated by using finer coke, instead of ½-in. (1.2 cm.) coke 10-mesh (0.25 cm.) coke was used which gave better results. In order to get complete reduction and a good extraction it is necessary to add a little excess of coke, and being in the fine condition it is easily carried from the surface with the slag.

The formation of carbides in the slag is a signal that the furnace will soon give trouble, unless the charge is changed or the carbon lessened. The carbides are easily detected by the odor of acetylene about the cool slag. A slag which decomposes as it cools is another indication that something is wrong with the fluxing. The furnace must be tapped at comparatively short intervals of not more than 30 to 40 minutes.

Granulation of the slag was tried and was quite successful; the slag is then easily removed from the metal by simply washing. The metal remains in fairly large pieces, and in the form of shot. On a large scale, granulation would be a very cheap method of separating the metal, and the slag could be easily flushed to the dump.

The Wilfley Concentrator with material through 30-mesh (0.8 cm.) gave excellent results.

The metal reduced from the ore and separated from the slag is in all cases an alloy of nickel, iron and silicon. In no run were they able to obtain a low-silicon alloy, and keep their extraction about 80 per cent. This alloy must from necessity carry considerable iron. The amount of metal separated from a ton of ore depends upon the ore treated. The brown ore will give about 440 lb. (200 kg.) of metal to the ton, while the

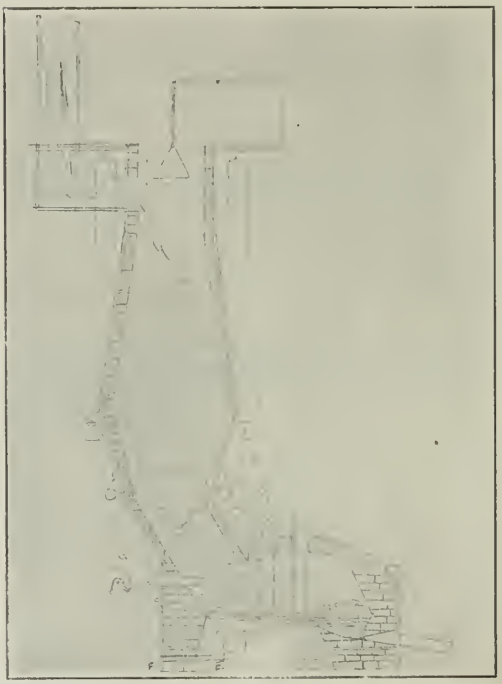

FIG. 5.—ELECTRIC SHAFT FURNACE.

green ore will not give more than 200 lb. (91 kg.) to the ton. Using a mixture of the ores the amount of metal derived, varies from 300 to 350 lb. (136 to 150 kg.) to the ton.

The following are analyses of metal obtained from the brown ores:

Nickel	10.90	11.00	11.50	10.20	
Iron	58.30	56.80	57.40	56.90	
Silicon	28.20	30.10	26.30	27.40	

The following are analyses obtained from green ore:

Nickel	23.95	21.80	22.60	19.30	18.96
Iron	50.70	51.20	48.90	49.10	54.00
Silicon	21.20	18.80	23.24	26.40	22.80

The following are analyses of metal obtained from the mixtures of the ores:

Nickel	15.04	13.70	13.10	13.30	14.80
Iron	54.80	53.90	56.00	57.80	54.70
Silicon	26.60	27.40	25.70	24.00	26.20

In looking over the above analyses, it will be noted that the green ore gives a metal much higher in nickel, all the runs from which this metal was derived were made on picked ore averaging about 6 per cent nickel. It is not advisable to pick ore too much, as it will leave a worthless ore which it would not pay to treat; then too the amount of rich ore to the lean ore is about 1 to 10 or 20 and means a large expense to sort out.

The ferronickel silicide also contains aluminum, calcium, magnesium in traces, besides 1.5 to 2.5 per cent chromium.

Notes are given in the paper on the methods of analysis of the ferronickel silicide and the ore.

Commercial Electric Smelter.—The electric smelter and equipment is located on the nickel deposit at its middle point.

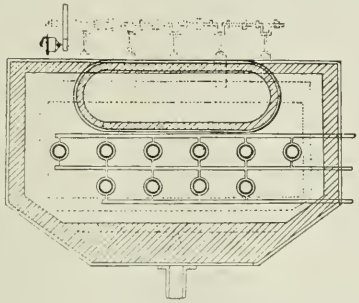

FIG. 6.—DETAILS OF FURNACE CONSTRUCTION.

In the boiler room there are four horizontal-fired tube boilers of 200 boiler hp. each, bituminous coal being fired. The steam engine is of the Hamilton Corliss type. The line shaft drives two 170-kw. generators, giving 3500 amperes at 500 volts direct current.

The furnace room equipment consists of the furnace and electrode control, switchboard, 4 slag pots, 500 lb. (225 kg.) capacity, and weighing scales for ore and flux.

The furnace used in Webster is similar to the one which was used at Sault Ste. Marie by Dr. P. L. T. Heroult, with a few modifications. The furnace was originally designed in two sections, it being intended that the top section could be removed in order to patch up the crucible, but later this was found to be unnecessary.

The bottom plate of the furnace is of cast iron 1.5 in. (3.8 cm.) in thickness, set on porcelain blocks for insulation. Tapered holes were bored in the cast-iron plate, and iron rods 10 in. (25 cm.) long by 0.5 (13 mm.) diameter were inserted, in order to give a large area of contact. A large copper plate was fastened to the cast iron at the rear, to which the lugs carrying the cables were secured.

Fig. 1 gives a side view of the furnace, the holder is shown, and method of holding the carbon electrode, also position of cables. The furnace shell is made up of ¾-in. (16 mm.) iron plate, and 3 in. by 3 in. by ⅜ in. (7.5 x 7.5 x 0.95 cm.) angle irons.

Fig. 2 gives a plan of the furnace, showing the thickness of the fire-brick lining.

Fig. 3 is the front elevation of the furnace, showing slope of hearth and position of spout, one spout being used for both the slag and the metal.

Fig. 4 is a section of the furnace after the lining is in; also showing the covering used.

The shell of the furnace was insulated from the cast iron bottom with heavy asbestos and fibre bushings around the bolts. The interior of the shell was first lined with ¼-in. (0.6 cm.) asbestos. A mixture of hot graphite and glucose was tamped into bottom of furnace around the iron pegs. Above the pegs the amount of graphite was lessened, and coke dust substituted, and near the top of the bed coke dust with a binder was used. The coke lining was carried up the side for a distance of ten inches; this coke lining appears to resist the corrosive action of the slags better than any other material we used. The cover of the furnace consisted of fire brick clamped together by tie rods.

The lining of the furnace required about four days, one man and helper. The graphite and glucose was heated in an iron soap kettle. Materials used in the lining and cover of the furnace were as follows: One barrel glucose, ¾ ton coke, 2,000 fire bricks, 1 barrel sand, 1 ton graphite, 1,000 circular fire bricks, 2 barrels fire clay, 20 sheets asbestos.

After the lining was all in, a wood fire was built in the furnace and kept burning three days. This dried the furnace very well. After this the electric current was run in the furnace for several hours, which finished the drying out of the bottom of the furnace.

Operation of Furnace.—The furnace was started with a little coke in the bottom, but after a few trials this was found to be an unnecessary precaution. The electrode was controlled by a hand-wheel located on the floor, connected to a worm and gear on a carriage, by a chain.

To the gear on the carriage was secured a notched wheel which carried a chain connected to the electrode holder. The holder is very heavy, being made of cast iron and weighing about 1,000 lb. (450 kg). The carbon electrode which was first used weighed about 1,400 lb. (635 kg.) when new. During the operation of the furnace if the current was shut off for

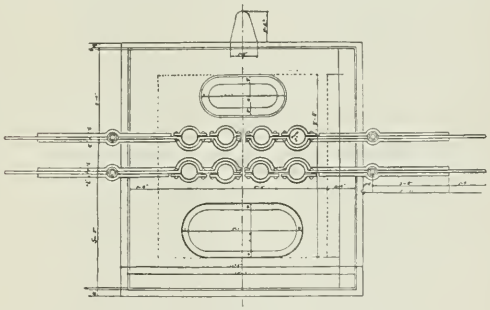

FIG. 7.—CRUCIBLE FURNACE

more than an hour it would usually cause the furnace to freeze up. At first the coke caused trouble in the furnace by accumulating, but this was eliminated by using finer coke and a little less of it. They also noted a decrease in the electrode consumption when finer coke was used.

The electrodes which we first used were of carbon, built up from smaller electrode sections. The large electrode was 18 in. (45 cm.) square by 7 ft. (2.2 m.) long, made from 3 by 6 in. (0.75 x 15 cm.) carbon slabs. The first time the electrode was heated by the arc it cracked and pieces broke off in several places. The pieces were picked out of the furnace, and ore with flux fed in, trusting that after a slag bath had been formed the cracking would stop, however this was not the case; after having to stop frequently to pick out solid pieces of the electrode weighing 25 to 50 lb. (11 to 23 kg.), the furnace was shut down, this electrode after so much damage being too short for further use. It was removed and the other carbon electrode placed in the holder.

Before striking an arc with the second carbon electrode a wood fire was placed beneath it in order to heat it up evenly. After two hours of this treatment the electrode was placed in the furnace, contact made, and ore started in. The electrode, however, went to pieces.

A copper bushing was then ordered for the holder, so that they could use two Acheson graphite eletrodes together. The Acheson electrodes were spliced so as to feed continually with-

out waste. These electrodes held up finely and gave very good results. The dynamos gave trouble, however, and they could only draw half load, consequently for nearly all the runs only one 8-in. (20 cm.) Acheson graphite electrode was used, which carried as high as 5,000 amperes at times.

Trouble was also experienced with the ore if not dried in advance.

The "efficiency" of the furnace under the present condition is said not to be very high. The author says: "The efficiency of this furnace as compared with one utilizing the waste gases to preheat and dry the ore, I would estimate at 60 to 70 per cent. The fact that we used wet ore instead of dry ore makes a difference of 6 to 8 per cent in efficiency."

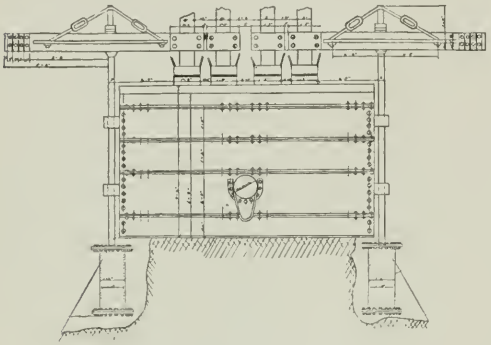

FIG. 8.—CRUCIBLE FURNACE

The following is the record of a furnace run made on December 9, 1909:

CHARGES.

No. 1.	No. 2.
4 tons brown ore.	3 tons brown ore.
1.02 tons limestone.	0.6 tons limestone.
0.48 tons coke.	0.48 tons coke

Moisture in ore	42.50 per cent
Total dry ore treated	8,050 pounds (3,660 kg.)
Net time of smelting	45.75 hours
Limestone used	3,600 pounds (1,635 kg.)
Coke used	1,940 pounds (882 kg.)
Power used, average kilowatts	170
Kilowatt hours used	7,755
Kilowatt-years used	0.896
Ore treated per kw.-year	9,000 pounds (4,090 kg.)
Ore treated per kw.-day	24.7 pounds (11.2 kg.)
Nickel silicide obtained	1,242 pounds (565 kg.)
Per cent of nickel in alloy	11.90
Silicide obtained per kw-year	1,380 pounds (627 kg.)
Silicide obtained per kw.-day	3.8 pounds (1.7 kg.)

In other runs, from 8,250 lb. (3,750 kg.) to 10,160 lb. (4,620 kg.) of ore was treated, and from 975 lb. (443 kg.) to 2,230 lb. (1,014 kg.) of nickel silicide obtained per kilowatt-year of electric energy consumed. The power consumption is nearly constant per unit weight of ore treated, independent of its metal contents, showing that the chief worth of the furnace is the drying of the ore and the smelting of the slag. The silicide produced contained 10.50 to 22.60 per cent of nickel.

The cost of production varies with the nickel content of the ore and of the silicide formed. The cost of smelting by hydro-electric power is only about 14 per cent of what steam power cost us. The above figures are quite conservative in the case of the hydroelectric power.

Cost of Operation.—The cost of operation is based on the approximate cost as the plant was operated from October, 1909, to April, 1910, and goes to show the expense of operating or trying to operate in a primitive country. Two shifts of 11 and 13 hours respectively were run. The furnace was run about 4 to 5 days out of every week, very little repair work being necessary on the furnace. The engine gave us considerable trouble and during every run several stops were necessary for adjustment of the crank pin or the valves. The generators giving the trouble they did, and forcing the plant to operate at 50 per cent of full load, caused a great decrease in the efficiency of the power plant. The cost of smelting cannot therefore be reasonably figured from the cost of operation which the author gives as follows:

Cost of operation per 24 hours:

1 Superintendent	$10.00
1 Assistant	2.50
2 Oilers @ $1.80	3.60
2 Firemen @ $2.40	4.80
2 Assistant firemen @ $1.80	3.60
2 Head furnacemen @ $2.50	5.00
4 Assistant furnacemen @ $1.80	7.20
2 Miners @ $1.50	3.00
1 Blacksmith	2.00
1 Timekeeper	2.00
Coal, 18 tons, @ $4.50	81.00
Machine oil	4.00
Electrodes	9.10
Flux and coke	3.00
	$148.80

The average power at the switchboard was 200 kw. and on

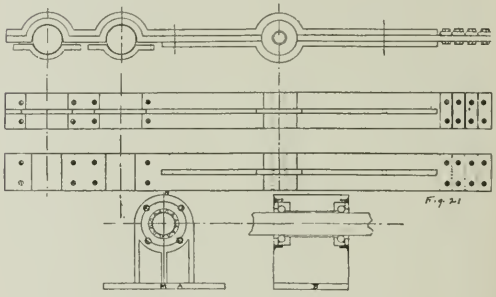

FIG. 9.—ELECTRODE CONTROL

an average 7,800 lb. (3,500 kg.) of ore were smelted per 24 hours.

Cost of power: $0.74 per kw.-day, $270.00 per kw.-year.

Cost of power under full load would be: $0.562 per kw.-day, $206.00 per kw.-year.

In the above figures no account is taken of depreciation, interest, and repairs, which would undoubtedly raise the above figures 10 per cent.

Output of Plant.—The output of the plant was limited to the available output of the generators, and varied from 800 to 1,200 lb. (365 to 545 kg.) silicide per day. This output on the present plant could be raised to 2,500 lb. (1,135 kg.) of nickel silicide, by operating the generators at full load, and using a dryer and preheater with the furnace. However, the furnace has served its purpose for a commercial demonstration, and has given the operators a chance for observations which are only possible with a furnace of this kind.

In the concluding part of this paper the author gives a discussion of various furnace designs and a proposed improved electric smelter design for treatment of the ore under discussion with estimated cost sheets.

The Shaft Furnace.—The shaft furnace for electric smelting is the ideal furnace. However, since the flow of gases is slow compared to the air blast furnace, it does not need to be so very high. For ordinary operations on the mixed nickel ores a shaft furnace should not be more than 10 to 12 feet high, *i. e.*,

above the fusion zone. There is considerable fines in the ore, which would cause trouble with a higher shaft. For this ore a dryer would be necessary, utilizing the waste gases from the furnace. Fig. 5 gives a general idea of the shaft furnace the author has in mind.

The ore with the flux is introduced at the top of the furnace from the charging floor. The furnace has a fore hearth for the collecting of slag and metal. The furnace is designed to carry ten 8-in (20 cm.) graphite electrodes. The ore enters the crucible back of the electrodes. To aid in the distribution of the sticky ore mass, a set of plungers (G) are arranged at back of furnace.

The furnace is designed for direct or alternating current (single phase). The bed of the furnace acts as one conductor, the dotted portion shows this bed. Tubular conductors carry

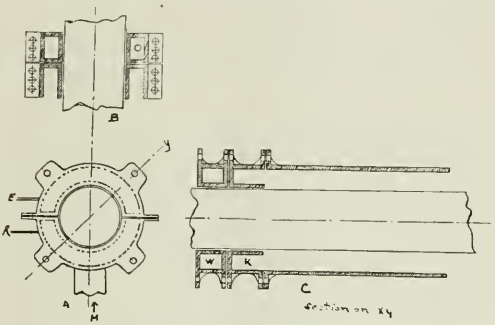

FIG. 10.—DETAILS OF JACKET CONSTRUCTION.

the current to iron distributers in the bed of furnace, which is heat insulated.

Coke is introduced at (c) independent of the charge; by so doing the electrode consumption is lessened; air enters for combustion of gases in the shaft at (A). The author has found that, by introducing the coke or reducer around or near the electrode, the consumption of electrode can be cut down one-half. Each electrode is operated automatically and independent of the others.

Although the shaft furnace is very good in theory, he does not think it practical at this time for the ore in question. The ore is extremely refractory and shut-downs are frequent. The cost of shutting down a shaft furnace and repairing would be very high. If it were desired to run the extremely fine ore alone at any time, then the crucible furnace would be the one to use. It would be impossible to run the extremely fine ore in a shaft furnace successfully. In the treatment of iron ores and other ores, the shaft furnace no doubt would be all right.

The crucible furnace.—By crucible furnace the author has reference to a furnace which is comparatively shallow and has no shaft for preheating and reducing the ores.

The crucible furnace illustrated in Figs. 7 and 8 is of a special design, which the author sketched, after careful observations on the present furnace. The furnace as shown is designed for direct current, which at the present time is installed.

The furnace is designed to carry eight 8-in. (20 cm.) Acheson graphite electrodes, operating under a maximum load of 2,000 electric h. p. The electrodes are worked in pairs and controlled by automatic hydraulic regulating device. The electrodes are carried in cast steel holders, to which are fastened eight flexible cables.

The holders are supported on a three-inch steel rod, which works in a hydraulic ram Fig. 8. To give the rod a free movement a special guide was designed, shown in Fig. 9. The ball bearings will not allow the rod to hang if properly lubricated and kept covered.

Fig. 7 gives a front view of the furnace, showing position of spout and electrodes. Fig. 8 is a side view of the furnace and gives an idea as to method of making the lower contact. The conductors are heavy copper tubing which enter the lower bed of the furnace; to these are secured wrought iron distributers.

The carbon bottom of furnace is not brought to the outside wall of furnace, but to the brick lining, which cuts down the radiation losses. There are openings in the top of furnace for electrodes, and a flue for escaping gases and an opening for ore.

The gases are taken off from the front part of the furnace and burned in the preheated. The ore as it leaves the preheater is dumped into the furnace at the rear. The two flues are brick lined. The interior of the furnace is lined very much in the way the experimental furnace was lined.

The electrodes are water jacketed; below the water jacket is a jacket constructed for the introduction of coke around the electrode. In Fig. 10 is a plan of jacket, B and C are sections. W shows section of water jacket. The water enters at E and flows out at R. K represents section of coke jacket. The coke enters at M and is fed by a screw device.

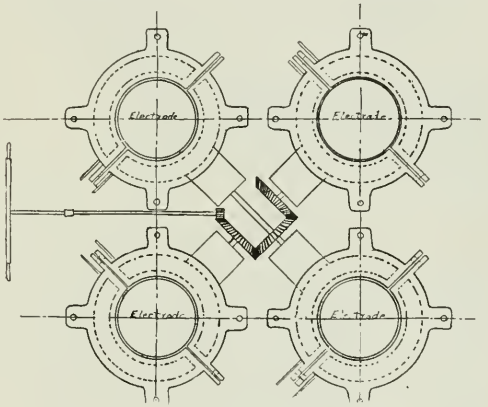

FIG. 11.—INTRODUCING COKE TO ELECTRODES.

The general plan of introducing coke to electrodes is shown in Fig. 11, feeding coke to four electrodes, the other four being taken care of in the same way. The two jackets are suspended on tie rods, then built in top of furnace. They are built in two sections so they may be easily renewed. For the first operations it is intended to feed the coke intermittently by hand feed.

By introducing the coke at this point, an extremely high reducing atmosphere is constantly kept around the electrode, consequently the electrode consumption is cut down. As to the reducing power, or action on the ore by this method, it is about the same.

The fusion zone is limited to a few inches immediately around the tip of the electrode, extending perhaps 8 or 10 inches (20 to 25 cm.). Under normal conditions there is a violent bubbling and boiling, which causes the fine coke 10 to 20 mesh (2.5 to 5 mm.) to intimately mix with the fused mass and bring about reduction. On a small scale the author has found that this method of introducing the coke works out very nicely. With frequent tappings the excess of coke is carried away in slag.

Electric smelter design.—Fig. 12 shows a proposed electric smelter design for the treatment of this ore. It consists of the generator room, furnace room, and ore bins.

The generator room contains the motor-generators for the

changing of the current from three phase to single phase. The room contains two 3,000 kw. motor-generators, the exciter, the high-tension switchboards, transformers and recording-meters. Current is to be furnished by outside power stations.

In the furnace room there are the furnaces, dryers, switchboards, slag and metal conveyors, hydraulic accumulator, and pumps. It is intended to keep three furnaces in operation, and have one for emergencies, which can be used at any time.

All electric cables are carried in conduits, except the cables to the electric holders. The hydraulic control is so arranged with each furnace that it may be regulated by hand or automatically.

All metal and slag is tapped into an iron trough of water, and is carried to the concentrating room by endless conveyor, where slag is flushed to dump.

The dryer is of such length that the ore is dried and preheated before entering the furnace. A check draft and explosion door is arranged at end of dryer. Each dryer has a stack to give better regulation.

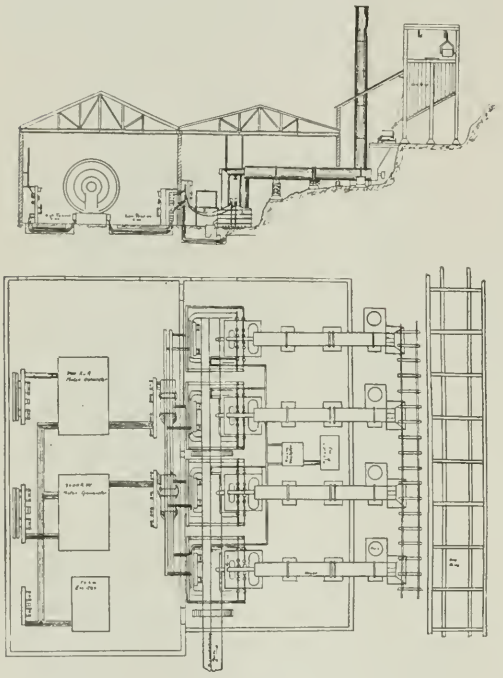

FIG. 12.—ELECTRIC SMELTER DESIGN.

The limestone and ore are crushed before being placed in the bins. From the bins they are drawn into weigh cars, then dumped into the feeding hopper of the dryer. A screw feed regulates the amount of ore being fed into the dryer.

Estimated cost of 100-ton plant.—Approximate cost of a 100-ton electric smelter, including aerial tramway, rock house, crusher, cars, buckets, etc.:

Ore bins	$ 3,000
Buildings	12,240
Tramways, cars and equipment	25,000
Weigh car	1,000
Crusher	900
Pulverizer for coke	800
Motors	1,600
Furnaces (5)	44,000
Motor-generators	45,000
Transformers	20,000
Structural work	22,000
Dryers and motors	15,000
Switchboard and equipment	36,000
Erection, labor, materials, etc	60,000
Total	$280,540

Although these figures appear quite high, from past experience the author thinks them conservative.

Cost of operation.—Estimate as to cost of operation of a 100-ton smelter, figuring operating 300 days per year, and cost of power $25.00 per kw.-yr.

Expense per day:

Interest and depreciation (14%)	$130.00
Mining @ 15 cents per ton	15.00
Power	450.00
Labor and supervising	75.00
Electrodes	130.00
Repairs	10.00
Coke and limestone	75.00
Total cost	$885.00

From 100 tons of ore on an average 15 tons of ferro-nickel-silicide would be extracted.

$885.00 ÷ 15 = $59.00 per ton, average cost of metal alloy.

The author concludes that the present plant for commercial operations is out of the question; that the wet process now existing is also out of the question, and that the only process available for this ore at present is the electric furnace process in a first-class efficient plant.

Entertainment of Ladies.

The program of the entertainment of ladies included a reception on Thursday afternoon by Lieut.-Col. and Mrs. J. B. Miller, at their residence. This was greatly enjoyed.

On Thursday evening there was a theater party at the Royal Alexandra ("Rebellion" with Miss Gertrude Elliott in the leading part.)

On Friday morning a motor drive was made through the city to the Lambdon Golf Club for lunch.

This report should not be concluded without emphasizing again the splendid hospitality extended to the Society by Toronto. The thanks of the visitors are due to all Toronto members and local committees, but special credit should be given to the chairman and secretary of the general committee, Dr. W. Lash Miller and Mr. W. P. Cohoe.

In the following we give an alphabetical list of all members and guests who registered at the meeting:

T. B. Allen, Niagara Falls, N. Y.; J. E. Babb, Pittsburgh, Pa.; L. H. Baekeland, Yonkers, N. Y.; T. F. Bailey, Alliance, Ohio; J. W. Bain, Toronto; W. D. Bancroft, Ithaca, N. Y.; E. A. Beck, New York; P. McN. Bennie, Niagara Falls, N. Y.; S. L. Bigelow, Ann Arbor, Mich.; Wm. Brady, Chicago, Ill.; Wm. C. Bray, Boston, Mass.; J. W. Brown, Cleveland, Ohio; C. L. Bryden, Scranton, Pa.; R. H. Bulley, Syracuse, N. Y.; A. Burton, Toronto; J. F. Callahan, Niagara Falls, N. Y.; H. R. Carveth, Niagara Falls, N. Y.; A. P. Cohoe, Toronto; E. R. Cole, Niagara Falls, N. Y.; W. M. Corse, Buffalo, N. Y.; J. L. Crider, Cleveland, Ohio; R. A. Crider, Cleveland, Ohio; Wm. C. Cuntz, New York; C. Dantsogen, Scotia, N. Y.; Tos. Davies, Toronto; S. Dushman, Toronto; J. W. Evans, Belleville; Mr. and Mrs. F. A. J. FitzGerald, Niagara Falls, N. Y.; M. W. Franklin, Schenectady, N. Y.; K. H. Gaines, New York; A. E. Gibbs, Wyandotte, Mich.; Miss M. E. Gibbs, Wyandotte, Mich.; Thos. W. Gibson, Toronto; W. L. Goodwin, Kingston, Ont.; A. M. Hamblet, Rumford, Me.; C. A. Hansen, Schenectady, N. Y.; H. E. T. Haultain, Toronto; Carl Hering, Philadelphia, Pa.; P. Heroult, New York; A. Hirsch, Corpus Christi, Texas; B. H. Hite, Morgantown, W. Va.; A. H. Hooker, Niagara Falls, N. Y.; L. E. Howard, Lockport, N. Y.; W. B. A. Howk, Elyria, Ohio; T. C. Irving, Jr., Toronto; A. von Isakovics, Monticello, N. Y.; O. S. James, Toronto, Ont.; A. J. Jones, Niagara Falls, N. Y.; W. P. Y.; Roy Winne, Schenectady, N. Y.

Screenless Diametric Sizing of Ore.

A prerequisite for successful dry concentration of ore is close sizing. This holds true for separation based on the principle of difference of specific gravity and for electromagnetic or electrostatic separation of raw or roasted ores. The necessity for close and accurate sizing increases with the complexity of an ore; that is, when several minerals of narrow differences in specific gravity are found in the same ore.

Quite naturally screens of various forms and methods of operation have been used for diametric sizing and such devices are widely used for separating coarser grades. But the difficulties of diametric sizing increase with the fineness of the pulp and consequently hydraulic classification is more commonly used on the finer sizes. Nevertheless it would be preferable in some cases to continue sizing into the finer grades, obtaining sized products within narrow limits without respect to the specific gravity of the constituent particles.

A screenless sizer is not easily conceived of, but such is the nature of the machine invented by Messrs. C. L. McKesson and B. F. Rice, of Colorado Springs, Col. Their dry concentrator was described in our issue of September, 1910, page 549, and it was for the purpose of obtaining accurately sized products for this machine that the screenless sizer was evolved.

The work of the sizer bears no relation to that of a concentrating table, but for the purpose of getting a mental picture of it a comparison can be made. On first sight the sizer gives the impression of a table deck set at an angle of almost 45°, vibrating somewhat after the manner of a concentrator and fed with ore at about the same relative position. This is as far as the comparison can go, however, for the principle of specific gravity does not enter into the work of the sizer as with a table.

By reference to the accompanying drawing and photograph the following description will be understood. The working surface of the sizer is a deck 15 ft. long, 6 ft. wide at the back or feed end and 4.5 ft. wide at the head or discharge end. The deck is heavily trussed to prevent vibration and mounted at an angle of 38° on four inclined toggle supports which, in turn, are firmly supported on a base of I-beams. The deck is attached to a head movement which imparts a longitudinal vibration and its weight is counterbalanced on four compression springs, two under the upper and two under the lower side.

The working surface of the sizer consists of a number of so-called deflectors extending across its width. These deflector surfaces are about 6 in. wide and rise successively from the deck at an angle of about 9°, giving the appearance of a series of steps from one end of the deck to the other. They are not arranged in a uniformly parallel manner on the deck, but their side lines correspond to slightly diverging radii extending from an imaginary center above and behind the deck. Thus the deflectors on either half of the deck have different angles of inclination, corresponding to the positions which would be assumed by a pendulum swinging through a gradually decreasing arc.

The deflectors are covered with corrugated rubber, the line of corrugations extending lengthwise of the deck, or, more exactly, corresponding to numerous arcs described from the imaginary center referred to above. The corrugations are about 1/8 in. deep and number eight to the inch.

In operation the speed of the head movement is 320 r.p.m. The motion imparted to the deck is a combination of the reciprocating head movement, modified by the toggles. On its forward movement the deck is also raised vertically by the toggles and lowered on the return movement. The accompanying Fig. 3 represents graphically the two motions. One marked "stroke" represents the horizontal motion, and the other marked "toggle" shows the vertical throw.

The material to be sized is fed at the upper corner of the

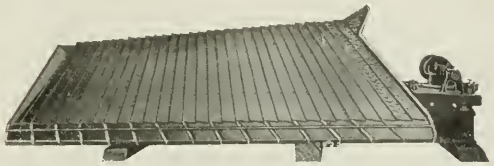

FIG. 1.—WORKING SURFACE OF SCREENLESS SIZER.

deck nearest the head motion. As the particles fall onto the deck they are acted upon by a combination of forces, including the peculiar motion of the machine and the arrangement of deflectors and corrugations, and make their progress across and down the deck. The coarsest particles will not progress beyond the first two deflectors which are covered with metal baffles, as shown in Fig. 1, and which act like a scalping screen

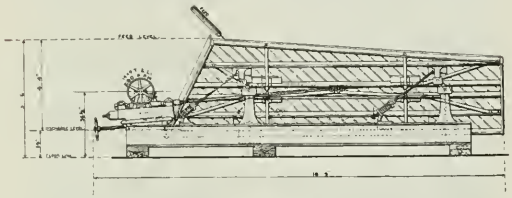

FIG. 2.—REAR VIEW OF SCREENLESS SIZER.

in cutting out an oversize for regrinding. Particles of successively smaller size will progress across and down the deck until they reach a critical point, beyond which they will not pass, whereupon they roll down the deflector and off the deck. The finest particles and dust remain on the deck longest and come off at the last deflectors or over the end of the deck. It must be remembered that this separation is wholly with regard to size and without respect to the specific gravity of the particles.

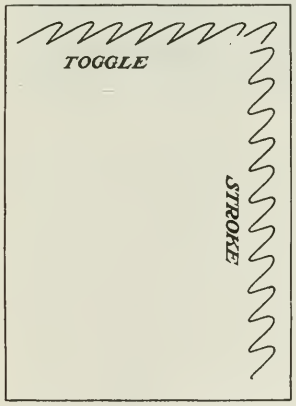

FIG. 3.—DIAGRAM OF DECK MOTIONS.

Along the bottom of the deck is arranged a series of cutting vanes to aid in collecting the various products according to grade. These cutters are adjustable, even when the machine is running. It is found that the zones yielding different grades do not necessarily correspond with a deflector, or any number of them, so the cutters must be set in positions determined by grading analyses to give the desired products. With the adjustments of the sizer once properly made it will continuously give uniform grades. The length of the stroke and inclination of the toggles will vary with requirements, and the capacity of the sizer also will depend in a measure on these adjustments as well as on the size of the material being treated. Recent tests indicate a capacity of from 15 to 20 tons per day of 24 hours on material crushed to about 20 mesh. It is ap-

parent, however, that a double deck can be arranged like an inverted V, which would have double the capacity, be lighter and more rigid, and at the same time require not much more power than the single deck, which is about 1 hp. The life of the sizer should be about the same as that of a standard concentrating table, and the cost of maintenance should be no more. The soft rubber surface of the deflectors should resist the abrasion of the ore very well.

The sizing efficiency of the machine is high and equally good work can be done on the fine and coarse sizes. The following tables show screen analyses made on 15 products obtained in a test. The ore was ground to pass a 24-mesh screen. The first table shows the uniform grading of the various products when divided into plus and minus 50 and 100-mesh portions. The second table gives screen analyses of the different products. It will be noticed that the grading efficiency in some of

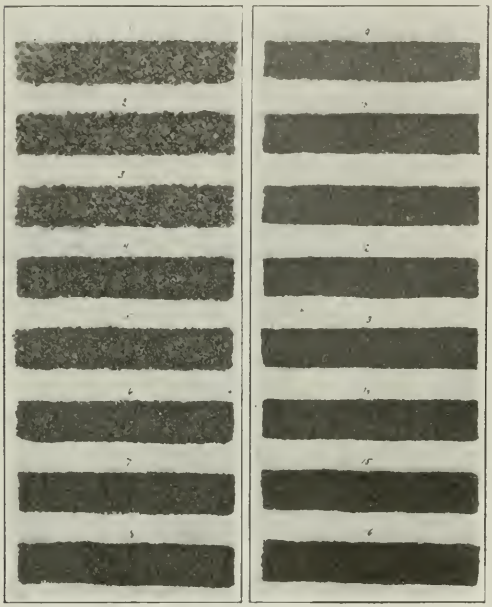

FIG. 4.—CARD SHOWING THE DIFFERENT SIZES MADE.

the products is lower than in others, but it is claimed that this can be remedied by adjusting the cutters to throw the oversize and undersize into the preceding and succeeding grades respectively, and thereby increase the efficiency of the sizing in all grades.

In addition to its use on ore, the sizer can find application in other industrial lines where sizing is required. Among the many materials requiring grading are sand and gravel, glass sand, abrasives, phosphate rock, mineral paints, salt, explosives, grains and seeds.

TABLE I.

Material ground through 24-mesh screen; graded into 15 products, each being screened through 50 and 100-mesh screens.

Automatic Temperature Control.

The object of the temperature controller described in this article is to maintain the temperature of a liquid, a vapor or a gas automatically and exactly at a desired point. It is made by the C. J. Tagliabue Manufacturing Company, of 396 Broadway, New York City.

The action of this temperature control is based on the fact that different materials have different coefficients of expansion with temperature. If two strips of different metals, but of equal length, are placed side by side and welded together at one end only, then on raising or lowering the temperature the lengths of the two strips will generally change, but not in the

same degree, and the difference in the change of the length of the two strips can be made use of.

This difference in the change of lengths is used to actuate a valve mechanism operated by compressed air.

Fig. 1 shows the general scheme for a case in which a tank of water is to be maintained at a uniform temperature. If left to itself it would cool off, but it is kept at the desired temperature by injecting steam. The amount of steam which is admitted at any moment is regulated so as to keep the temperature constant; and the mechanism of the valve which regulates the supply of steam is operated by compressed air, and the air valve is actuated by the two-metallic expansion stems, as will be described below.

A is the water tank, *B* is the pipe for the steam which heats the water. *C* is the valve in this pipe which regulates the amount of steam which is passed at any moment into the water. This valve is actuated by compressed air from the supply line *D*. The air-valve mechanism which regulates the pressure of

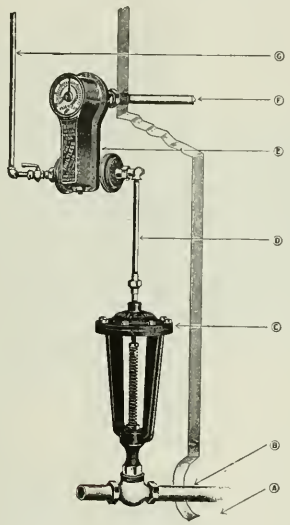

FIG. 1.—TEMPERATURE CONTROLLER.

the air for the valve is shown at *E*, while *F* is the expansion stem of the controller, which expands or contracts more or less according to the temperature of the water in the tank. It supplies the movement for operating the valve mechanism of the controller. *G* is the pipe line which carries the initial supply of compressed air which is required as auxiliary motive force.

In case the temperature of the water would for some reason rise slightly beyond the desired temperature on which the controller is set, then the expansion stem *F* of the controller will expand, and its slight movement will be greatly multiplied by the lever mechanism of the controller and will then be transmitted to the air valve mechanism which now will admit more compressed air to the valve, so that the valve will now admit less steam to the water tank, and so on.

Fig. 2 shows the interior mechanism of the controller with the expansion stem. *J* is the inner rod of the expansion stem, *K* the outer tube part of the stem. The inner rod *J* is made of a material of zero coefficient of expansion; that is, the length of the inner rod remains always the same, whatever the temperature. On the other hand, the outer tube part *K* is made of a material with a high coefficient of expansion so that its length changes considerably with a change of temperature.

The controller is attached to the tank by means of the threaded hub *L* in such a way that the stem *K* extends unobstructedly into the apparatus.

The left-hand end of the inner rod *J* of the stem is constantly pressed by means of the spring *M* against the plug at the left-hand end of the tube *K*; hence when the outer tube *K* elongates or contracts then the inner stem *J* (which remains of constant length) is forced by the spring to move in unison.

To the right-hand end of the inner stem *J* is attached an extension rod *N* which is made of the same material as the expanding outer tube *K*. Hence, the inner and outer parts of the expansion stem to the right of the hub *L* are contracting and expanding equally, so that any changes in temperature outside of the apparatus, the temperature of which is to be controlled, do not affect the functioning of the controller.

It is, therefore, only the inner and outer parts of the expansion stem *to the left** of the hub *L* which are made of

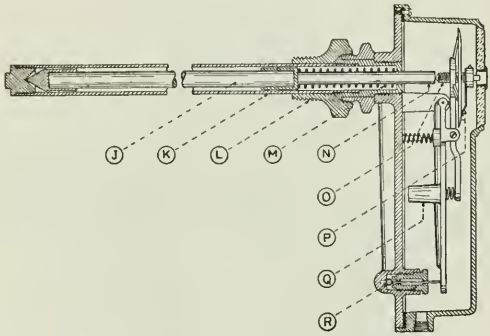

FIG. 2.—EXPANSION STEM AND CONTROLLER MECHANISM.

different materials and which are, therefore, affected unequally by a variation of temperature.

The extension *N* is held against the point of the adjusting screw *O*, the adjustment of which determines at which temperature the controller will function. To the adjusting screw *O* is attached the pointer *P* which indicates the adjustment on a dial beneath, facilitating close adjustments.

Q is the lever mechanism through the short end of which the adjusting screw *O* passes. At this point the lever is held by spring tension against the extension *N*.

The auxiliary motive force (in this case compressed air) is controlled by the valve mechanism *R*. This valve has three ports; one for the admission of the motive force (compressed air), another for supplying the diaphragm motor and another for the escape of the diaphragm-motor supply. The construction is shown on a larger scale in Fig. 3.

U is the inlet port through which the initial supply of motive force (compressed air) enters from the compressed-air supply line; the connections for the line being shown at *T*.

V is the valve-ball, which assumes a position in accordance with the position of the valve stem *X* against which the long end of the lever *Q* in Fig. 2 is held by spring tension, thus regulating the amount of compressed air passing through the ports.

W is the outlet-port connecting with *Y*, the outlet (if the position of the valve-ball *V* allows).

Y is the connection for the line carrying the motive force between the controller and the diaphragm motor.

Z is the waste-port, which provides an escape for the motive force (compressed air) when it is in excess of the amount needed to hold the diaphragm-motor valve open or shut to the desired extent.

*That is the parts within the apparatus the temperature of which is to be maintained constant.

We can now trace in detail, by means of Figs. 2 and 3, what happens if the water in our tank (which is to be held at constant temperature) shows a tendency to rise in temperature.

The temperature will rise, indeed, very slightly. But this will at once result in an elongation of the outer tube *K* of the expansion stem in Fig. 2. As *K* is fixed to the tank at the connection *L*, the left-hand end of *K* will move away from *L* to the left. The inner rod *J* is not affected in its length by the change of temperature and is therefore caused by the spring *M* to move along to the left. The extension *N* moves in unison and consequently the upper arm of the lever *O* moves also, on account of the spring tension which keeps *O* constantly in touch with *N*.

Since the one arm of the lever *Q* moves one way (to the left in Fig. 2), the other arm moves in the opposite direction (to the right in Fig. 2), a pivot being arranged between the two ends of the lever.

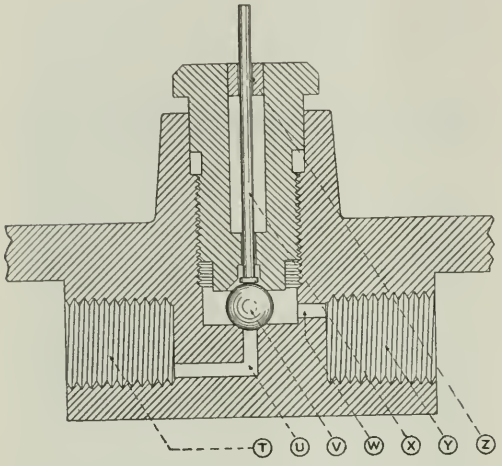

FIG. 3.—VALVE MECHANISM.

Consequently the valve stem *X* will now move also (upward in Fig. 3). The valve-ball *V* being pressed constantly against the head of *X* by the compressed air supply will now also move upward so that more air can enter through the inlet *U* and pass through the port *W* and connections *Y* to the diaphragm motor. Thus a greater pressure of air is supplied to the diaphragm motor, which thereby closes the steam valve to a greater extent and curtails the steam supply to the tank.

Should, however, the water in the tank show a tendency to cool off so that more steam is required, the controller will cause the diaphragm-motor valve to open further (thus letting in more steam) by functioning in just the opposite manner from that above described.

In practice the diaphragm-motor valve is rarely wide open or dead shut. Usually it is "throttling"—the controller being so sensitive to the slightest change in temperature within the apparatus to which the controller is attached that the diaphragm-motor valve is constantly "throttling"—letting in just a little more or just a little less steam, as required to keep the temperature constant.

The above-described design and operation permit of various modifications. Compressed air was assumed as the motive power and is generally best suited for this purpose. The initial supply should be of at least 15 lb. per square inch pressure, but the volume needed is comparatively slight.

The controller may also be built in some cases, however, for operation by water (instead of compressed air) as motive power. But when water is used the construction of the valve mechanism is somewhat different, although the principle is the same.

In the above example the controller mechanism was so arranged that when the stem of the instrument is subjected to a higher temperature the diaphragm motor closes the valve which controls the heat supply. This is the "direct-acting" type of controller.

In other cases in practice it may, however, be required that a rise in temperature be checked by turning on a greater supply of a cooling madium. In such cases the "reverse-acting" type of controller is used. In this type the controller mechanism is so arranged that when the controller stem is subjected to a higher temperature the diaphragm motor opens the valve further.

The many applications of this controller for industrial work, especially in the chemical industries, are so evident that only a few typical applications may be mentioned.

In the case of air to be heated by steam coils to a given temperature the controller stem is placed in the air duct (in which the temperature is to be adjusted) and the diaphragm-motor valve adjusts the steam supply to the steam coils.

If the temperature of a heated air in a closed chamber (an incubator, dryer, etc.) is to be maintained constant the controller may be used with both diaphragm-motor valve and diaphragm-motor lever. In case the temperature tends to rise the diaphragm-motor valve decreases the steam supply for the heating coils, while the diaphragm-motor lever opens the damper for the air supply to a greater extent.

For this controller, which is one of the latest Roesch-designed devices, the following principal points of advantage are claimed:

The inner rod of the stem of the controller is of a material which has a zero coefficient of expansion. If the inner stem has even a slight coefficient of expansion (though much less than the outer portion) the action of the controller would not be changed in principle, but in practice the controller would show the troublesome phenomenon of "creeping" due to the fact that the functioning point of the controller varies as the temperature effect slowly permeates the internal part of the stem. It would, therefore, take such a controller quite a while to settle down. With the above-described controller, with its internal stem remaining rigidly of constant length, all this trouble is avoided.

There is but one valve mechanism in the working parts of this controller, and this valve mechanism is also self-cleansing and self-adjusting. Since the proper working of the device does not depend upon a number of parts being in fine adjustment in relation to each other the effects of wear and tear are greatly reduced.

The cover which incloses the working parts of the controller can be removed while the controller is in use, and thus the working parts be exposed while in operation, thus permitting easy inspection.

No stuffing box arrangements are used in the mechanism. Further, that part of the mechanism which multiplies and transfers the movement of the expansion stem to the valve mechanism is never in contact with the compressed air supply.

Automatic Temperature Control in Electric Ovens.

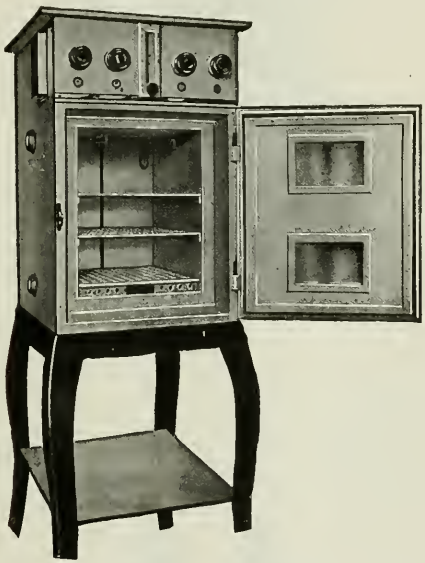
For use in research as well as industrial laboratories the easy and exact temperature control which is possible with electric furnaces is one of their greatest advantages. Usually this temperature control is obtained by some sort of rheostat which is adjusted by hand.

For many purposes it would, however, be greatly advantageous to have automatic temperature control, but the problem in general meets with great difficulties. For the restricted field of electrically-heated ovens with temperatures from that of air to 175° C. (347° F.) the Freas oven, which has just been placed on the market by Messrs. Eimer & Amend, of New

York City, has solved the problem. Even in the restricted field, indicated by the above given temperature limits, the exact automatic temperature control should prove exceedingly useful for many purposes.

The temperature-regulating device in the Freas oven is entirely of metal and its action depends on the expansion of a metallic tube running through the chamber from top to bottom and operating a lever which makes and breaks a contact, proper means being provided to prevent arcing. The lever is extended to serve as an indicator operating up and down a temperature scale on the outside of the oven near its top. By turning the screw at the bottom of this temperature scale the indicator is moved to the desired temperature; this is all that is required of the operator and the regulating device does the rest in maintaining the temperature to which the furnace is set.

The oven, as shown in the adjoining illustration, is built of asbestos wood, which has the triple advantage of being fireproof, a good heat insulator, and not attacked by acids or alkalies. The oven is fitted with one or two shelves, perforated with small holes to distribute the heat uniformly



ELECTRIC OVEN, WITH AUTOMATIC TEMPERATURE CONTROL.

throughout the chamber. This insures uniform temperature, there being less than one degree difference between the top and bottom.

The door is fitted with a mica window, so that parts of the chamber can be inspected without opening the door. Complete ventilation to get rid of fumes and moisture from the substance being dried is obtained by two openings on each side of the oven and two through the top.

The heating resistors are placed at the bottom of the oven and consist of wire coils so insulated that they are not injured by acid fumes, etc.

The furnace can be operated on alternating current as well as on direct-current circuits. The power consumption is 660 watts, which for the lower temperatures can be reduced one-half by means of a switch, provided the closest regulation is desired.

The regulator at any temperature between air and 175° C. is sharp and accurate to less than one degree and remains so indefinitely, while under most favorable conditions it is accurate to one-tenth degree. For continuous operation at such high accuracy the oven is equipped with an extra fan, driven by a motor.

To heat the furnace up to 50° C., about 15 minutes' time is required with maximum current, and 45 minutes to heat it up to 110° C.

A Liquid Flow Recorder.

Liquid flow recorders have become a necessity in recent years chiefly for two kinds of work; firstly in large power stations for the measurement of condensed steam and boiler feed-water, and secondly in chemical and metallurgical works for recording the rate of flow and the quantities of acids and solutions in operation. There can be no doubt that especially in the latter field their use will rapidly increase, when the practical reliability of modern flow recorders is properly understood. In the following we give a description of the Lea liquid flow recorder, which was first developed in England and is placed on the market in this country by the Yarnall-Waring Company, 1109 Locust Street, Philadelphia, Pa.

Liquid flow recorders are essentially based on the laws governing the flow of water over wires and notches. The Lea flow recorder employs for this purpose a sharp-edged V notch to which the formula of Prof. James Thompson applies, according to which the flow in cubic feet per minute through a 90-deg. notch is $0.305H^2VH$, where H is the height of the notch in inches.

For simplicity's sake, let us assume that water is the liquid, the flow of which is to be measured. Then it will be easy to plot a "curve of flow"; that is, a diagram which gives the rate of flow of water for different depths H of the water according to Thompson's formula. If now a float is placed in the water, the rise and fall of this float may be connected to an indicating or recording device, such as a recording pen, through an intermediary mechanism in such a manner that the recording device moves at any instant in direct proportion to the rate of flow of the water in that instant, and therefore plots on a revolving drum a curve which is directly a continuous record of the flow of water during any length of time. Clearly the problem is to devise a suitable and exact intermediary mechanism, as mentioned above. This problem is solved in the Lea recorder in an ingenious manner in the following way:

The float in the water rises and falls with the water level. Above it is the instrument case, and the float spindle passes through the bottom of the instrument case upwards into the latter. Upon this float spindle a rack is cut, which gears into a small pinion upon the axis of a drum, revolving between centers.

Upon the body of the drum is a screw thread, the contour of which is the "curve of flow" (as defined above) for the V notch in connection with which the recorder is used, and just as the flow through the notch increases rapidly with the depth, so the pitch of the screw increases in the correct proportion.

Above this drum is a horizontal slider bar, supported on small pivoted rollers, and carrying an arm, at the upper end of which is a pen or pencil point in contact with a paper chart, upon a clock-driven recording drum, which revolves once in twenty-four hours.

As the float rises or falls, the drum spiral is rotated, and its motion is imparted to the slider bar (and pen arm), by means of a saddle arm, projecting from the latter and engaging at its lower end with the screw thread.

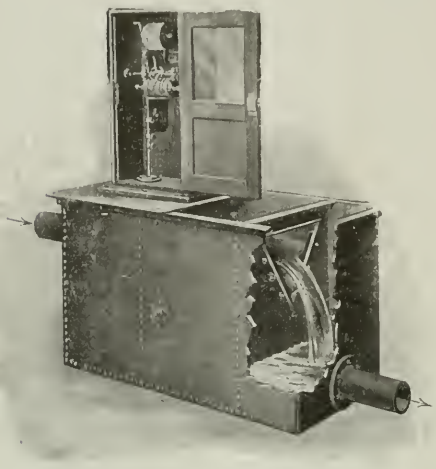
On the body of the spiral drum is a graduated scale, adjacent to the screw thread, and computed in pounds per hour. It is thus seen that the spiral drum serves a double purpose:

Firstly, its screw thread rectifies the motion of the pen, so that it moves equal distances for equal increments in the rate of flow.

Secondly, it provides a magnified scale for making an accurate observation of the rate of flow at any moment.

Thus the actual depth of water in the notch can be observed at any time. The instantaneous rate of flow, in pounds per minute or gallons per minute, can be read off directly. Finally the recording pen which moves in direct proportion to the rate of flow plots a diagram whose area is a measure of the total quantity of liquid passed.

The adjoining illustration shows the lower part of the apparatus in which the water acting on the float passes through



LIQUID FLOW RECORDER.

the V notch, and the upper instrument case with the vertical float spindle and the record drum. The illustration is otherwise self-explanatory.

When the flow to be measured is so small that it would show only a depth of 1 or 2 in. in a 90-deg. V notch, notches having angles less than 90 deg. may be used, like 45-deg., 22.5 deg., etc. Speaking generally, the flow through such notches is approximately proportional to their width, for a given depth.

Hence by means of these acute notches, a large float movement is obtained when only a small quantity is being measured.

Further, a measuring tank and recorder having a maximum capacity of say, 10,000 gal. per hour through a 90-deg. notch, if supplied with two other notch plates—say 1 of 45 deg. and 1 of 22.5 deg.—can be used for measuring either 10,000, 5000 or 2500 gal. per hour.

Moreover, one recorder may be used for measuring large or small quantities of liquids by providing several identical notches, of which a greater or smaller number may be closed according to the requirements. With such a multiple-notch arrangement the total flow at any instant is obtained by multiplying the reading on the recorder by the number of notches open.

It is clear that in principle the operation of the apparatus is exactly the same whether it is used for measuring the flow of water or of acids or any other liquids. But for the use with corrosive liquids it is all-important that nothing but the float is in contact with the liquid, the instrument case itself being above the flow arrangement, out of contact with the liquid.

In the case of a sulphuric acid solution, for instance, the lower tank through which the acid passes, may be made of lead-lined wood, and the notch also of lead. But glass may be used equally well.

Another point which is important for certain chemical operations, is that a float may be placed above the weir to control the inlet, thereby insuring a constant head of the liquid. This is especially valuable in manufacturing processes where a definite percentage of solution has to be added.

There seems no doubt that these liquid flow recorders and adjusters can be of considerable service in large-scale chemical operation.

Carboy Rocker.

The carboy rocker, shown in the adjoining illustrations, is so handy that a brief description of its construction and method of use should be interesting to all users or bottlers of acids, ammonia, etc., from carboys. It is made by Messrs. Rockhill & Vietor, 114 John Street, New York City.

FIG. 1.—ATTACHING ROCKER TO CARBOY.

This carboy rocker is attached to a carboy or detached from it in one-fourth of a minute. One man can roll a full carboy to any desired position on the floor and completely empty it without spattering. In use the carboy can be left resting on the first or second stop, as there is no need of placing it back. It is ready for immediate use.

Fig. 1 shows the method of attaching the rocker to the

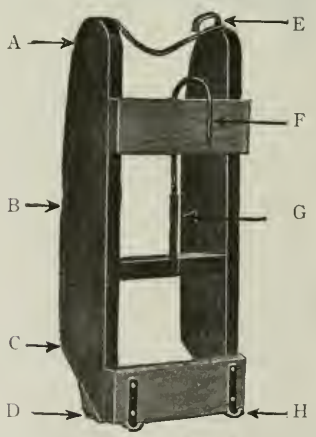


FIG. 2.—STOP CARBOY ROCKER AND VENT TUBE, DETACHED.

carboy. The workman holds the rocker with the right hand by the curved, pointed, sliding hook. He then, with his left

hand, takes hold of the cleat on the side of the carboy, lifts one side of the carboy sufficiently to catch the pointed supporting hooks underneath it, pulls the curved sliding hook up and over and presses it down on top of the rocker. He then removes the stopper of the carboy and inserts the celluloid vent tube, closing the outer end of the tube with the forefinger while inserting it.

Fig. 2 shows the construction of the rocker and vent tube detached: *a* is the last position; this point is in contact with the floor when the carboy is empty; *b* is the middle stop; this point is in contact with the floor when the carboy is half empty; *c* is the first stop; the carboy remains stationary when the stop touches the floor.

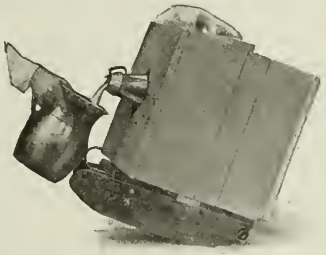

FIG. 3.—FIRST PITCHER FULL.

The wheels *d* facilitate moving. The celluloid vent tube, ready to insert in carboy, is shown at *e;* attention should be called to the fact that it is made of celluloid; *f* is a pointed steel sliding hook; *g* a spiral steel spring, and *h* are supporting hooks.

Fig. 3 shows the position of rocker and carboy when the first pitcherful is taken.

Notes.

Erratum.—The article of Prof. J. W. Richards in our September issue (p. 463) mentions 250 *million* tons of Lake Superior ore running 35 to 50 per cent of iron; this should have been 250 *billion* tons, i. e. 250,000 millions.

The **Scientific Materials Company,** of Pittsburgh, Pa., have recently enlarged their glass-blowing department, increased their force, and added the latest and approved machinery. This department is now in charge of an expert German glass blower, who has made a specialty of intricate laboratory apparatus. An expert engraver takes charge of the graduating of the most precise volumetric apparatus. Special glass apparatus according to drawings may be obtained on short notice, and broken apparatus will be repaired and returned promptly.

The **Zaremba Company,** manufacturers of evaporators and chemical machinery, with main offices in Buffalo, have opened a branch office in New York, Room 95, 97 Liberty Street.

The **Brown Instrument Company,** the first concern to manufacture pyrometers in the United States and whose office and laboratory have been located at 311 Walnut Street, Philadelphia, since 1860, has been forced to move to larger quarters by the great increase in its business. As electrical instruments play an important part in the construction of pyrometers, it was found desirable to be able to superintend the construction of milli-voltmeters for use in their pyrometers. With this end in view, Mr. Brown, the president of the Brown Instrument Company, has now also become president of the Keystone Electrical Instrument Company, of Philadelphia, which, for a number of years, has been manufacturing voltmeters and ammeters, and the shops of the Brown Instrument Company are being combined with those of the Keystone Electrical Instrument Company at Ninth Street and Montgomery Avenue, Philadelphia. This places the Brown Instrument Company in the unique position of controlling the construction of their milli-voltmeters for their pyrometers, even to the manufacture of the raw materials, such as the magnets. By this arrangement the Brown Instrument Company and the Keystone Electrical Instrument Company will manufacture pyrometers, thermometers, speed indicators, draft gages, recording gages, voltmeters and ammeters. In fact, they are now in a position to manufacture or repair practically any type of instrument. In addition to the works and office at Ninth Street and Montgomery Avenue, Philadelphia, an office will also be maintained for the present at 311 Walnut Street, and the branch offices of the Brown Instrument Company at Pittsburgh and Chicago will also be continued.

Carbon Electrode Factory at Niagara Falls.—The new carbon plant which the National Carbon Company, of Cleveland, Ohio, is building at Niagara Falls will be ready for occupancy some time in October. The company has been working for about a year in building this new branch. It will be a thoroughly modern factory in every respect and will engage in the manufacture of carbon electrodes exclusively. This is the second plant which the National Carbon Company has built during the past year, the other being at Toronto. In nearly every one of their nine factories considerable improvement and expansion has been made during this year. The main plant and general offices of the National Carbon Company are located at Cleveland. This plant alone covers about 30 acres of ground, and is engaged in the manufacture of a miscellaneous line of carbon products. The eight outside plants manufacture a special line of product for which the locality, equipment and organization is best adapted. The Cleveland plant is by far the largest industrial carbon factory in the world, while the total facilities of the nine branches make a tremendous organization for the development and manufacture of a complete line of high-class carbon products.

The production of secondary metals, meaning those recovered from scrap metal, drosses, sweepings, etc., amounted to a considerable industry in the United States in 1910, according to figures compiled by the U. S. Geological Survey. Of secondary copper, including that in alloys other than brass, there were produced 25,396 short tons; remelted brass, 27,347 tons; secondary lead, 17,822 tons; recovered lead in alloys, 23,327 tons; secondary spelter, 33,040 tons; recovered zinc in alloys other than brass, 1,181 tons; secondary tin, 2,423 tons; recovered tin in alloys, 3,092 tons; secondary antimony, 27 tons; recovered antimony in alloys, 1,529 tons. The total value of these metals and products was $45,525,500. The production of secondary copper amounted to 17 per cent. of the domestic consumption of new copper. The secondary lead was equal to 11.5 per cent. of the refined lead produced in the United States. The secondary zinc including that in brass equaled 23.2 per cent. of the total production as primary spelter in the United States. The secondary antimony and tin constituted practically the only domestic production of those metals.

Quicksilver in California.—In 1910 California produced 83.5 per cent. of the total output of that metal in the United States. The county leading in production is San Bernardino in which are the New Idria mines, at present the most important producers in the American hemisphere. Fifteen quicksilver mines contributed to the California output in 1910, which amounted to 17,211 flasks of 75 lb. each, valued at $800,484.

The Bureau of Mines has issued within the past month two technical papers; No. 3, Specifications for the Purchase of Fuel Oil for the Government, with directions for sampling oil and natural gas, and No. 4, the Electrical Section of the Bureau of Mines. Miners' Circular No. 4 describes the use and care of mine-rescue breathing apparatus.

PERSONAL

Mr. Louis D. Bastian, of Silverton, Colo., has been engaged as superintendent of the Vermillion mill near Animas Forks, Colo.

Mr. Raymond C. Benner, of the department of chemistry

at the University of Arizona, has gone to the University of Pittsburgh, where he will investigate the smoke problem with Professor Robert K. Duncan.

Mr. Gelasio Caetani, of San Francisco, has been spending some time in the Telluride district, Colorado, making tests and advertising improvements in the milling operations there.

Mr. R. S. Davis, chemist for the Primos Chemical Company, Newmire, Colo., has returned to his work after a short leave of absence.

Dr. Wilbur A. Hendryx, of New York, has gone to South Africa on business for the Hendryx Cyanide Machinery Company.

Dr. H. R. Low, of Platteville, Wis., recently spent several weeks in the San Juan district, Colorado, in the interests of the American Zinc Ore Separating Company.

Mr. A. J. McMillan, formerly managing director of the Le Roi Mining Company, and now closing up the affairs of that company, has returned to Rossland, B. C., after spending three months in England.

Mr. Charles L. Parsons, secretary of the American Chemical Society, and until recently professor of chemistry in the New Hampshire College, Durham, N. H., has been appointed chief chemist of the mineral division of the Bureau of Mines at Washington.

Prof. Robert H. Richards, of Boston, spent the month of September in Denver.

Mr. John E. Rothwell, of Denver, has just completed a tour of the principal western metallurgical centers.

Digest of Electrochemical U. S. Patents.

Ore-Treatment (*Continued*).

399,209, March 5, 1889, Julio H. Rae, of San Francisco, California.

Gold and silver. Treats ore held in suspension by an agitator, the metal being deposited on the cathode. Several cells are shown, each consisting of a tub of wood lined near the bottom by a vertical cathode ring of copper, silver or silver-plated metal. An agitator is journaled on a vertical shaft extending through the bottom of the cell, having radial arms carrying stirrers, some of which are inclined outward to scrape the ore from the cathode ring and throw it to the center, while others are inclined outward. The anodes consist of a number of vertical carbon rods, arranged in two concentric circles and depending from a wood ring into the upper part of the ore-pulp. Each rod has a spring connection and is readily removable.

459,023, Sept. 8, 1891, Curt Schreiber and Hans Knutsen, of Broken Hill, New South Wales.

Gold, silver and antimony. Antimony ore is hand-picked into three classes containing more than 25 per cent of antimony, 5 to 25, and less than 5. Each lot is then crushed to pass a sieve of 900 meshes to the square inch, and is lixiviated with a solution containing sodium monosulfid, in the proportion of 235 parts to each 336 parts of antimony sulfid. Or barium or calcium sulfid may be used in molecular proportions. One cu. yd. of solution, say 200 gal., is sufficient for each ton of ore, the strength being varied according to the percentage of antimony therein. The three lyes from the three classes of ore are differently treated. Each lot of ore is leached with three or more solutions, first with solution used twice previously, then with solution used once, and finally with fresh solution. Strong solution is mixed with the weaker ones, and antimony sulfid is dissolved in the weakest ones. The resulting saturated solutions of antimony double salts are electrolyzed, the conductivity being increased by the addition of a small amount of sodium chlorid. The current is regulated according to the concentration of the lye. Antimony is deposted at the cathode, with production of sodium hydrosulfid which is oxidized at the anode to sodium disulfid. Sodium hydroxid is added from time to time to convert the sodium disulfid into monosulfid, which is returned to the lixiviators. The residual ore, freed from antimony, is amalgamated for the recovery of the gold or silver.

460,354, Sept. 29, 1891, Werner von Siemens, of Berlin, Germany, Assignor to Siemens & Halske, of same place.

Copper, etc. Various cells for carrying out the process of his patent No. 416,576. The first cell is a rectangular wooden pan, covered inside and out with lead, and having a perforated false bottom on which is supported the anode, of corrugated sheet-lead or corrugated and perforated plates of retort-carbon. Lying on the anode is a screen consisting of two spaced-apart sheets of fine wire-gauze, to prevent agitation of the liquid at the anode. The cathode consists of a number of horizontal cylinders of wood coated with wax and then with metal, submerged in the electrolyte and slowly rotated. The solution, containing a salt of the metal to be deposited, a ferrous salt and free acid, is supplied at the top of the cell, and passes from the cathode, where two-thirds of its metallic contents are deposited, down to the anode where the ferrous salts are reoxidized, being drawn off at the bottom through a syphon. The second cell consists of a semicircular or V-shaped trough, its inner surface lined with an anode having small transverse grooves. The cathode is a revoluble cylinder, as before, separted from the anode by the double wire-gauze screen. The solution enters at the top and the resulting ferrous salts are reoxidized, as before, oxidation beginning at the edges of the grooves and being completed at their bottom. The third cell is a circular pan of hard lead, on the bottom of which are supported a number of short vertical carbon rods, or a grate of horizontal carbon rods, constituting the anode. Or the anode may consist of grooved carbon plates. Above the anode is a sheet of wire-gauze, and above this is a horizontal rotating disk cathode of metal. The solution passes downward as before. The motion of the cathodes is necessary for the production of good copper and the use of a high current density.

473,105, April 19, 1892, George J. Atkins, of London, England.

Gold, silver, etc. The first cell illustrated comprises two vertical cylindrical portions, subdivided by a diaphragm of matting, flannel, felt or a porous plate, mounted to slide vertically in grooves. In and nearly filling the anode chamber is an anode comprising a shaft, e.g., of wood or protected metal, carrying a broad-bladed screw of carbon or lead. The cathode compartment contains a revolving cylinder of perforated sheet-copper. Flexible rubber scrapers project from the walls of the compartment against the surface of the cathode. The cell is filled with a solution of sodium chlorid, sodium sulfate, potassius cyanide, or potassium ferro-cyanide. Ore is fed into the top of the anode compartment and descends downward in contact with the screw. The screw may be rotated to accelerate or retard the descent of ore, the contact being sufficient to effect the desired oxidation or chlorination. The solution is re-pumped from the bottom of the anode compartment to the top. The ore, freed from base metals, generally silver and sometimes gold, is withdrawn from the bottom of the anode compartment. If the electrolyte liberates chlorin or other solvent of gold, this is generally reprecipitated by a base metal in solution, such as iron. The metals loosely deposited on the cathode are scraped off and removed below. The gold is recovered by treating the purified ore in an amalgamator. A modified cell consists of a vertical copper cylinder, forming the cathode, containing and separated from the anode screw by a diaphragm of canvas, flannel or felt

The Abrogation of the Hill Iron Ore Lease.

There are two reasons, each amply sufficient in itself, for the abrogation by the United States Steel Corporation of its lease upon the Great Northern or James J. Hill iron ore lands, the one being that the operation does not promise, from the present industrial position, to be profitable to the Steel Corporation, the other that the lease stands open to question under the Sherman law.

As to the extent of the ores, it may be said that there has come to be reasonable assurance that more than 300,000,000 tons will be found, of fair quality. None of the ore is of good quality, judged by the standard of other ores being mined. Practically all requires washing. The Colerine washer, installed by the Steel Corporation to treat the first of the Hill ores mined, cost to the end of 1910 the tidy sum of $1,461,584.33, established to wash practically the first of the nearly 250,000,000 tons of ore which has thus far been taken out of the Mesabi range. The analyses of the Steel Corporation's Mesabi ores in 1910 were as follows as to iron content:

	NATURAL.	DRIED AT 212 DEG.
Group No. 1	52.9201	60.2171
Group No. 1 (high Mn)	50.0105	56.6986
Group No. 2	54.4243	60.9739
Group No. 3	49.5229	57.0558
Group No. 4	47.2340	56.0731
Group No. 5 (D. M. & N.)	50.4048	56.7034
Group No. 5 (G. N.)	51.5741	57.7271
Group No. 7	46.4202	53.4499

Group No. 5, Great Northern Railway, may be taken as fairly typical of the best of the Hill ore. The royalty rate in the Hill lease is 85 cents for the year 1907, upon ore analyzing 59 per cent metallic iron when dried at 212 deg. The custom in the ore market is to sell ore upon a guarantee in the natural state, the base guarantee being 55 per cent for Bessemer and 51.50 per cent for non-Bessemer. The Hill lease rate advances and declines by 4.82 cents per unit for ore above and below 59 per cent, except that a flat rate of 30 cents is placed upon ore below 49 per cent, that being regarded as the limit for ordinary merchantable ore. For each year after 1907 the royalty rate advances by 4 per cent of the 1907 rate for the ore of iron content involved. The minimum to be mined (and paid for if not mined on the assumption that it would have been 59 per cent ore) is 750,000 tons in 1907 and 750,000 tons more for each succeeding year until 8,250,000 tons is reached in 1917, the minimum remaining at that rate thereafter. A quantity of ore, whether of Hill or other ore, equal to the year's minimum is to be transported over the Hill road, the Great Northern, at the rate of 80 cents, which has been the fixed rate from Mesabi range to Lake Superior ports for years.

Should the open rate decline, the reduced rate is to be paid the railroad, but the royalty rate is to be correspondingly increased, royalty payments being made to the three trustees who act for the holders of "certificates of beneficial interest" distributed in 1907, certificate per share, to the stockholders of the Great Northern Railway Company.

The lease provided that the Steel Corporation could terminate it upon Jan. 1, 1915, provided it gave notice not later than Jan. 1, 1913. Our understanding is that the Steel Corporation purposes to take advantage of this clause, but that, while nothing definite has been done thus far, there is opportunity for negotiation with the Hill trustees, and not impossibly with the aid of the Department of Justice, looking toward an earlier termination.

The general impression seems to be that none of the Hill ores will be found to equal or exceed the base rate of 59 per cent metallic iron, dried at 212 deg., that only a relatively small proportion will fall within a couple of units of that iron content, and that the bulk will fall considerably below it. This alignment operates to depreciate very seriously the apparent value of the Hill ores, considered as an 85-cent royalty mining proposition, because the penalty rate of 4.82 cents per unit does not cover the increased cost of mining, transporting, and smelting the lower grade ores. It is, indeed, very much smaller than is represented in the trade custom in selling ore as that custom is to compute the unit price by taking the price at lower lake dock and adding a 60-cent arbitrary (assumed as the average inland freight rate), making the unit value at the present season's price on Mesabi non-Bessemer ore 7.96116 cents, and ores below 49 per cent iron content, natural state, are subject to penalties at greater than the straight unit rate. The season's price is $3.50 for ore containing 51.50 per cent iron, natural state. Thus the lease is a less desirable one than were the ores actually to be mined rich enough to involve the payment of the base rate.

During its entire life the lease involves a constantly increasing royalty rate, at 4 per cent of the 1907 rate, equal to an annual increment of 3.4 cents on the 85-cent rate. For ten years it involves an annual increase in the minimum to be mined. In 1917 the minimum would be 8,250,000 tons, at $1.19 for base ore, equal to a payment of $9,817,500. Very onerous also is the provision that the ore or an equivalent tonnage shall be carried over the Great Northern road, at 80 cents a ton, for the Corporation has two roads of its own, and it is common report that the service is performed at a cost of not more than 40 cents a ton, so that here is a direct loss, 40 cents on 8,250,000 tons, of $3,300,000 additional. In discussing this phase of the lease reference is frequently made to the possibility of the open rate of 80 cents being reduced. Such reduction would, however, neither increase nor decrease the Corporation's loss through the operation of this lease. In computing the advantages or disadvantages the payment stands in relation to the cost at which the Corporation could perform the service of carrying its ores on its own roads, and not in relation to the open rate charged to outsiders.

It is the common impression that the Steel Corporation entered upon the Hill lease for the direct purpose of preventing these ore deposits from falling under the control of existing or prospective competitors. In that sense, of course, the lease may possibly be interpreted as having been in restraint of trade and perhaps under the ban of the Sherman law. It may be observed that many of the features of the United States Steel Corporation, viewed in the light of a "trust," are in line with those modern developments which are held to represent progress toward a beneficial form of socialism, but it is difficult to see how the Hill lease represented such progress. It would seem that the value of the lease to the lessors was created by the desire of the Steel Corporation to control the properties. There was a distribution, regarded purely as a gift, of 1,500,000 "certificates of beneficial interest" to shareholders of the Great Northern Railway Company, and the stock market value of these certificates at one time rose to above $80, equal to $120,000,000 for the entire issue, a valuation which had dropped to about $75,000,000 prior to the announcement that the lease would be terminated. So it would appear that this value, if it may be regarded as a value, was created chiefly by an effort to monopolize, and shrewd lawyers' logic would be required to defend it as representing progress toward a better form of conducting industry.

Aside from this feature, however, it is pertinent to observe that no evidence has appeared of competition being restricted. The pig iron capacity of the United States in 1906, the year in which the lease agreement was made, was 25,000,000 tons per year. Partly through new erection by the United States Steel Corporation, but largely through new erection by outside interests, the capacity has been increased to between 33,000,000 and 34,000,000 tons at the present writing, with furnaces in course of construction sufficient to make at least 35,000,000 tons total capacity. Present demand and production, however, are at the rate of only about 25,000,000 tons. The excess is such as to preclude any important influence upon prices of pig iron or finished steel products through the existence of this lease, as compared with the condition which would have existed to-day had the Steel Corporation allowed the Hill ore lands to remain upon the market. The Lake Superior region is developed as matters stand to such an extent that it can easily ship 50,000,000 tons of ore, and quite possibly not far from 60,000,000 tons in a season whereas this season's actual shipments promise to fall below 35,000,000 tons, and no season has yet shown a movement of 44,000,000 tons.

The burden of the Hill lease would have been less onerous, through distribution over a larger tonnage, if the Steel Corporation's operations had grown as was expected in 1906. Its capacity has grown in the intervening five years, but its actual output this year is not 10 per cent in excess of that of 1906. Doubtless the expectation in 1906 was that its productive requirements would be doubled by 1917, whereupon the ore required to be mined in that year under the Hill lease would have been less than 20 per cent of the total.

On account of the annual increment in the minimum tonnage until 1917 and the indefinitely continued increment in the royalty rate, the Steel Corporation relieves itself of a large part of the total burden by a discontinuance upon Jan. 1, 1915. We may compute roughly that the total royalty payments in the period 1907 to 1914, inclusive, amount, at the nominal rates, to $27,234,000, and the loss in freight payment, at 40 cents a ton, to an additional $10,800,000, making about $38,000,000. Royalties, though much smaller, would have to be

paid elsewhere if this ore were not mined, but, on the other hand, the development and mining of the Hill ore during this eight-year period are presumably more expensive than the cost would have been elsewhere with continued mining promised. The abrogation of the lease may be effected for an earlier date by arrangements which may yet be perfected. In any event the Steel Corporation will find itself in better condition from a business standpoint, while it is fairly clear in view of the attitude of the Government that it will find itself in a much more comfortable position from a legal standpoint.

The Power-Factor of Electric-Furnace Circuits.

Managers of central stations using an alternating-current system are unpleasantly familiar with the word "power-factor." It connotes to their minds the necessity of buying copper for their generators, distributing mains and transformers to carry the "wattless current" that does no useful service.

In electric furnace plants which are generally operated by alternating current the power-factor must be taken into consideration, and it is especially important to look at the power-factor problem from the standpoint of future increased size of furnace units. In small furnaces such as those which are used for experimental work, say, of 25 kw to 100 kw, the power-factor is high, being from 96 per cent in the first named capacity to 85 per cent to 90 per cent in the second named capacity. But as the wattage rating of furnaces increases, other things being equal, the power-factor decreases, hence the wattless current increases. Consequently we have an untoward state of affairs, quite unlike the case with thermal economy, which increases with the size of the furnace.

An electric furnace has been well called "a short-circuit under control." It has a very low ohmic resistance. The current flow is opposed by the magnetic "reactance" as well as the ohmic resistance. The power in a direct current is equal to the product of the volts and amperes. With an alternating current this product is spoken of as the "apparent watts" or when divided by 1000 as kilovolt-amperes and not as kilowatts. The reading of the wattmeter gives the "actual watts." The ratio of the "actual watts" to the "apparent watts" (which is unity under ideal conditions and otherwise always smaller than unity) is called the power-factor of the circuit.

In an alternating current, therefore, Ohm's law in its simplest form does not apply and a modified form must be employed. Here the amperes are equal to the volts divided by the "impedance." The impedance is equal to the geometrical sum of the resistance and the reactance. The "reactance" can be described as that physical quantity which opposes the current flow by virtue of the electromagnetic properties of the circuit. Now these very electromagnetic properties of the circuit or more properly speaking the "self-inductance" are proportional (1) to the ampere-turns, (2) the number of lines of force that are cut in unit time by circuit and (3) to the frequency.

Let us suppose that the third of these, the frequency, remains constant as it does in any commercial plant and that while the electric furnace increases in size the voltage remains constant; then the amperes and consequently the ampere-turns increase. Furthermore, the number of lines of force increase because they are generated by the electric current in the iron work that encases the firebrick of the furnace. It is plain, therefore, that the "reactance" increases with the increase in size of the electric furnace. However, the resistance decreases with increase in size. Both the decrease of resistance and the increase of reactance tend to reduce the power-factor and therefore to increase the wattless current. Let us consider two electric furnaces of 50 kw and 100 kw capacities respectively. If the emf is 100 volts and there is a power-factor of 100 per cent, the current of the first is 500 amp and the second 1000 amp. The resistances are 0.2 ohm and 0.1 ohm respectively. If the smaller furnace had a power-factor of 96 per cent at 60 cycles it must needs have a current of 521 amp of which only 500 would be useful. But even if the larger furnace were carefully designed its power-factor might be as low as 80 per cent and so it would require a current of 1250 amp, of which only 1000 amp are useful. If the design were careless the power-factor might drop as low as 50 per cent. The current would need be 2000 amp. to produce 1000 amp. of useful current.

Let us interpret this in commercial language. Let the electrometallurgist who utilizes only 1000 amp. picture to himself the busbars, cables and secondary windings of the transformer to carry 2000 amp. and also the increase in copper necessary to carry the primary current and convert this into dollars and cents. The picture is not pleasing, especially when large capacities, say upward of 2000 kw, are needed.

There are several ways to mitigate this evil by proper design. One possible method is to reduce the frequency. But this means electrical machinery of special design and increased cost.

A more practical way (for usually the electric installation is already placed) is to increase the ohmic resistance by change of design of the furnace. Such a procedure results in the increase of the working voltage and of the power factor.

A third way is to increase the magnetic reluctance of the iron work of the furnace by change of design. For instance, it is possible to use large firebrick block 18 in. x 12 in. x 8 in. instead of the small 9-in. x 4½-in. x 2½-in. firebrick backed up by iron plates so often and so conveniently used. With this iron eliminated the magnetic circuit has a greater reluctance and so the reactance is diminished. It might be even possible to have the buck-staves, tie rods and facing plates made of some non-magnetic special steel. All these possibilities must be considered in designing a 1000-kw electric furnace.

We are glad to call the attention of our readers to this most interesting aspect of electric-furnace design. In this twentieth century it is necessary to attain the maximum of commercial efficiency. When viewed from the proper standpoint commercialism has a broad and ideal meaning and a sense quite different from that used by the poor muckrakers. There must be the application of the pure sciences such as chemistry, physics, and economies in the profession of metallurgy. These must be coupled with the use of arts. We have then a pleasing combination of the "knowledge why" and the "knowledge how." It is plain that this combination is needed in electric-furnace developments. We are especially glad to call attention in these columns to the subject of the power-factor of electric furnaces at a time when the electric furnace is invading the metallurgy of iron, steel, copper, lead and brass. For it is in these columns that all the first achievements of electric furnaces have been recorded, and electric-furnace pioneers have always been our readers, contributors, and friends.

The San Francisco Meeting of the American Institute of Mining Engineers.

(*Special Correspondence.*)

The Pacific coast has seldom offered such attractions as it spread before the mining engineers at this meeting. The meeting is, in reality, a fête, a festival of good things.

Starting from Chicago by special train on Sept. 30, the Eastern members, gathering in numbers as they sped westward, paid their first respects to Western scenery by halting two days at the Grand Canyon of the Colorado. The first day was perfectly clear, and the marvelous depths and details of the canyon stood out clear-cut and distinct; the second day clouds and mists, with here and there a rift and patch of sunshine, showed the great gorge in its most playful mood, and, to many, in its most artistic setting.

Los Angeles was reached on the afternoon of Oct. 5, and then followed a strenuous day and a half of unceasing pleasure and unstinted hospitality from the local members. Trolley ride to Pasadena, lunch on the ocean pier at Venice, fish dinner at Redondo and banquet at the Los Angeles Club were incidents of these days, while the local oil field at Bakersfield was also visited. Mr. Mullholland, of the Los Angeles Aqueduct staff, gave a fine illustrated lecture on this gigantic scheme, and its power possibilities. Mr. Comstock, head of the committee on local arrangements, proved a wonderfully efficient manager. A day at Santa Barbara and one on the cliffs at Del Monte or off to Santa Catalina island completed the sojourn in southern California.

Reinforced by the southern California members, the expedition reached the city by the Golden Gate on the morning of the 10th. Here the serious and formal work of the meeting began. The afternoon of the 10th and the mornings of the 11th and 12th were given over to sessions for reading and discussion of papers, sessions more than ordinarily interesting for variety and value of papers presented and vitality of discussion. The full program of these sessions was as follows:

Tuesday Afternoon, Oct. 10.

Chase, C. A.—"Notes on the Liberty Bell Mine."

Aldrich, Jr., T. H.—"Electrolytic Oxygen in Cyanide Solution."

Young, Geo. T.—"Slime Filtration."

Hall, E. J.—"A Modification of the 'Gay Lussac' Method for Silver Bullion Containing Tin."

Durham, E. B.—"Electrolytic Refining at the U. S. Mint, San Francisco."

Daniels, J.—"The Fritz and Coxe Laboratories of Lehigh University."

Bahney, L. W.—"Rapid Estimation of Available Calcium in Lime Used in the Cyanide Process."

Lass, W. P.—"Cyanide Plant at the Treadwell Mines, Alaska."

Christy, S. B.—"Progress in Electro-Amalgamation."

Wednesday Morning, Oct. 11.

Requa, Mark L.—"California Oil."

Janin, Chas. (Introduced by H. Foster Bain)—"Present-Day Problems in Dredging."

Yale, Chas. G.—"Gold Production of California."

Reinholt, Oscar H.—"Fuel Problems of the Pacific."

Reinholt, Oscar H.—"Government Coal Mines in the Philippines."

Dilworth, J. B.—"The Black Mountain Coal District, Kentucky."

Discussion by J. Langdon.

Locke, Augustus—"Notes on the Geological Structure of Tonopah, Nev."

Catlett, Charles—Phosphorus in Coking Coal."

Porter, J. J.—"National Valuation and Quality Efficiency of Furnace Stock."

Thursday Morning, Oct. 12.

Nisho, K.—"Historical Sketch of the Mining Industry in Japan."

Brunton, D. W.—"The Laramie Tunnel.

Locke, Augustus.—"Classification of Ore Deposits for Miners."

Stevens, Blamey.—"The Laws of Igneous Emanation Pressure."

Stevens, Blamey.—"Physical Data of Igneous Emanation."

Irving, J. D.—"Some Features of Replacement-Ore-Bodies and the Criteria by Means of Which They May Be Discovered."

Gamba, F. P.—"Geology of Some Mines in the South of Colombia, S. A."

Keyes, C. R.—"Vadose Ore-Deposition in Arid Regions."

McCollum, Burton.—"Electrical Practice in Mines."

Vallat, B. W.—"Geology and Operation of the Newport Mine."

Read, T. T.—"Mineral Resources of China."

Thursday Afternoon (in the open-air Greek Theater at Berkeley.)

Raymond, R. W.—"Reminiscences of the Beginning of the Institute."

Becker, G. T.—"Biographical Notes on S. F. Emmons." Abstracts of some of these papers, and the discussions will follow in our next number.

The excursions arranged for the meeting were pleasurable and highly interesting. On the afternoon of the 11th, a special train left for Palo Alto, where over two hours were spent at the Stanford University. The next afternoon a similar trip was made to the University of California, at Berkeley, with a short session held in the famous Greek Theater.

Oct. 13 was given over entirely to seeing the gold dredges of the National Consolidated Company, along the American River

near Sacramento. The visit was a revelation of the latest triumphs of this manner of mining gold. The enormous new electrically operated dredge No. 9 was eating into *terra firma* at the rate of 12,000 cu. yd. per 24 hours. Digging to 55 ft. below water level, and taking down 10 ft. above, this enormous 2400-ton craft, operated by 1000 hp, was said to be working over earth carrying 8 cents worth of gold per cubic yard, at a total cost of not over 4 cents per yard, including depreciation and interest on capital invested.

Equally interesting was the effort being made to reclaim this worked-over ground. Working in a pond, the dredge leaves the gravel piled high as heaps of stones, while the soil or silt impregnates the lower layers under water. The most successful scheme seems to be the crushing of the stone for railroad ballast, road material and concrete. This crushed stone is worth 75 to 90 cents per ton at the crushers, and is being shipped all over central California. This disposes of the stones down to the silt or soil. The ground is then leveled off and planted with eucalyptus trees or rubber trees. These grow in the stony ground if silt or soil is not over 2 ft. beneath, and the tract of land becomes green again. An alternative would be to strip 2 ft. or 3 ft. of soil from the land before working, pile it aside and return it to the leveled-off ground. In any event, appropriate legislation should compel all the gold diggers to leave the country in a cultivable condition, as part and parcel of the expense of getting out the gold, and prohibit leaving the worked-over ground a stony waste, more barren than the desert of Sahara.

Returning from Natoma through the beautiful Sacramento valley, another sacrilege was visible from the train in the shape of a tall smelter stack vomiting out a poisonous cloud of white smoke which enshrouded the valley and mountains for miles away. Such a white pest, prejudicial to health, agriculture and natural beauty, should be suppressed with a firm, determined hand. Some practical methods of stopping the smoke are now known; it is simply a question of private greed *versus* public good, and may the public quickly win out!

Saturday, Oct. 14, 1911, is now memorable in California as the day of breaking ground for the great 1915 exposition. The President of the nation was on hand to start "making the dirt fly." Members of the Institute and guests were presented with grand-stand tickets, and joined the throng, 100,000 strong, which gathered in the stadium of Golden Gate Park. In bright sunshine, under a perfect sky, the surrounding hills green with verdure as a background, the tranquil Pacific visible to the west, and to the accompaniment of a military parade, martial music and echoing salutes of cannon, the first sod of the great exposition was turned. Just before, President Taft, in a ringing address audible to thousands, reviewed in brief the history of the canal, told them that 75 per cent of the work on it was now done, and predicted its completion by July, 1913. One sentence of the President's address lodges in our memory as unusually forcible and strikingly true: "Had the sea-level plan of the canal been adopted it is altogether probable that no one who now hears the sound of my voice would have lived to see the canal completed."

Finally, Oct. 15 is now memorable in the remembrances of the visiting mining engineers for the day—one glorious day of throbbing life—in the sacred groves of the red-woods. Bohemia the spot was called. Here the Bohemia Club stopped the woodcutter's ruthless axe and spared a spot in which to bury care, to worship in nature's temple. It is a small valley, the ground springy with its forest carpet, with scores of congenial spirits in the shape of our giant brothers, the big trees. Some are 10 ft. in diameter and over 300 ft. high. Among such we pigmies stalked and strutted and enjoyed our little day. A splendid orchestra added to the charm some lovely music of Bohemia, two of the numbers being conducted by the composers themselves. A more harmonious assemblage of artistic enjoyments, beauteous surroundings and congenial society cannot be imagined. Here the above photograph was taken.

On the evening of the 16th the California section of the Mining and Metallurgical Section met at dinner, with many members of the Institute as guests. Later the withdrawal of the public coal lands in Alaska was discussed pro and con. with considerable spirit. The wide diversity of opinion expressed showed how impossible it must be, in the nature of the case, to secure a uniform verdict on any such matter which would correctly represent the views of the society as a whole. While the discussions are certainly profitable and instructive and lend a proper interest to the meetings, yet a final expression of the opinion of the society as a whole could not be arrived at without great difficulty and arousing of bitter antagonisms. Such a practice is a principle of separation, a source of discord which would ultimately disrupt any society trying to put it into practice.

Tuesday, Oct. 17, saw the fortunate "100" leaving for their seven weeks' trip to Japan, and the more occupied and less fortunate remainder leaving for their homes. The trip to Japan, stopping at Honolulu, promises to be of absorbing interest. Dr. Kanda, of Japan, has come across the Pacific as the advance guard of welcome, and a glorious eighteen days of strenuous experience awaits the expectant engineers in the Kingdom of the Rising Sun—of which more anon. J. W. R.

The Western Metallurgical Field.

Company Reports.

The metallurgical results obtained by El Oro Mining & Railway Company, Ltd., El Oro, Mexico, are made public in the last annual report for the period ending June 30, 1911. The total ore mined during the year was 360,504 tons as compared

with 317,824 tons in the preceding year. Changes have been made so that sulphide ores can be crushed and cyanided separately, thus improving results. Additions were made to plant consisting of six agitation tanks, two thickening tanks and three revolving filters. These were installed principally to aid in the treatment of sulphides and high silver ores.

The percentage recovery for the year was slightly lower than in the preceding period, but this was due to the fact that a lower grade ore was treated in larger quantities, thereby reducing the percentage recovery but making an increased net profit on operations. If the former high recovery had been maintained it would have resulted in a loss on the extra bullion produced. The principal data are in the following table.

Mill in operation, days	349.4
Tons crushed per stamp per 24 hours	10.3
Tons crushed	360,294
Gold value per ton	$5.99
Silver value per ton	$1.64
Per cent gold extracted	91
Per cent silver extracted	73
Per cent total extraction	87

The costs per ton for the year under consideration are as follows:

Mining	$1.55
Development	0.74
Milling	0.17
Cyaniding	0.91
Water supply	0.02
General expense	0.22
Taxes	0.29
Total	$3.90

The Consolidated Mercur Gold Mines Company, Mercur, Utah, is apparently nearing the end of its life as a prosperous concern. The mines of the company have had a most excellent record for the past twenty-five years, but for the last three years it has been apparent that the grade of the ore was becoming lower and the profit less. The net profit in the last fiscal period was less than $500, and this did not come directly from the mill but from outside sources. The average gross value of the ore treated was $3.21, this including the value of old tailings retreated which amounted to 12 per cent of the total. The total quantity of material treated was 239,190 tons, and the value extracted was $2.32 per ton. Loss in tailing was $0.88 per ton. The cost of producing gold was slightly higher than its value, or $20.9218 per ounce. This shows a loss per ounce of approximately $0.25.

Of a more encouraging nature is the August report of the Goldfield Consolidated Mines Company, Nevada. It shows the largest tonnage ever produced by the mines in any one month, the total being 30,580 tons, or nearly 1000 tons per day. The average gross value was $29.77 per ton, and the total net profit was $634,658. Of the total mine production, 30,508 tons were treated in the mill with an average extraction of 94.75 per cent, or $20.75 per ton. The total operating costs amounted to $7.46 per ton. The company is now engaged in constructing a plant to treat both the accumulated and current residues from the present concentrate treatment process. Two Edwards duplex roasting furnaces, one Baker cooler, one 5-ft. by 18-ft. tube mill and other accessory apparatus are being installed in a steel building erected for the purpose. The additional tanks for collecting the roasted product and agitating in cyanide solution will be contained in an addition to the present plant. Tests show that an average of 90 per cent of the value of these residues can be recovered with an annual saving of at least $80,000. The cost of the additional plant will be about $70,000.

Renewed Interest in Mining.

The decisive steps taken by Western commercial and scientific bodies to renew public interest in mining are apparently bearing fruit. From present indications it is certain that mining in general but ore treatment in particular is going to profit by the efforts being made to bring the operator and technical man closer together, and there can be no doubt that the general education of the public will result in attracting money for mining investment on a sane basis.

The latest developments on this line which give promise of improving general conditions are two, viz., the proposed unwatering of the downtown district of Leadville, and the meetings planned jointly by the Colorado School of Mines and the Colorado Scientific Society. Co-operation for mutual benefit is the underlying motive in each case.

The downtown district of Leadville has been unproductive for some years owing to the large volume of water encountered in the mines and the expense of pumping it to the surface. Drainage tunnels have not been feasible, and until recently all proposals for pumping have seemed impossible. The one link necessary to complete the chain of forces which make the plan attractive is the Central Colorado Power Company, which has ample power at its disposal. At a recent meeting held in Leadville the power company outlined a plan for the formation of a pumping company with sufficient capital to purchase and install the necessary machinery. The power company proposes to furnish most of the working capital, and it is expected that the pumping company will ultimately operate at a profit to be derived from a tariff placed on net smelter returns of ore mined as a result of the pumping. Naturally the power company has a selfish motive in proposing this plan, but on the other hand, the plan is such that no one will profit unless valuable ore is produced. It is not expected that any one will benefit at the expense of any other party concerned.

The most important matter is to secure the co-operation of the owners of the mines which it is proposed to unwater, and to receive assurance from them that if they do not wish to work their mines they will make reasonable concessions to leasers. Taken as a whole the plan is very encouraging, for it is known that ore exists in the flooded district, which was only abandoned when the expense of combating the water became unbearable. The power company has competent engineers at work on the details of the plan and it is expected that a definite scheme will be ready for presentation to the mine owners in the near future.

The other plan referred to, that of meetings under the joint auspices of the School of Mines and the Colorado Scientific Society, is expected to bring improved results not only in renewed interest, but also in improved technical work. The plan contemplates holding meetings in the different mining and metallurgical centers in the State at which a selected speaker will open a discussion on some pertinent subject. The discussion will bring out the views of local operators as well as visitors, and the exchange of opinions must undoubtedly do much good. The list of speakers already obtained comprises the best technical talent in the State. Experts on mining, mine management, ore treatment and plant construction will discuss their subjects in districts where they are most appropriate. This will bring the engineer in closer touch with the problems of the various districts, as well as familiarize the local operator with the ideas and experiences of the engineer.

Improvements at El Paso Smelter.

For some time past the American Smelting & Refining Company has been making additions to its El Paso (Tex.) plant, for the purpose of handling the copper concentrates from the Ray and Chino concentrators. Three new oil-burning reverberatories have been built and are probably now in commission. Hitherto the Ray concentrates have been going to Mexican smelters, but will now be diverted to El Paso. The new Ray smelter recently taken over by the American Smelting & Refining Company will not be ready for operation for some time to come, and until then the Ray concentrates will be shipped to El Paso.

Ray Central.

Engineers Weed and Probert have recently estimated the cost of building a 1500-ton concentrating mill at the property of the Ray Central Copper Mining Company, Arizona, and for permanently equipping the mine for large production, at $1,500,000. They estimate a 75 per cent extraction in the mill, concentrating six tons into one, and a smelting charge of $6 per ton of concentrate. Assuming the smelter to pay for 95 per cent of contained copper, less 2.5 cents New York quotations, and a 13-cent copper market, the high grade ore should yield $5 per ton net. The cost of production should be about 7 cents per pound, exclusive of amortization and interest.

Flotation Process in Idaho.

It is reported that the Macquisten tubes installed in the Morning mill at Wallace, Idaho, are giving satisfaction and producing a good grade of zinc concentrate. Reference to this installation was made more fully in our issue for May, 1911, page 236. The material being treated by the tubes is tailing from Wilfley tables, and contains about 10 per cent zinc. Siderite is present to the extent of about 35 per cent of the ore pulp, and is the principal substance to be separated. Its specific gravity is 3.8, while that of blende is about 4. Thus there is little margin for separation by ordinary concentration methods, and the flotation scheme was resorted to as offering the best medium of separation. It is reported that the installation is turning out zinc concentrate containing 50 per cent zinc.

The Iron and Steel Market.

Bookings of orders for finished steel products in October showed no material change in the total as compared with September, and on the whole fell slightly below the production, through orders for rails and fabricated steel being light, while in practically all other lines bookings were up to the production. Output showed a slight gain over September, being thus better than in any preceding month of the half year. The increased outputs were in the main obtained without the putting of any additional productive units in operation, the month being normally one of heavy outputs per unit, on account f favorable weather conditions.

There has been no break in the monotony of the price decline. Plates and shapes have suffered a decline of about $2 a ton, and steel bars and black sheets a decline of about $1 a ton, while tin plate was definitely reduced 20 cents a box or $4 a ton. While nominally open market conditions prevail in the tin plate market, there is definite leadership by the American Sheet & Tin Plate Company, the subsidiary of the steel corporation, which last year made more than 60 per cent of the country's total tin plate output, and its prices are customarily adhered to by the independent producers. Its reduction was made because there had been such a general decline in other steel products and because the shading on small lots for early shipment which had already appeared suggested clearly the impossibility of the old price being maintained for the new season's business. About this time of year the large can makers customarily place their contracts for the first half or the whole of the new year.

In the products outside of tin plates which declined open market prices prevail in practice as well as in theory. Of the country's sheet production last year the American Sheet & Tin Plate Company made less than 40 per cent. In these strictly open-market lines the declines have occurred gradually, through a given low price first being made in the case of a few exceptionally attractive orders, then upon less attractive orders, and finally upon the common run of orders.

Weighting the important finished steel products outside of standard section rails approximately in the order of their tonnage importance, the declines per net ton in the average price of finished steel products during the past four months have been as follows:

July	$0.70
August	.50
September	.95
October	.90
Four months	$3.05

The average decline of $3.05 a ton in the past four months came upon a market which had already declined $1.35 since the beginning of the year and $8.05 since the late months of 1907, when the maximum of the past nine years was reached.

That the cost line has been closely approached in the present market is declared by all producers, and there is no reason to doubt the statement. Attention should be called, however, to the fact that as a rule the mills are accepting specifications of a very much mixed character, and filling them, by prompt shipment, at practically the minimum market prices. That mill costs per ton would be materially lower were operations conducted upon better selected and arranged specifications there can be no question. Buyers are insisting upon prompt shipment against all specifications accepted, and the mills appear to be powerless, on account of the competitive situation, to exact premiums in proportion to the undesirableness of the specification. A great deal is said in the market about specially low prices being made on orders involving "attractive specifications" and of course there is some selection, but in the final analysis specifications being filled result in costs much higher than in periods when mill capacity is strained and orders are so long in filling that judicious selection and arrangement can be practised.

The industry is operating at about 75 per cent of its full capacity, making pig iron at the rate of about 25,000,000 tons a year, approximately the average of the three-year period of great activity immediately preceding the panic of October, 1907. The independents are operating at an average of slightly less than 75 per cent, and the steel corporation at a slightly better proportion, but nearly 15 per cent of its entire capacity is engaged upon export material, the independents conducting very little export trade.

There is no definite promise in general industrial conditions of an improvement in iron and steel consumption in the near future. Purchases, production and actual ultimate consumption are all proceeding at an even pace. Stocks in the hands of jobbers and manufacturing consumers are at a very low ebb, and there is the possibility of present prices proving so attractive to buyers as to induce them to increase their stocks toward normal proportions. No movement of this sort is discernible, but many buyers are openly stating that the moment they observe a hardening tendency in prices, or a slight falling behind in deliveries by the mills, they will promptly place orders for much larger tonnages. A very small event may thus at any time lead to important consequences by way of heavier buying, producing a spurt not altogether healthy through actual ultimate consumption not being correspondingly increased. On the other hand, the approach of winter may operate to curtail consumption in a minor degree and lead to slightly decreased operations. In a word, tonnage is very heavy, prices unsatisfactory and declining, and the market decidedly uninteresting.

Pig Iron.

Sales of pig iron have been light as to tonnage, but a large number of small orders have been placed, and deliveries on contracts are very good. Buyers had contracted very conservatively. There is scarcely any forward buying, no advancing tendency being observed in the market, while occasionally slight declines occur at one point or another. The actual consumption of merchant iron is believed to have been measurably in excess of production during the past two months, effecting a slight decrease in the rather large stocks in merchant furnace yards. These decreases are chiefly at inactive furnaces. An event of considerable interest in October was a break in the price of Bessemer pig iron. This market, the scene only two

years ago of transactions in 10,000 to 25,000-ton lots, held at $15, valley, for more than a year, and then broke early in October on a sale of 1,000 tons at $14.65, valley, iron being later offered at $14.50, valley, without any important sales being effected. The market stands quotable as follows: Birmingham, $10 for No. 2 foundry; delivered Philadelphia, $15 for No. 2 X, $14.50 for basic; f. o. b. Chicago district furnaces, $14 to $14.25 for No. 2 foundry; f. o. b. valley furnaces, 90 cents higher delivered Pittsburgh; Bessemer, $14.50; basic, $12.50; malleable, $13; No. 2 foundry, $13.25 to $13.50; forge, $12.75 to $13.

Steel.

An awkward situation arose in the sheet bar market regarding settlements for October and fourth quarter tonnages. Practically all the consumption stood covered by term contracts, providing for price adjustment monthly or quarterly in a variety of ways, and frequently at the open market, or a slight fixed differential below the market. There was, however, no actual market in existence. There was the tradition of the old price of $22, f. o. b. maker's mill, Pittsburgh or Youngstown. This had not been broken in Bessemer steel, for which the term contracts almost invariably called, but open-hearth bars had sold in small lots as low as $19.50, and the entire finished steel market had declined since the $22 price on sheet bars had first been named. In these circumstances a condition of open competition developed, even though all consumers had contracted for their tonnage, and settlement prices were finally reached at a considerable range, $21, delivered Pittsburgh district or Youngstown, being done in some cases, while in other cases lower prices, down to $20.50, were made. The market is not precisely quotable, and we name the following quotations, which are more or less nominal: Bessemer billets, $20, maker's mill, Pittsburgh or Youngstown; Bessemer sheet bars, $21, delivered Pittsburgh district or Youngstown; open-hearth billets, $19, and open-hearth sheet bars, $20, both f. o. b. maker's mill and subject to frequent concessions.

Finished Material.

Strictly open-market conditions prevail in plates, shapes, bars, and sheets, and on these we quote minimum prices done on fairly attractive orders, these prices being occasionally shaded, while on the least desirable orders slightly higher prices are obtained; in wire products the market is maintained in Pittsburgh and the East, but is frequently if not usually shaded in the South, Southwest and West; in tin plates the market is steadily held. The Pittsburgh basis, as a universally controlling factor, has disappeared in several lines.

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.15 cents, Pittsburgh.

Shapes, 1.20 cents for beams and channels, 3 in. to 15 in., inclusive, zees, and angles 3 x 3 and larger, Pittsburgh.

Steel bars, base, 1.10 cents, Pittsburgh; 1.15 cents, Buffalo; 1.20 cents, Chicago; iron bars, 1.25 cents, Pittsburgh; 1.22 cents, delivered Philadelphia; 1.17 cents, Chicago.

Wire nails, $1.65, base; plain wire, 1.45 cents, base, Pittsburgh.

Black sheets, 28-gage, 1.85 cents; galvanized, 2.90 cents; blue annealed, 1.40 cents, f.o.b. Pittsburgh or Mahoning Valley; 2 cents, 3 cents, and 1.50 cents respectively, Chicago; painted corrugated roofing, $1.35 per square, and galvanized $2.50 per square, Pittsburgh, but frequently shaded.

Tin plates, $3.40, Pittsburgh, for 100-lb. cokes.

CORRESPONDENCE.

An Instructive Experiment with the Flow of Heat.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The following simple experiment may be of interest, as it shows some of the peculiarities of the flow of heat through bodies.

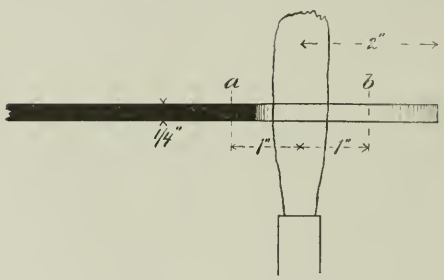
A copper rod ¼ in. in diameter was held in a Bunsen blast lamp flame as shown in the figure, the essential feature being that one end projected only slightly beyond the flame, while the other was practically infinitely long. When the stable state was presumably reached and the rod was at a bright-red heat in the flame, the visibly hot part was unsymmetrical, extending much farther toward the short end, in fact quite to the end of the rod.

This is shown in the figure, the white representing the red-hot part.

The heat enters the rod in the middle of the flame and flows from there to the two ends. It seems to follow, therefore, that more heat flows through the section *a* of the long end than through section *b* of the short end, both being equally distant from the middle of the flame; at *a* it was black and at *b* it was red-hot.

There is, therefore, less loss of heat to the air from the red-hot surface than from the cold surface.

It seems that the heat flowing to the hot end meets with a high virtual resistance at the surface of contact of the metal and the air, and that this resistance is in effect far higher than that of the metal. It would therefore seem to follow that if one side of a tank containing a red-hot liquid were made of a thin copper sheet, while another side was formed by the end of a long massive bar of copper, hence very thick, less heat would be lost through the thin wall than through the thick one.



ARRANGEMENT OF EXPERIMENT ON FLOW OF HEAT.

Or, in other words, the loss through the walls per square inch would be greater than that from the exposed top surface of metal.

If this were also true of the materials which are generally used for furnace walls, it would seriously upset our present ideas that a thick wall insulates better than a thin one. But a repetition of this experiment, using a rod of clay (the stem of an ordinary clay pipe) of the same diameter, in place of the copper, fortunately showed no such dissymmetry. A more carefully made test would probably even have shown a dissymmetry in the other direction.

A carbon rod acted like the copper one, but the dissymmetry was far less.

This apparently very high surface resistance to the flow of heat may be similar to the one existing in steam boilers, the presence of which can be shown by the fact that a postage stamp pasted on the fire side of a water tube will not even be charred by the flames. This high-surface resistance could be made use of in furnace walls in the form of joints between bricks.

The virtual resistance at surfaces seems to be high as compared with that of copper, but may be low as compared with that of the usual heat-insulating materials. Existing data on this subject seem to be deplorably meager, and perhaps quite unreliable in some respects.

If the thermal resistivity of copper decreases greatly with an increase of temperature then the above results might be explained quite differently. Carl Hering.

Philadelphia, Pa.

Reminiscences of Robert Wilhelm Bunsen.

By Dr. Hans Goldschmidt.

The centenary of Bunsen's birth has given me as an old pupil of the great savant, the idea of writing down some reminiscences of my student days at Heidelberg.

Of the many who have taught me in school, at home and at the University, Bunsen is the one teacher who impressed me most deeply as being truly a teacher by nature.

All who worked in Bunsen's laboratory had every possible opportunity of learning every detail of the science of chemistry from the great master, not only theoretically, but also from the purely practical, manual point of view.

Of course, Bunsen only devoted himself in this way to the regular and diligent worker in his laboratory. He was always ready, however, to help the occasional student, and was never otherwise than friendly to the less diligent; but the student who did not work at the laboratory regularly, could not but feel that Bunsen preferred to give his time to those who worked hard.

He put himself at the disposal of the latter out of working hours as well; indeed, I always had the feeling that Bunsen liked to be "bothered" by those students who were in earnest in their work. Strange as it seems, the constantly repeated monotonous teaching never seemed to be a torture to him.

I am speaking too of a time when Bunsen was fully 75 years old. I was, therefore, among the last of his pupils.

Bunsen attached special importance to his pupils being thoroughly conversant with qualitative analysis; he only allowed experiments in quantitative analysis when he knew that the student was complete master of the former.

As in other laboratories, so in Bunsen's, certain numbered mixtures were given out to be analyzed. He had the results put down in a small note book which he always carried about him. I shall never forget his delightful remark, when I asked him to tell me if the results of the qualitative analysis which I put before him were correct. I named the three or four elements which I had found, and the old gentleman gave me a glance full of meaning and said: "I don't want to know what you have found, please tell me what you have *not* found." He then went through the different groups of elements with me and made me describe exactly the process of analysis. I had to explain in each case how the reactions had taken place, and had furthermore to write down the respective chemical equations and put down separately what I had seen, and what I had not seen. From this it can be seen how seriously the great savant dealt even with beginners.

Bunsen was never tired of showing his students even the smallest secrets of the science; how a cracked test-tube can be made fit for use again by the blast lamp, how glass filaments are drawn, how a filter is correctly placed in the funnel, and many another useful piece of knowledge.

The tests known under the name of "Bunsen flame-reactions" were of very special interest. Even at his advanced age and in spite of a somewhat trembling hand, Bunsen could carry out these fine microscopical chemical operations with a skill and a perfection that excited wonder.

The palm of the left hand of the experimenter played an important part in this. Bunsen used it in this way: he rubbed the ingredients into it with the help of a penknife; during the experiment, the fold of the hand made by closing the little finger over the palm, formed the provision store for the mixture, used in various ways during the analysis. The thumb and the first and second fingers of the left hand remained free for use, in spite of the closed little finger.

These researches, which were carried out in the flame of the Bunsen burner, took the place of and were an improvement on the so-called blowpipe analysis, which Bunsen did not like. It was his capacity for obtaining the most striking reactions with the smallest means, that marked Bunsen's teaching and was of the greatest value didactically.

Those who wished to take their degree were not allowed by Bunsen to work out a doctor-thesis, the viva voce examination was enough for him. His point of view was that the young student was not in a position to do independent work, and that, therefore, the doctor-thesis could only be due to the initiative of the teacher; he, therefore, thought it better for the student, as long as he remained at the university, to deepen and widen his knowledge thoroughly in all the fundamental parts of the science placed before him, without trying to break out new ground himself.

As an examiner, Bunsen was particularly thoughtful and kind. Every one who had listened to his lectures attentively and worked through them thoroughly, was certain to get a good place in the examination. In my examination, he questioned me specially on his iodine titration, which he had gone into with me in the laboratory with special care so that he could not but be certain that I had it all at my finger-ends.

I may be allowed here to repeat a remark made by Geh. Rat Kopp and which was current among the students in those days—si non è vero è bene trovato—"Whoever passes his examination in Heidelberg with rite (the lowest class), has it written down in pen and ink that he is an ass." Little Geh. Rat Kopp, who is best known through his great work on the "History of Chemistry," was the faithful companion in walks, and above all on journeys, of the physically much bigger Bunsen.

Bunsen was pleased if any of his pupils, even after the examination, continued to work under him on subjects of inorganic chemistry, which he had worked at himself. I myself, for instance, seized the opportunity of working at the production of calcium and strontium from molten chlorides, by means of electric current.

In those days this was a hard piece of work, as it had to be carried out with a Bunsen battery, and the only electrical measuring instrument was a tangent galvanometer. Not only was it hard, but particularly hot work, and very troublesome, because the chloride had to be melted on an open charcoal fire.

In spite of the heat of summer, Bunsen insisted on watching the experiment for hours, even long after the closing of the laboratory. He even considered it necessary to be present at the separating of the crucibles, in order to see and control the results.

He then went carefully through the theoretical calculations with me and took care too that the small reguli of calcium and strontium (which I still possess) should be fused in petroleum free from water, which he gave me himself out of an old store. He showed me also the process of fusing in the small tubes.

On these occasions the old gentleman sometimes became very talkative and would converse on matters that lay far outside

the realms of chemistry. He liked to talk about his journeys. A visit to the island of Majorca had left particularly pleasant memories behind.[1]

Another time he told me stories of his teaching days at Göttingen, even then fifty years back. Among other things, he told me of a friend who, in consequence of a bet, had deciphered an Assyrian inscription within three weeks. These old memories seem to have struck particularly deep root in him.

Of greatest interest to me was a remark Bunsen once made, when he was discoursing on the advanced technical knowledge of the Egyptians: he said he had been shown small ancient copper bowls from the old wonderland of the pyramids, which by their form had suggested to him the idea that they must have been precipitated with the help of the electric current. This bold suggestion from a man of very sober thought is very striking.

I remember a particularly interesting occurrence when Bunsen allowed me to make some spectral-analytical experiments, such as were often made in his laboratory by the students. The experiment consisted chiefly in this, that the student, who had at his disposal a considerable number of pure substances in small glasses, attached a little of one substance to a platinum wire by dipping it into that substance, and then introduced it into the Bunsen flame, observing the rays or lines in the spectroscope and putting them down on a graduated scale.

The sodium line served as basis. Bunsen would point this one out with a cigar he held in the flame. As is well known, he was a smoker of strong Havanas. He never failed to point out that in every Havana you could see clearly also the red lithium line. If, by chance, a student himself had a cigar which showed no lithium reaction, Bunsen can scarcely ever have missed the opportunity of making a little joke, by pointing out that the student's cigar was no "Havana."

Among the elements I had to analyze were small quantities of the salts of caesium and rubidium discovered by Bunsen.

When Bunsen saw the lines I had put down for caesium, he shook his head doubtfully and expressed his opinion that it was impossible for me to see the two lines in the violet. The test was repeated over and over again, but I always put the lines exactly in the same place.

I never saw the old gentleman so excited and interested as on that occasion. He thought I must have made a mistake, for both the lines observed by me belonged to rubidium. The caesium given me to work with had not been perfectly pure, it contained traces of rubidium.

I could see these rubidium lines clearly, a fact that led Bunsen to declare that my eyes were exceptionally sensitive to violet rays, and he added: "Had I had your eyes, the separation and above all the discovery of rubidium would have been rendered much easier to me."[2]

He then invited me to go with him to his private laboratory. He had there larger quantities of salts coming from the Dürkheim mother liquors which contained only infinitesimal portions of rubidium and caesium.

He wanted to try if I could see the lines in this extreme dilution, though he scarcely thought it possible. And, as a matter of fact, it was impossible to recognize the salts in the substance handed to me by Bunsen. He made certain once more, however, that there was no mistake on my part in what I had seen and put down before in my earlier tests.

The last work Bunsen gave me was purely preparative and related to the preparation of cadmium borotungstate. The solution of this salt with its very high specific gravity was to be used for the separation of minerals.

As a rule, Bunsen was to be met among his students in the laboratory for some hours both in the morning and in the afternoon. During the summer months, he was often even before his first lecture at the disposal of those who wished to learn from him his gas-analytical methods.

Besides this, he gave a daily lecture on experimental inorganic chemistry, a lecture which was probably unique. In one semester he gave a complete survey of inorganic chemistry and what he demonstrated and expounded was from beginning to end his own work, his own experience, his own research.

Bunsen attached the greatest importance to the illustration of his lectures by means of experiments. I cannot remember the failure of a single one. They too were carried out with the simplest means. For instance, Bunsen showed the working of the geysers with a simple apparatus, and prepared before his hearers electrolytically metallic lithium in a porcelain bowl.

One experiment was especially effective: oxy-hydrogen gas was introduced into a small china bowl full of soap and water. Soap bubbles filled with this gas formed at once on the surface. If a light were applied to them, they exploded and the bowl broke in pieces. Bunsen then repeated the experiment by forming the soap bubbles filled with the gas on the palm of his hand. The explosion was quite as loud, but the hand remained absolutely unhurt, because it formed an elastic foundation, not a hard one like the bowl placed on the lecture table.

After such experiments, the students' applause was particularly stormy, it expressed itself in noisy stamping. Clapping of hands was proscribed. These student ovations were also given to Bunsen when he entered and when he left the lecture room, and he always thanked with a friendly glance and a scarcely perceptible nod.

Bunsen's manner of lecturing may be described as classic, in the best sense of the word. His sentences were short, his delivery clear, his voice even in advanced age sonorous and fairly strong. He despised every kind of hollow figure of speech or brilliant comparison. In this respect one could find no greater contrast to him than the orator and philosopher Kuno Fischer, who was lecturing at the Ruperta-Carola, the Heidelberg university, at the same time as Bunsen.

Bunsen's favorite study was neither chemistry nor physics, it was geology. In his lectures he often referred to this branch of science.

But Bunsen was also in possession of more than ordinary knowledge in zoology, botany and above all, in medicine,[3] so that it is not too much to maintain that he belongs to the men of his age who could claim the greatest general scientific culture.

Bunsen was of a meditative nature with an indubitably highly developed inner life. And this explains his dislike to ostentatious display, his wish not to appear in public or be disturbed by social duties more than was unavoidable. He was perfectly natural in his whole manner of being and acting. He was so thoroughly absorbed by his work, so taken up by it, that he felt no desire for things that seemed to him paltry.

With him, one always had the feeling that he placed the problem itself above everything and all that was personal as far out of sight as possible. That was why in his lectures, one never heard the expression: "I have found" or "I have discovered." He always spoke with the impersonal "one." Whether he spoke of the Bunsen burner, of the Bunsen battery, of the Bunsen valve, or of the spectral analysis-inventions that bore his name already while he was yet living—he never put himself forward, never mentioned his own name.

Bunsen was a great, even enthusiastic lover of the beauties of nature; he preferred wandering about on foot, so that he might gain strength in the fresh open air. Heidelberg, with its wooded surroundings, had become very dear to him. There is no doubt that he was deeply attached to his German Father-

[1] He had gone there with the zoologist, Dr. H. A. Pagenstecher, professor at the University of Heidelberg. The latter has given a clear and charming account of this journey in a small book, which is still worth reading, "The Island of Majorca: Sketches of a Journey," by Dr. H. A. Pagenstecher (Leipzig: W. Engelmann, 1867).

[2] Cp. on a fifth element beloneing to the alkali group. By Bunsen. *Berichte* der Akad. der Wissenschaften z. Berlin, 1861, L 27.375.

[3] I may point out here that Bunsen owed his invention of the well-known contrivance the "Bunsen valve" to his medical knowledge of the flaps or valves in the veins.

land, through which he had wandered much in earlier years, but he was free from any onesided overweening appreciation of German intellectual efforts. His views and opinions were not limited by a narrow circle. Our planet did not suffice for his chemical and physical research, the eye of this gifted searcher pierced to the furthest worlds.

Much has been said about Bunsen's great modesty. Since Goethe declared that "only rascals are modest" this quality requires a certain reservation, when it is attributed to a great man. And this is specially called for in the case of our savant. He was an exceptionally high-minded man, most courteously kind in intercourse with others. That was noticeable even in small things. For instance, when a student entered his private laboratory with him, he would never go in first, but obliged the student to do so. If any one met the old gentleman out for a walk, he had to be careful to be in time in bowing first, for Bunsen never waited till he was saluted, but would take off his hat a long way off to the student whose face he recognized.

But together with this well-bred politeness, this simplicity in ordinary intercourse, there was in him a great, one may confidentially say, a too great consciousness of his merits. For Bunsen believed in, and set a value almost exclusively in, what he himself had seen, investigated, and discovered. Others' work he considered doubtful as a matter of course, very often ignored it and even treated with scorn many an investigator who did not deserve such treatment. He expressed this scorn, of course, only in incidental remarks and conversations, for he never wrote a controversial paper. In this depreciation of others' work and the careful avoidance of printed replies, he resembled the great Linnaeus, who, however, unlike Bunsen, took special delight in being himself in the foreground.

As an example, I may quote Bunsen's drastic remark—repeated to me by his late assistant Pagel, who was many years with him—on the periodical system of Mendelejeff, who was in Heidelberg from 1859 to 1860: "If a clever mathematician takes the Stock Exchange column of a newspaper, he also can discover fixed series of values that have no connection with one another." Bunsen never mentioned Mendelejeff's system in his lectures.

The great investigator also stood aloof from the then modern views on atoms and their groupings. His friend Kopp tried to enlighten him in an exceedingly clever and witty publication "From the world of molecules,"[4] which first appeared anonymously. This little book can be warmly recommended to every chemist who has a sense of humor, as far as that can enter into purely scientific questions. Often a very pertinent doubt on the part of the author pierces through the explanations, and this must have made the small work still more savory to the doubter Bunsen.

As Bunsen lectured substantially only on what he had himself investigated, so in his laboratory he only allowed work on subjects he suggested himself, and on which he had worked himself. As soon as a laboratory student chose a subject on his own account, the master's interest ceased. This peculiarity finds its explanation in his conscientiousness as a teacher; he wished to demonstrate and teach in his laboratory only what he was thoroughly acquainted with himself.

There were already a great number of Bunsen anecdotes current during his lifetime. Many of them were meant to prove the helplessness of the savant in things which were likely to be unfamiliar to him, especially as a bachelor, or which showed his awkwardness in society in general. The absentmindedness attributed to every German savant played its part too in these anecdotes. If we were to trust these traditions, even only in their general tendency, our mental picture of the great man would be a gross caricature. Bunsen was a thorough man of the world, who had traveled a great deal and had associated with men of every condition, high and low. He knew perfectly well how to behave correctly and befittingly in every situation in life. On the other hand, the great savant possessed a delicate sense of humor and a great taste for irony, both of which he often turned against himself; he liked to be ironical about himself. Probably those often foolish Bunsen stories owe their origin to this peculiarity of his, his joke having been misunderstood.

The domain of chemistry, especially of inorganic chemistry, that Bunsen was master of, was extraordinarily wide, for he possessed it in all its smallest details, whether it were a problem of the separation of rare earths, of the group of platinum metals, of the most difficult gas analyses, or of smelting processes of every kind. The work he did, as pioneer, in almost every department that he touched upon, was so comprehensive and always so thorough, that he did not seem able to find the time to make himself sufficiently acquainted with the realms of investigation of his contemporaneous colleagues. Thus he had not many collaborators; the best known are Kirchhoff and Roscoe.

To us, who look back, he stands out in solitary grandeur, far above others. His weakness, in ignoring the work and success of others, became finally a source of strength. His immovable trust in his own creative power absorbed him so exclusively, that he gave the world a great deal of new and most valuable knowledge, a fruitful and priceless possession for all time.

Proposed Treatment of Sulphide Ores with Nitric Acid, or So-Called Rankin Process.

Editorial Correspondence.

The difficulties attending the economic treatment of ores containing the sulphide minerals of several metals have resulted in classifying such ores as refractory. This term is generally taken to mean that these ores do not yield readily to known methods of treatment, and consequently the newer developments in metallurgy are heralded as means of successfully treating refractory ores.

The proposal to treat mixed sulphide ores with nitric acid is an endeavor to solve this problem in an economical way. The recovery of the nitric acid is a vital feature of the process. In its present state of development it represents the original idea of Mr. H. D. Rankin as modified and improved by his coworkers.

In the following description of the process reference will be had to the treatment of an ore containing some form of the sulphides of iron, copper, lead and zinc, with accompanying gold and silver, either native or combined. The statements given represent the claims for the process as outlined to the writer by Mr. E. H. Westling, metallurgist for the company controlling the process. Experimental work has been done at Pittsburgh, Pa., and Lake City, Colo., and it is announced by the company that a commercial plant is to be built and operated immediately at Chloride, Ariz.

With the exception of gold, the products of the process are not metals ready for refining, but salts of the metals equivalent to high-grade ores suitable for reduction by present processes of smelting. In some instances the precipitated salts may find commercial use as such, as in the case of iron and copper, but for the most part they must be reduced to metals. Briefly, the primary products of the process are: Gold in the form of amalgam, silver as silver chloride, iron as hydroxide, copper as basic carbonate, zinc as hydroxide and lead as sulphate. Thus the process is designed to effect a chemical separation and concentration of the valuable constituents of an ore in a more economical manner than might be done in other ways.

A number of objections and queries will at once arise in the mind of the investigator as to the feasibility of the process. The complete precipitation and washing of salts in large quan-

tities; the economical regeneration and recovery of nitric acid; the completeness of the various reactions; the operation of a process with a gas under pressure; the economical operation of a process combining many separate operations; and the recovery of unfinished products which must stand further cost of reduction and refining—all these are points which call for proof by commercial operation on a large scale. The sponsors of the process, however, feel sufficiently assured on these points and claim that the method can be operated profitably.

Description of Plant.

The process naturally divides itself into three parts: The decomposition of the ore, recovery of the metallic salts and recovery of the nitric acid.

The decomposition of the ore is effected in a digester of cast iron lined with an acid-resisting mixture. This piece of apparatus is egg-shaped and supported in a vertical position. Within is an air lift agitator made of aluminium, connected by aluminium pipe with an air compressor outside. The proportional dimensions of air lift and digester are about the same as in a Pachuca tank. Above the digester, and tightly connected with it, is the ore bin, which can be tightly sealed. In the connection between digester and bin is a revolving cup feeder. In a suitable position above the digester is a receptacle for nitric acid.

The recovery of the metallic salts is accomplished in a series of precipitating and settling tanks, with such filtering and washing apparatus as may be needed. Ordinary amalgamating devices are provided for gold recovery, and a concentrating table is used for the separation of lead sulphate from the gangue.

The acid recovery system consists of a series of condensers and water towers. Aluminium pipe is used in all connections and cooling coils, and the tanks and towers are protected with acid-resisting mixtures wherever exposed to the acid gases. The water towers are constructed of paraffined redwood or cypress and filled with clean quartz. The first of the three towers is half full of water and the others are two-thirds full. At suitable places in the aluminium pipe are two indicators to show the condition of the gases at those points. These indicators are glass sleeves surrounding openings in the pipe, and the first is placed ahead of the first water tower and the second beyond the last tower.

Treatment of Ore.

Although the treatment of ore and recovery of acid are simultaneous operations, they will be described separately for the sake of clearness.

The process is worked intermittently on successive charges of ore and acid. Six tons of ore per charge is a convenient unit of capacity, and the time of treatment of each charge is between two and three hours.

The ore should be ground to about 30-mesh size, and contain at least 2.5 per cent to 3 per cent sulphur. If the sulphur content is below that figure the ore should be concentrated before treatment. At least 5 per cent sulphur has been found necessary if the reaction is to proceed without the application of heat. With 5 per cent or more sulphur the reaction with nitric acid generates sufficient heat for complete decomposition of the ore, but with less than 5 per cent it is necessary to heat the mixture. This is usually done by agitating with live steam instead of air for five or ten minutes at the beginning and end of the treatment.

The acid is run into the digester in quantity proportional to the amount of sulphur in the ore. It is claimed, however, that, if pyrite is present in considerable quantity, 5 per cent less than the theoretical amount of acid can be used, as the ferric salts act as catalyzers in oxidizing the sulphides to sulphates. It is customary to use acid of 1.15 to 1.42 sp. gr. The recovered acid has a sp. gr. of 1.25 to 1.35 and is used at that strength.

With the necessary charges of ore and acid in the sealed ore bin and digester respectively, the feeder is started which slowly delivers the ore in small quantities into the acid. At the same time the air agitator is started and the feeding and agitation continue until the sulphide minerals have been converted into sulphates, all of which are soluble excepting that of lead. Some sulphuric acid may be used with the nitric if the ore contains lime, or to prevent the formation of basic iron sulphate. It is claimed that the conversion of sulphides to sulphates is practically complete, only about 2 per cent of the nitric acid remaining as nitrates of the metals. The following equation is typical of the reaction on which the process is based.

$$3PbS + 8HNO_3 = 3PbSO_4 + 8NO + 4H_2O$$

Throughout the treatment of a charge of ore the digester and acid recovery system are under about 25 to 30 lb. pressure. When the reaction is completed the digested mass is drawn into a tank where the solution is separated from the gangue by filtration or decantation. The residue is washed and passed over an amalgamated plate and Pierce amalgamator for the recovery of the gold. The lead sulphate is then separated from the gangue by concentration on a Wilfley table, the sulphate flowing off as a slime and collecting in settling launders. Naturally it will be contaminated with the fine gangue formed in crushing the ore, but it forms a high grade lead product for smelting.

The metals in solution are precipitated successively in a system of tanks, and the precipitated salts are washed and dried. Silver first is precipitated with salt, giving silver chloride which must he reduced to metallic silver. Iron next is precipitated with pulverized limestone (30-mesh) giving a fine granular precipitate of ferric hydroxide which settles rapidly. This precipitation is carried out at a temperature of 55 deg. C., which is about the normal temperature of the solution at this stage of the process.

A remarkable claim is made in connection with the precipitation of iron and the subsequent precipitation of copper Ground limestone is used as the precipitant in each case, but the temperature is 20 deg. C. higher for copper than for iron It is claimed that at 55 deg. C. limestone will precipitate iron without copper, and that upon raising the temperature of the solution to 75 deg. C. the same precipitant will throw down copper as basic copper carbonate. Wherefore, after the precipitation and separation of iron the solution is heated by passing live steam through it until a temperature of 75 deg. C. is obtained, when copper is precipitated.

The iron precipitate has no value unless circumstances should warrant its use as a paint pigment. A market might be found for the copper precipitate as such, but in all probability if any considerable quantity were produced it would have to be reduced to copper.

With iron and copper removed the zinc is precipitated with milk of lime, giving zinc hydroxide which is to be calcined and smelted. The zinc precipitate will be free from iron but may contain some manganese. It would seem that, inasmuch as lime in some form is the precipitant for iron, copper and zinc sulphates, certain amounts of calcium sulphate must contaminate the precipitates. Calcium sulphate is soluble at ordinary temperatures in about 500 parts of water, the solubility increasing slightly until a temperature of 100 deg. C. is reached, when it decreases rapidly. Hence the salt will precipitate unless enormous volumes of solution are used.

The precipitating tanks for these operations are fitted with pipes for air agitation, bronze pipe being used in all precipitations where copper is still in solution. The entire precipitation system is preferably arranged in duplicate to facilitate cleaning up.

Nitric Acid Recovery.

The principle upon which the recovery of nitric acid is based is shown in the following cycle of reactions. As shown before, the treatment of a sulphide with nitric acid gives nitric oxide

as one of the products. Nitric oxide and oxygen unite to form nitrogen peroxide, which is soluble in water at ordinary temperatures, forming nitric acid and nitric oxide. The latter then combines with more oxygen and the cycle is repeated.

$$3CuS + 8HNO_3 = 3CuSO_4 + 8NO + 4H_2O$$
$$NO + O = NO_2$$
$$3NO_2 + H_2O = 2HNO_3 + NO$$

The oxygen necessary for the reaction is supplied by the air used in agitating the charge of ore and acid. The nitric oxide and oxygen are constantly being forced out of the digester through the acid recovery system, the oxygen being supplied in sufficient quantity so that the gases escaping into the air at the end of the system will show an excess of at least 2 per cent O. It is claimed that 95 per cent of the acid used is recovered.

The gases first enter a large narrow cylinder having about two-thirds the volume of the digester. The function of this so-called mixer is to allow time for thorough mixing of the gases and formation of nitrogen peroxide. Some nitric acid is formed here by reason of the fact that when the reaction in the digester is well under way steam will issue with the other gases, giving the right conditions for the formation of some nitric acid. It is claimed that about 10 per cent of the acid is recovered here.

The gases are next cooled in an aluminium condenser or cooling coil, where another 10 per cent recovery is made. Following the cooler is the first water tower, through which the gases bubble and where the greatest part of the recovery is made, amounting to 60 per cent. Between the cooler and first tower is placed an indicator, where the gases should show reddish brown in color. Following the first tower is another cooler where about 3 per cent of the recovery is made. Finally, the second and third towers make about 12 per cent recovery. The acid drawn from the mixer and coolers is 1.25 to 1.35 sp. gr., while that in the towers gradually builds up to 1.35 to 1.40 sp. gr. before it is drawn for use. The first tower builds up in strength most rapidly and when its contents are withdrawn they are replaced by those of the second tower, and so on. The gases issuing from the last water tower pass through a second indicator, where they should appear colorless if the system has been working properly.

The cost of chemical treatment is determined by the quantity of sulphur in the ore. The acid loss is claimed to be only 5 per cent, and the precipitants used are inexpensive. In addition there will be the usual cost for preparation of the ore, pumping and agitating solutions, filtering, drying and marketing the products.

The results of the first attempt to operate the process on a commercial scale will be awaited with interest

Fiber Testing Plant for Paper Manufacture.—Construction is under way on the paper machine house to form a part of the new laboratory of Arthur D. Little, Inc., engineers and chemists, Boston, Mass. This miniature paper mill will be L shaped, consisting of two rooms measuring approximately 25x35 and 25x52. Being located in the park system of Boston its exterior will be made especially attractive with brick and stucco walls and tiled roof. Although the entire equipment will be a miniature with a capacity of only 5 to 10 per cent of that of an ordinary machine, each piece of apparatus will be perfect in itself. The combination cylinder and Fourdrinier machine which is being made by the Pusey & Jones Company, Wilmington, Delaware, will be constructed along the same lines as the machines made by this company for the Forestry Service and the Bureau of Standards, but will differ somewhat in the method of driving as well as in the number of calendar rolls and suction boxes. Its length over all will be about 44 feet. The balance of the equipment will include two 50-lb. beaters with washers, pulp washer, Jordan, soda, sulphite and rotary digesters, steam generating plant, bleach dissolving system, vacuum pump, stuff chests and pumps.

The Grönwall Steel Refining Furnace.

By Thomas Duncan Robertson.

The development of the electric furnace for iron and steel manufacture is comparable in its rapidity to that of the automobile or the aeroplane. In 1904 there were only four electric furnaces in Europe, while to-day there are over one hundred working in different parts of the world, some reducing iron ores, the majority, however, being used to melt or refine the products of older metallurgical processes and produce the material generally known as electric steel.

It is only natural that many types of electric furnaces have been proposed from time to time; some have existed on paper, some in the experimental stage and others have made iron and steel on a commercial scale. The latter class is generally subdivided into induction furnaces and arc furnaces. The former, it would appear, are on the decline, although they are fairly efficient melting machines when of small size, yet it is found to be very difficult to accomplish with them any appreciable refining. On the other hand, in the arc furnace cold materials are easily melted and the fluid charge can be refined to a degree of purity unequalled by any known process used in the iron and steel industry.

At the present time several types of arc furnaces have proved themselves capable of making good steel economically.

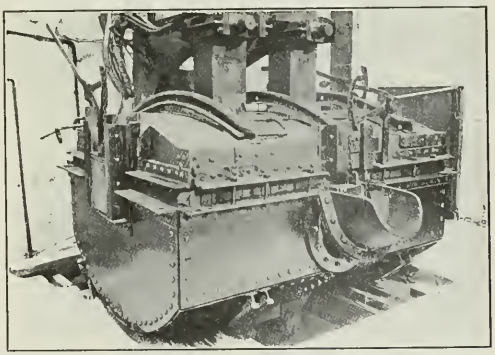

FIG. 1—VIEW OF GRÖNWALL STEEL FURNACE.

One of the latest types to be introduced—and one that possesses several distinct advantages over others—is the Grönwall furnace. This is the invention of three Swedish engineers—Messrs. Assar Grönwall, Axel Linblad and Otto Stalhane, of the Aktiebolaget Elektrometall of Ludvika, Sweden.

Having originally worked with various types of induction furnaces without great success, they decided to design an arc furnace which would embody the mechanical and electrical advantages of existing types, at the same time eliminating their weak points.

The invention consists in the method of supplying electric energy to the furnace, the form used being two-phase alternating current.

Furnace Construction.

As will be seen from the illustration (Fig. 1) the furnace has two carbon electrodes passing through the roof. These electrodes carry the two phases, the current arcing across from them to the charge, passing through this, and then through the basic lining to the neutral return, which is a carbon block fixed in the bottom of the furnace.

The iron tank of the furnace is lined with magnesite brick, and inside this lining the hearth of dolomite or magnesite is rammed. (See Figs. 2 and 3.)

The carbon block forming the lower terminal is set in a casting bolted to the furnace bottom, and good electrical con-

tact is secured by a special mixture which is used as cement. The top of this bottom electrode comes level with the brickwork so that it does not project into or in any way weaken the basic lining. The hearth of the furnace is not broken by any projections, being similar to that of an ordinary basic open-hearth furnace, repairing after each charge being effected in the same manner.

The roof consists of a channel iron framework holding silica bricks, and is detachable, so that when the bricks are worn thin it can be taken off and replaced by a new one, this

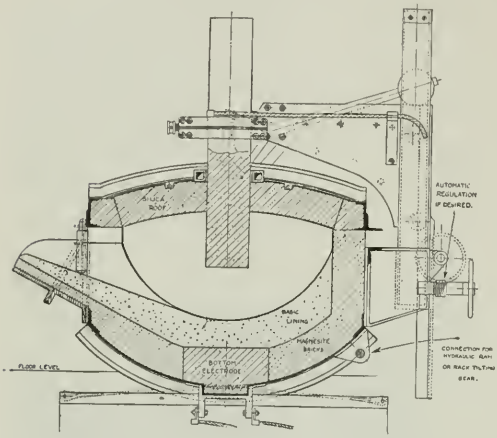

FIG. 2—SECTION OF GRÖNWALL STEEL FURNACE.

operation of changing only requiring about twenty minutes.

There is a working door at each end of the furnace and another one at the tapping spout. At the back of the furnace are the cranes for raising and lowering the electrodes. This is the only method of regulating the current and the electrode cranes can be operated either by hand or by automatic regulators.

The electrode holders for the electrodes passing through the roof offer three distinct advantages over the usual types employed:

1. The electrode holder at the same time grips the electrode and makes electrical contact.

2. The construction is simple and efficient; the holder consists of strong iron castings and T irons, a construction which will stand the rough usage to which it is exposed, and at the same time does away with complicated parts, such as springs, steel bands, etc., which are liable to get out of order.

3. The improvement is introduced of making the electrical contact low down on the electrode, thereby reducing to a minimum the loss of energy due to the resistance of the electrode.

The furnace is mounted on curved rails and is tilted by hand wheel gearing or by hydraulic cylinders. These rails rest on channel irons supported by strong foundations. The furnace construction, although simple, is cheap, strong and efficient.

Electrical Equipment.

The high-tension supply, if three-phase, is transformed by means of two single-phase oil-insulated self-cooling transformers, with Scott's connections to the tension suitable for the furnace, viz., 65 volts. Tappings are, however, provided on the primary side of the transformers for obtaining 50, 60, 70 or 80 volts.

The switch gear consists of an automatic oil switch, with cut-outs for overload, in circuit with the high-tension mains. On the low-tension side there is an ammeter on each phase and one on the neutral return. In addition a voltmeter with a three-way switch shows the voltage of each phase, and also that between phases. The power consumed is measured by a watt-hour meter.

The current is conveyed from the transformers to the electrode holders by means of flexible bare copper cables, and from the bottom casting to the transformers by similar cables.

Advantages of the Two-Phase System.

Practically all power supplies are either two- or three-phase high-tension current. It is, therefore, a great advantage of this system that such current can be used direct by means of static transformers without the intervention of costly running plant.

Where the available supply is two-phase the furnace is coupled directly to the mains through two single-phase static transformers, giving suitable voltage in the furnace. In the case of a three-phase supply, as mentioned above, the current is transformed into two-phase by means of Scott's system of connections. In this manner a great saving in first cost and a high economy in working are gained as compared with the rotary transformers (converters or motor-generators) required for converting three-phase current into single-phase current.

In the Grönwall furnace each phase is connected to one of the top electrodes. Each arc is, therefore, formed independently of the other, so that if one arc is broken the other remains, while in furnaces with arcs in series the breaking of one arc also breaks those remaining. The Grönwall system ensures steadier running. Assuming the furnace to take 500 kw, i. e., 250 kw per phase, if one arc breaks only about 250 kw are immediately switched off the mains, whereas with the arcs in series the whole 500 kw would be cut off, causing a much bigger fluctuation in the power supply. This feature is so marked that in Sheffield, England, where one of these furnaces is installed, the authorities at the municipal power

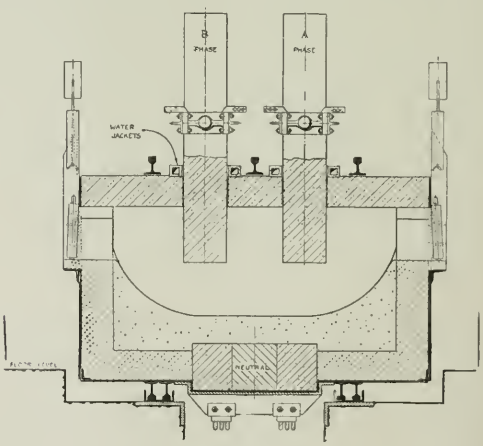

FIG. 3—SECTION OF GRÖNWALL STEEL FURNACE.

station permit the furnace to be started on a cold charge during their peak load.

In all arc furnaces the arc is, of course, the heat generator. During the melting stage the current passes from the electrodes to the charge, and as small pieces of this melt from under the electrodes from time to time the arcs are being continually made and broken. With a single-phase furnace with the arcs in series, this means a continual switching on and off of the entire current, with consequent disturbance of the supply system, loss of time in melting and loss of heat in the furnace by reason of the discontinuity of the supply of energy.

Apart from electrical considerations, it has been found that this two-phase system has decided metallurgical advantages.

The passage of the current through the basic lining uses very little energy, but it raises the temperature of the bottom sufficiently to prevent any metal cooling and solidifying in the bottom of the bath. The lining is not damaged in any way by the passage of the current, and experience has proved that there is no appreciable increase of wear and tear on the bottom.

The arrangement of two arcs in parallel with a neutral return through the bottom produces a vertical as well as a horizontal circulation of the metal in the bath. This facilitates chemical reactions by bringing all parts of the charge successively into intimate contact with the refining slag.

Due to this circulation, heat is taken away from the very hot region below the electrodes, so that the reflection of heat from this part on to the roof is much less than with single or three-phase surface heating, the result being to prolong the life of the roof. The roof of these arc furnaces is made of silica brick, so that when unduly overheated pieces of silica drop down into the basic slag the equilibrium of the reactions would be upset. The longer the roof can be made to last the greater is the reduction in cost and the less silica will pass into the slag per charge.

The process of steel-making in the Grönwall furnace is the same as that employed in the earlier and better known types of furnace. The quality of the resulting steel is so well known that it needs no emphasizing. It is generally admitted, however, that the absence of oxygen from the steel partly accounts for its remarkable properties. The process of deoxidation carried out in the Grönwall furnace is facilitated by the circulation of the charge referred to above.

The advantages of the Grönwall furnace may be summarized as follows: The utilization of two-phase current from a three-phase supply eliminates rotary transformers; an even distribution of heat is obtained throughout the charge, and at the same time a circulation of the molten metal is set up, resulting in improved refining conditions.

Toronto, Ontario.

The Remelting of Ferromanganese and the Deoxidation with Molten Ferromanganese.

In *Stahl und Eisen* of Aug. 24, 1911, appeared an article by J. Bronn and W. Schemmann, of Rombach, Lorraine, giving some valuable information about the use of molten ferromanganese.

In view of articles recently published about this subject (*J. Tr. Rev.*, 1911, March 16, page 526) the authors deem it necessary to give some practical advice. They fear that on account of the difficulties and failures experienced in remelting ferromanganese at the present time in cupola furnaces, open-hearths or electric furnaces, steel men may lose confidence in this process and abandon it, although if properly carried out it has very important advantages.

In 1906 the Rombach steel works began to remelt ferromanganese. The molten metal was poured into the ladle, together with the heat from the converter, thus preventing any waste of ferromanganese due to smaller pieces remaining in the slag. Any reduction of phosphorus from the slag back into the bath, which hardly could be prevented before, was avoided.

Samples analyzed from all the ingots gave not the least differences between the first and the last ingots. This proves a quick and uniform distribution of ferromanganese in the bath.

The casting into ingots proceeded very smoothly and in none of the 1000 heats with molten ferromanganese any difficulties were experienced in casting. Even "dead heats" could be poured.

It is a surprising fact that heats with such a low manganese content as 0.22 per cent to 0.25 per cent could be rolled easily and with only a small percentage of "bad ends."

This permitted a considerable saving of ferromanganese per ton of steel. Further small pieces of ferromanganese, such as result from long storage, could now be used without loss, while in former practice a good deal of the smaller pieces were always lost with the slag.

These favorable results induced the Rombach Steel Works to adopt the process on a larger scale. There were some difficulties involved in the problem how to melt the ferromanganese. Cupola and open-hearth furnaces could not be considered, since too much of the manganese would be oxidized or lost with the slag.

On account of the low boiling point of manganese (1900 deg. C., against that of iron, 2450 deg. C.) the ordinary electric arc furnace is also unsuitable. In a test made with a small electric furnace such an immense smoke of oxide of manganese was developed (the manganese evaporating first as such, but being at once changed into oxide) that the laborers were unable to operate the furnace and the trial was abandoned after half an hour.

Another difficulty was found in the method of feeding electrical energy to the furnace. Girod's bottom electrode did not work at all. After many trials in an electric furnace of 300 kw to 400 kw it was found that the bottom electrodes were exceedingly corroded and penetrated by the ferromanganese. Nearly a dozen different types and sizes of bottom electrodes were tried out, but none lasted more than three days.

Investigation of these steel-bottom electrodes showed a transformation into a high-percentage and very brittle ferromanganese. Observations made by Wüst and Felser have also proven that iron in contact with highly heated ferromanganese absorbs a great amount of carbon and especially of manganese. The use of the bottom iron electrodes was therefore discontinued.

Another problem had to be solved in the construction of the hearth of the furnace so as to prevent leakage. Since only small portions of the bath were taken from the furnace they had to be heated to a high temperature in order to prevent any freezing during transportation. But this hot and very liquid alloy in the furnace penetrates easily into the porous lining of the hearth and causes undesirable damage. These troubles were overcome by a special lining.

Numerous tests were made until a final satisfactory solution was found by using low-tension electric currents. In opposition to the ordinary arc furnaces with a drop of 45 volts to 75 volts between electrode and bath, a "far lower" tension was employed. (The exact voltage is not given in the article.)

The melting process then occurs smoothly without any of the troubles mentioned before. For example, the furnace contained more than 1.5 tons ferromanganese and after six days of continuous operation the furnace content showed not the slightest increase in percentage of iron or decrease in manganese.

With such low-tension current the distance between electrodes and bath surface could be reduced to a minimum without increasing unduly the consumption of electrodes (which was only 1 cm, or 0.4 in., per working hour as a weekly average). But the consumption of electrodes may be still reduced considerably.

It seems that in most cases the saving of manganese, which amounts to 35 per cent of the usual consumption of manganese, pays several times for the costs for remelting.

The results already obtained make it possible, according to the authors, to produce in one heat at reduced cost from Thomas iron an excellent quality of steel which may in many cases replace the ordinary basic open-hearth steel.

The Röchling Iron & Steel Works in Völklingen have also introduced this process in their mills. The remelting was undertaken in a small Roechling-Rodenhauser induction furnace, the results being satisfactory. R. J. W.

A Simple Method for the Determintion of Methane in Producer Gas and Enriched Water Gas.

By S. H. Worrell.

The constantly increasing use of producer gas and enriched water gas for power in gas engines suggests the necessity for either a daily analysis or a b.t.u. determination with a calorimeter. The analysis is necessary to determine, ofttimes, just where the trouble lies in the process of making the gas. The calorimeter is useful in determining the value of the gas when bought on a contract of a rated b.t.u. delivery.

If an analysis is to be made, the simpler the method used the better. The following method is in almost daily use in the University of Texas Testing Laboratory. The apparatus used is a modified form of that put out by the United Gas Improvement Company. Instead of the graduated burette with a bulb and three-way stop cock, a burette calibrated its entire length, without a bulb, and having a two-way stop cock is used with a water jacket to maintain a constant temperature.

One way of the cock is attached permanently, that is, it does not have to be removed during the analysis, to a potassium hydroxide pipette. This leaves the other branch open to attach the various other bulbs in succession during the analysis.

The method in detail is as follows. One hundred cubic centimeters of the gas at atmospheric pressure are taken. Then as each constituent is absorbed the burette is read, the amount so obtained is subtracted from the previous reading and this difference is at once the percentage of the constituent under consideration. This subtraction is all the arithmetical calculation necessary in this method, the final residue being nitrogen.

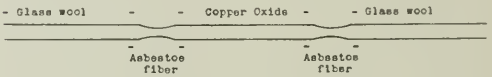
The carbon dioxide is first removed with potassium hydroxide solution contained in the permanent pipette, then the "illuminants" are removed with bromine solution, the gas being run back into the KOH pipette to remove the bromine before the reading is made. It is then run into the phosphorus pipette to remove the oxygen. The fumes of phosphorus pentoxide thus formed are soon absorbed by the water in the phosphorus bulb. The time consumed for these three constituents is from ten to fifteen minutes. A three-minute sand glass will be found to be quite a convenience in this connection. The carbon monoxide is then removed with cuprous chloride in acid solution. This particular constituent requires that the pipette be disconnected from the burette and thoroughly shaken for from two to three minutes to produce complete absorption. The gas is then transferred to the other side of the pipette, a double pipette being used, and shaken for another three minutes. I have never found that the second treatment was necessary but always make it as a precaution. The gas is then run into the KOH bulb again to remove HCl fumes, after which it is measured again, of course. It is next passed through a palladium oxide tube contained in a beaker of water heated to about 90° C. to 100° C. It is best to pass the gas slowly at least three times, renewing the hot water or reheating it as may be necessary. It usually takes about fifteen minutes to make this absorption. The gas is then brought back to room temperature by replacing the hot water with tap water and recirculating the gas, after which it is measured. To regenerate the palladium oxide tube simply attach to the filter pump and pull air through it as long as may be necessary; I usually let it run for about thirty minutes.

The gas, having been cooled, is measured and then run into the KOH pipette. If this treatment causes loss in volume it shows that not all the CO was absorbed by the CuCl solution and the percentage of CO is accordingly corrected by the diminution in volume here shown. Before the next analysis is made the CuCl solution is renewed.

There now remains methane and nitrogen. It is customary to run a measured amount of oxygen or air with a portion of this residue and explode it in an explosion pipette. In either case an involved arithmetical calculation is necessary. One never knows how much of this residue is nitrogen and how much is methane, hence cannot tell how much air or oxygen to add. If too much is added the result may be a dilution beyond the point of a successful explosion. If not enough is added the result is equally unsatisfactory. If the correct amount is added the result may be too satisfactory. Even if the apparatus is not destroyed by a successful explosion, the analyst acquires the habit of throwing the switch with one hand and dodging behind the other.

If the methane is known to be low as it *generally* is in producer gas and *frequently* is in enriched water gas, the hydrogen must either be left in (and there is no check on the CO unabsorbed by CuCl) or a measured quantity of hydrogen has to be added. This involves further arithmetical calculation with results equally as unsatisfactory as above.

To obviate all this the idea was conceived of burning the methane to carbon dioxide and water by passing it through red-hot copper oxide. A fairly thorough search through the chemical journals failed to reveal anything published on the subject. It was then decided to try it, which was done in the following manner. The tip of a hard-glass arsenic tube was cut off, thus giving a straight tube shaped as in the following illustration:



ARRANGEMENT OF TUBE.

The first section is loosely filled to the constriction with glass wool to take up the space and so restrict the volume. The constricted portion is then filled with asbestos fiber. The central section is then filled with wire oxide of copper such as is ordinarily used in organic combustion analysis. It should be ground in a mortar to about forty mesh and the fine dust screened out with an 80-mesh or 100-mesh screen. This allows free passage of the gas but fills the tube thoroughly. The outside of the tube is then wrapped around with about two layers of copper gauze or screen. This prevents the blaze striking directly on the glass and at the same time gives a uniform heating. The gas is then passed slowly through this heated copper oxide at least twice. When it cools to room temperature it should be measured. Any diminution in volume other than that due to the oxygen of the air enclosed in the tube when the combustion was begun is due to hydrogen not removed by the palladium oxide. The gas is then run into the KOH pipette to absorb the carbon dioxide formed. The loss in volume is the methane and is read direct in percentage, since one volume of methane on burning gives the same volume of carbon dioxide. There is, of course, an error introduced by the fact that the tube contains air and the oxygen in this is consumed, thus diminishing the volume by a certain amount. This amount can be determined by filling the apparatus with water, allowing the water to drain out and measure the volume so obtained. This total volume will hardly exceed 1 c.c., and the oxygen content in this cubic centimeter is the correction to be applied if desired.

The copper can be reoxidized by passing air through the red-hot tube. This method has been found applicable to percentages of methane as high as ten. If found necessary a second tube can be used or the same one reoxidized while still hot and the process repeated.

Testing Laboratory.
Bureau of Economic Geology and Technology.
University of Texas, Austin, Tex.

The Elmore flotation process at Sulitelma Mines produced in the month of April, 1911, a total of 3924 tons of concentrate containing 6.9 per cent copper.

Sizing with or Without Screens.

By Carl F. Dietz and Dyke V. Keedy.

The greater interest taken in recent years in the possibilities of the dry concentration of ores has brought out, aside from marked improvements in magnetic and electrostatic processes, several new and ingenious forms of dry concentrators, or rather tables, which have successfully overcome the difficulties of the early attempts at dry concentration. The prejudices against dry concentration in general, which in some instances may be justified by the many failures of the past, are most generally the result of ignorance or a disregard of the fundamental principles involved.

It is not the purpose of this paper to discuss the relative merits of dry vs. wet concentration. It may, however, be mentioned that each has its own field. Only a careful study of the mixture to be separated, together with local conditions, can determine which system is the more desirable. Such decision should, of course, in every case be verified by the treatment of a representative quantity of the material. While it is evident that close and accurate sizing as a requisite to successful dry separation, especially in the case of a complex mixture showing close specific gravity differences, is gradually becoming better understood, it remained for the advent of the Keedy ore sizer to make the application of a system of accurate and close sizing of practical importance. Reference may be had to *Engineering and Mining Journal*, Feb. 5, 1910, "The Keedy Sizer for Classifying Complex Ores."

This machine is based on diametric sizing, that is, the grades are actually measured by the aperture of the screens, limiting each grade, and therefore the ratio in volumes between the largest and smallest particles in any one grade is as the cube of the apertures of the limiting screens. This law, while it is applicable to all minerals breaking into massive particles, is directly affected by the coefficient of fracture. The latter is variable, and as yet extensive investigations have not resulted in determining a suitable factor for each of the usual minerals. Hopes, however, are entertained that something of value in this connection may soon be developed and published. It has been found in practice that the law of cubes gives very satisfactory results and can be relied upon with the exception of certain minerals, such as mica and specular hematite, which break into flat scaly particles, presenting a large area as compared to their volume.

Exception was taken to the cost of sizing an ore into, say, 12 or 15 grades because of the complexity of the apparatus and flow sheet, wear and tear and cost of screen renewals. When considering the old methods of using shaking or bumping screens or reels, the objections are well founded, but are no longer tenable with the more modern form of apparatus. The system is compact, noiseless, dustless and requires but small power. Attention required is at a minimum and screen renewal cost, while varying with the class of material treated, is well within the limits of expense which any given ore can stand if it is worth treating at all.

The objections to the cost of grading in this manner, even though actual operations in a number of instances prove them to be unfounded, still continue and have caused the minds of metallurgists and inventors to seek other means.

Recently there have been given to the mining and metallurgical world some details of a new and ingenious device designed to size ore into any number of grades from 10 to 30 without the use of screens. Details of this new machine, invented by Messrs. C. L. McKesson & B. P. Rice, of Colorado Springs, are presented in *Mining Science* of Sept. 14, 1911, and in Metallurgical and Chemical Engineering of October, 1911.

This new "screenless sizer," in the operation of which the laws of gravity are reported as having but a very slight influence, is capable of some rather remarkable performances, and the published results of an official test will bear some close mathematical analysis. It is barely possible that this machine performs a function as yet apparently not recognized by the inventors or their associates, and if such is true, the apparatus should have a wider range of usefulness than would be accorded to a machine intended to be used as only a sizer.

The measurement of efficiency of any sizing operation is determined by test screening any particular grade through screens which supposedly mark the limits of that particular grade.

In preparing a complex ore for dry table separation it is necessary to make as many sizes as may be demanded by difference in specific gravity between the minerals which vary the least, so that the most perfect stratification may result and that clean zones of minerals, with a minimum of accidental middlings, may arrange themselves on the tables; these conditions can result only when the ratio of volumes between the largest and smallest particles, in any one grade, equals or is less than the ratio between the specific gravity of the two closest minerals.

As an example, in the case of iron pyrite and zinc blende, in which the respective specific gravities are 5 and 4, let Vp be the volume of the pyrite particle, while Vb is the volume of the blende particle. Then

$$\frac{Vp}{Vb} = \frac{5}{4} = 1.25$$

As pointed out, grades in which such ratios exist can be produced by considering the apertures of the screens, and if S_1 is the aperture of the coarse screen while S_2 is the aperture of the fine screen, we have

$$1.25 = \frac{S_1^3}{S_2^3}$$

Of course, a series of screens from, say, 20 mesh to 200 mesh, which throughout would have its aperture cubes bear a relation to each other as 1.25 to 1, leads too far for one sizer and necessitates two machines, as some 22 sizes would be required.

It may be mentioned that in the case of a very complex Mexican ore such a series was employed with the most gratifying results, showing sharp lines of demarcation between the fields occupied by galena, pyrite and blende, so that it was not necessary to cut a zinc-iron middlings.

This, of course, is an ideal condition, but it was found that the system could be much simplified by making only 13 sizes and collecting the accidental pyrite-zinc and zinc-gangue middlings, which, by resizing together over a machine dressed differentially, that is, making between-sizes, prepared them for successful treatment for the reason that the particles were rearranged, and therefore they could not all again report themselves as middlings.

The McKesson screenless sizer is designed to make as many as 30 grades in one operation, which, if the ratios of volumes between the largest and smallest particles in any one grade should prove to be as above shown, would be admirably suited as feed for a dry concentrator.

The aperture dimensions of the screens used to test the various grades must be known, but for illustration we may arbitrarily use the following in discussing the results of the official test on the McKesson sizer.

Mesh.	Aperture inches.
24	.0342
28	.0282
30	.0268
34	.0229
40	.0185
44	.0172
50	.0145
66	.0102
82	.0079
97	.0058
116	.0047
139	.0033
172	.0028

The results on p. 587 show that, except in the two coarse grades, efficiency is based on the material reporting in the two heaviest screen products, which, when taken together, show a large volume-ratio between the largest and smallest particles lying between the limiting screens used in determining measure of efficiency.

The results of a test on the McKesson machine making 15 products are reported to be as follows:

Product No.	Screen.	Per Cent.	Efficiency.

	Average		81.32

The efficiency, determined even in this most favorable manner, cannot be said to be high, and when considering the vitiating effect of the relatively large amount of "through" product recorded, and its detrimental effect on table work, the results cannot even remotely be compared to those obtainable by diametric sizing, when making even a lesser number of products and covering a wider range.

To quote from Metallurgical and Chemical Engineering, page 554: "It will be noticed that the grading efficiency in some of the products is lower than in others, but it is claimed that this can be remedied by adjusting the cutters to throw the oversize and undersize into the preceding and succeeding grades respectively, and thereby increase the efficiency of the sizing in *all* grades."

In the above statement the absence of such positive action as exists when sizing diametrically is clearly admitted.

That the efficiency shown in one grade may be improved by throwing the over and undersizes into the preceding and succeeding grades respectively is obvious, but on the basis of the published screen analyses of the products, instead of thus increasing the efficiency of all the grades, those into which the oversize and undersize are cut would be more likely to suffer, with the result that, while one grade would be improved at the expense of its tonnage, the two grades affected by the improvement of the one would probably show not only a lower efficiency, but would represent a correspondingly larger proportion of the whole. If the action of the machine were positive the explanation of the possibility of improving the grades would have some force which, in view of the results, is lacking.

Taking the basis of the efficiency calculation as given, and applying the law of cubes, we can calculate the ratios existing between the largest and smallest particle in any one product, giving the machine the advantage of using the screens specified, which limit the efficiency calculation. We have then:

Product No.	Limiting Screens.	Per Cent. Efficiency.	Vol. Ratio of Largest to Smallest Particle.
1	— 30 + 40	81.20	3.04:1
2	— 28 + 40	93.75	3.50:1
3	— 34 + 44	82.83	2.30:1
4	— 40 + 50	62.50	2.70:1
5	— 44 + 66	89.06	4.80:1
6	— 50 + 82	90.52	6.20:1
7	— 50 + 82	90.63	6.20:1
8	— 66 + 97	87.50	5.40:1
9	— 66 + 97	87.50	5.40:1
10	— 66 + 97	84.37	5.40:1
11	— 66 + 97	75.00	5.40:1
12	— 82 +116	78.12	4.70:1
13	— 82 +116	81.25	4.70:1
14	— 97 +139	71.87	5.40:1
15	—116 +172	68.75	4.80:1
	Average ratio		4.66:1

In the practical application of close and accurate screening we have adopted, as a standard, a series of 13 screens between 20 and 200 mesh conforming to a harmonic series, thus producing 14 products, including oversize and fines. The average volumetric ratio is 2 to 1, while the efficiency, when measured by the screen aperture actually limiting the grade, averages better than 90 per cent, the only drop under 90 per cent being in the — 150 + 200 grade, which, with the screen area usually exposed, varies between 80 and 85 per cent.

The percentage of oversize is practically nil and the particles passing through the fine limiting screen, in testing the grade, are usually of such a size as to just pass through the aperture, but much too coarse to go through the next screen of the series. If the efficiencies in testing the products from the Keedy sizer were figured in the same manner as those for the McKesson sizer products the former would show an average efficiency of from 95 to 98 per cent, as against 81 per cent for the latter.

The series as developed and used by us as a standard is the following, in which screen cloths have been selected of apertures conforming with the law of cubes:

Mesh.	Apertures, Inches.	Ratio of Volumes of Largest to Smallest Particle.
20	.0410	1.722 to 1
24	.0342	1.722 to 1
28	.0282	1.783 to 1
34	.0229	1.867 to 1
42	.0183	1.959 to 1
50	.0145	2.012 to 1
62	.0116	1.953 to 1
74	.0089	2.214 to 1
86	.0068	2.242 to 1
109	.0054	1.996 to 1
125	.0041	2.284 to 1
150	.0032	2.103 to 1
200	.0026	1.865 to 1
Average		2.000 to 1

A comparison between these ratios and those of the screenless sizer work, entirely aside from the considerably better efficiency of diametric sizing, clearly indicates which products may be expected to yield the better table results.

The results of the McKesson test show that in a general way the efficiency varies inversely as the ratio of maximum to minimum particles in the grades, excepting in the extreme coarse and fines, but the most important characteristic revealed is the gradual gradation by size almost identical in its character with, but somewhat more emphasized than, that resulting from feed-

ing an unsized pulp over a dry table of the Sutton, Steele & Steele type.

It may be especially pointed out that in every instance in the screen analyses the coarse *limiting* screen used is of larger aperture dimension than the fine limiting screen of the preceding grade. The efficiency of products 8, 9, 10 and 11 is measured by exactly the same screens, the only difference in the grades being that they grow finer by reason of the fact that the oversize is gradually reduced while the undersize increases. The latter is also true of products 12 and 13.

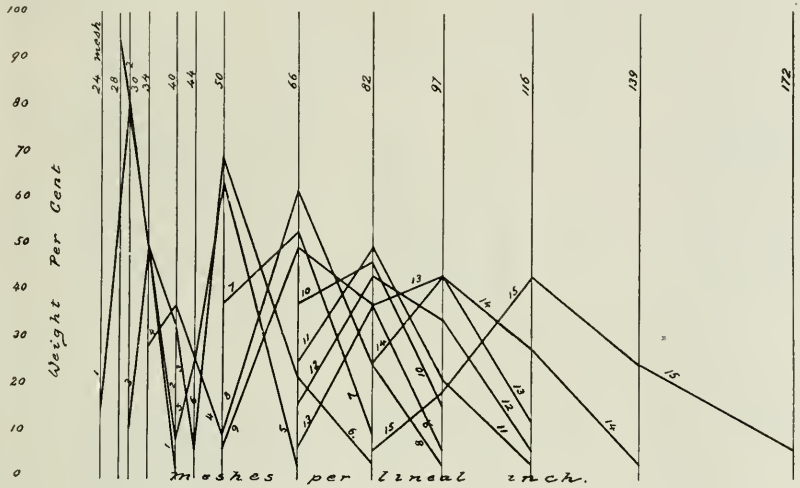

FIG. 1.—GRAPHICAL REPRESENTATION OF SCREEN ANALYSES OF PRODUCTS FROM A MC KESSON SCREENLESS SIZER.

This fact proves that the products very considerably overlap, and thus the sharp line of demarcation existing between diametrically sized grades is wholly lacking in the new method of sizing. The overlap of the products is graphically shown on Plate I, and it is to be clearly noted that no sharp line exists between any two or even three of the grades, while the overlap, in specific cases, is sufficiently great to completely destroy the effect of sizing. For example, products No. 7 and No. 15 are so poorly sized that $-82+97$ mesh material is contained in each.

With an average recorded efficiency of but 81 per cent, and that, too, on an average particle ratio of 4.66 to 1, the actual average particle ratio on the whole product exceeds 6 to 1, which is far too much to permit of anything like desirable table work.

The above discussion is, of course, all predicated on the statement that specific gravity plays an unimportant part in the operation of the McKesson apparatus.

That a machine of this general type will operate as a sizer has been pointed out, but the sizing is of an extremely indifferent quality, and specific gravity actually does play a part well worthy of notice. In one instance, an unclassified ore was treated on a Sutton, Steele & Steele table, primarily for the purpose of noting the sizing effect. The tendency was marked but the gradations along the periphery of the table were so gradual as to be characterized as only an abortive attempt at sizing. The feed to the table and the four products caught at the periphery gave the screen analyses on top of next column which are graphically represented in Plate II.

These results were obtained on a magnetic iron ore, and the products "b," "c," "d" and "e" clearly showed that the finer heavy magnetite particles had a distinct tendency to associate themselves with coarser gangue particles—the result of the ever-operating law of gravity. If 15 products had been cut, the result would have been quite as perfect as that of the McKesson machine.

Mesh.	Feed.	Products B	C	D	E
— 50					
+ 58	1.50	4.1	.10	.25	0
+ 68	.50	2.3	.45	.25	0
+ 90	9.50	16.0	10.00	7.25	2.50
+100	12.00	28.7	13.00	13.75	3.50
+140	14.25	18.0	19.25	14.75	5.00
+163	21.50	10.1	16.25	11.25	6.00
+200	18.00	14.1	24.00	26.75	32.25
—200	20.50	6.5	16.00	24.00	49.00

Another notable instance—in the treatment of a mixture of galena, pyrite, zinc and fluorspar, it was invariably found that the finer galena traveled under the pyrite, the finer pyrite under the zinc, and the finer zinc under the fluorspar. In air, a particle of zinc need be only 25 per cent greater in volume than a particle of pyrite to weigh the same, while a particle of fluorite need be only 30 per cent greater in volume than a zinc particle to weigh the same.

Now these particles of equal weight are acted upon equally, and necessarily produce a middlings which when screened over a cloth of proper aperture results in a concentrated product either on or through, or both, the heavier mineral reporting in the finer product.

The published screen analyses of the products from the McKesson sizer do not indicate that specific gravity plays no part in the operation, and the question obviously arises whether this machine does not perform a function of greater importance than the one which its inventors desire it to perform. Certain it is, on the basis of the recorded efficiencies and the evident gradual classification of the products, that the name screenless sizer is a misnomer. As far as the usual understanding of sizing is concerned, this machine is not a sizer, as its products overlap far too much. It would be more appropriate to call the apparatus a dry classifier, which in effect it is.

Mr. Charles J. Downey, in *Mining Science*, Sept. 14, 1911, page 247, states: "Concerning the theory of the McKesson method, I have no disposition to enter into a discussion of it, beyond what has already been said. An outline of the laws governing the selective action, in which differences of specific gravity play but a very small part (and then only in the case of widely different minerals, according to the engineers) will be the result of systematic and prolonged experiment. That the sizing is effected to a high degree of efficiency is apparent to an observer, while the operation of the machine has all the aspects of simplicity."

Now going back to the thought expressed above that this machine is essentially a dry classifier, all speculations vanish as to a new principle having been stumbled upon, and viewing the action as one of classification is the more tenable, when considering the analogy between the operation of the McKesson machine and the Sutton, Steele & Steele dry table.

It is difficult to conceive of one making separations between minerals of equal size, on the basis of their specific gravity differences, while the other collects together the various minerals according to their size, regardless of their relative specific gravities. These two thoughts are distinctly contradictory.

If the McKesson sizer acts in the nature of a classifier, which is exactly what a table does (only the new machine by means of the deflectors and discharge arrangement takes advantage of and emphasizes the action), it must be shown by the character of the screen products of each grade.

A hydraulic classifier when making 15 products appears to deliver a fine string of perfect sizes, however a screen analysis and assays of the screen products reveal the true action, which is classification both by size and specific gravity.

In each grade it will be found that the lightest mineral reports, to the greatest extent, in the coarsest grade; while the heaviest mineral will be found, to the greatest extent, among the finer particles of the particular product under consideration.

This same action is to be expected in a machine of the McKesson type.

It can readily be verified by testing a mixed sulphide ore and screen—analyzing the products, just as was done in the reported official efficiency test.

The investigations should, however, be carried further, and each of the screen products should be assayed for the principal metals contained in the mixture, thus readily establishing the actual facts of the operation.

We anticipate that results of such an investigation will show each product to be made up of coarse gangue, finer zinc, somewhat finer pyrite, and still finer galena. If this explanation of the operation of the new machine is found to be true, we will no longer be confronted with a new and paradoxical theory to worry the research metallurgist, but will realize the ease with which appearances may deceive and the danger of a too ready acceptance of an apparent overthrow of fundamental principles that have served us long and satisfactorily.

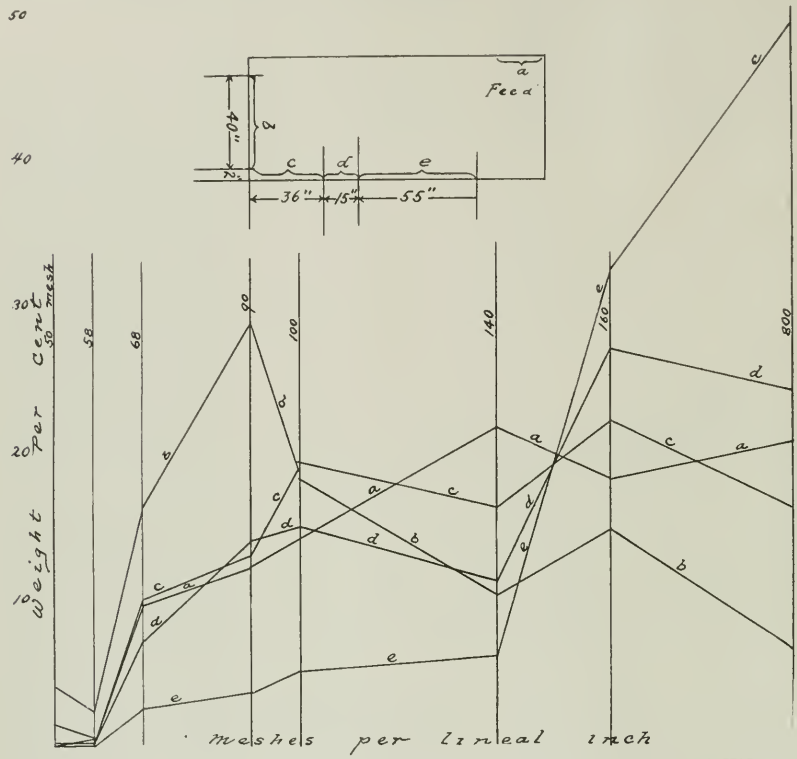

FIG. 2.—GRAPHIC REPRESENTATION OF SCREENLESS ANALYSES OF PRODUCTS FROM A SUTTON, STEELE & STEELE TABLE, WHEN FED WITH UNSIZED ORE.

The diagram on the top represents the Deck of Sutton, Steele & Steele Table, showing Peripheral Discharge of Products b, c, d, e.

The development of a dry classifier should have a wider field of application than a sizer, if its capacity is sufficiently high, since, if the machine acts as herein discussed, its products should make an admirable feed for a wet table.

That the new machine is not in any sense a sizer of mixed minerals seems well established, and that it follows the laws of classification in which specific gravity plays an important part is strongly indicated by an analysis of the published results.

We may express a hope that the inventors will shortly supply the metallurgical world with further, more complete data, preferably along the lines suggested, including a screen analysis of the feed to the machine for purposes of comparison, so that speedily a more definite understanding of the principle involved in the performance of this ingenious new contrivance may be had.

Boston, Mass.

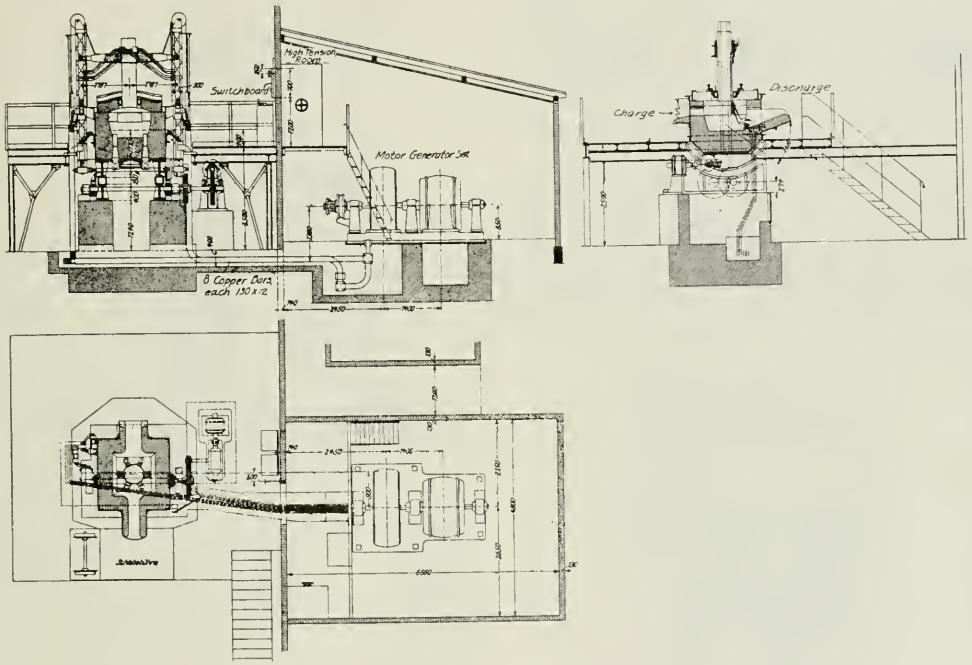
Producer gas is the source of power for seven mines in one of the oldest mining districts in Mexico, viz., in the district of Sultepec in the State of Mexico. Electric power has recently been brought into the district and is furnished at a cost of $170 per hp-year (presumably Mexican currency.) The mine pays for the construction of the substation, and the power discounts 25 per cent of the cost from the power account until the line is paid for.

The Eclipse filter is an Australian device for filtering cyanide or other valuable solution from ore pulp. It consists of a wooden frame 28 ft. long, 4 ft. wide, and having a fall of 3 ft. in its length. The filtering medium is an endless three-ply rubber belt, 3½ ft. wide, with numerous holes punched through it. Over the belt, and attached to it at the sides only, is a strip of filter cloth. In the middle of the machine is the filtering or squeezing gear, which consists of a series of cast iron rollers. The belt travels in a horizontal position except as it passes between the squeezing rollers, when it assumes a vertical position, being folded along its median line. The pulp is fed onto the belt at the upper end of the machine and as the belt passes between the rollers the solution is squeezed out of the pulp, the latter forming a cake which is discharged at the lower end of the machine. If the cake has to be washed it must be passed through a second machine. The capacity is about 900 lb. per revolution, or 650 tons daily. It requires about 3 hp. One is installed and working in the Associated mill, Kalgoorlie, and is more fully described in the August issue of the *Mining & Engineering Review* (Melbourne).

Manufacture of Steel in the Girod Electric Furnace.*

BY DR. A. MUELLER.

The Gutehoffnungshütte has installed a three-ton experimental Girod furnace in their Martin Works No. 1 for the purpose of electrically refining molten steel from their 25-ton open-hearth furnaces.



FIGS. 1, 2, 3.—ARRANGEMENT OF ELECTRIC FURNACE PLANT.

Figs. 1 to 3 show the equipment of the entire electric furnace plant, and the various details of the furnace and the electrical equipment. Fig. 4 is an outside view of the furnace. Only small details have been changed in the original design of Girod. The single-phase current for the furnace is furnished by a motor-generator consisting of a 3000-volt 95-amp. 575-hp three-phase induction motor (with a power factor of 0.92) and a single-phase 75-volt, 6700-ampere, 25-period, 500-kw generator (with a power factor of 0.8) with exciter unit.

These machines, as well as all conductors carrying high-tension currents are placed in a separate room adjoining the furnace room. The electrical conditions can be watched from the furnace by means of ammeters and voltmeters in the low-tension circuit and a kilowatthour meter in the high-tension circuit. The switchboard at the furnace contains the excitation-current regulator for the furnace voltage, the manual and automatic regulator for the electrodes, and the device for tilting the furnace.

The arrangement of the electrical-conductors is of great importance. There are three methods in use for conducting the current to the carbon electrode at the top and the steel electrode in the bottom, employed in the Girod furnace.

In method I (Fig. 5) the shortest path from the motor-generator set to the carbon and steel electrodes has been chosen; all of the cables are on the side of the furnace which faces the motor-generator.

In method II (Fig. 6) the cable to the carbon electrode is divided into two sections which run parallel to each other. The steel electrode is connected by the shortest path with the motor-generator set.

Method III (Fig. 7) is the one used since August, 1910, at the Gutehoffnungshütte. The current is conducted to the carbon electrode in a manner similar to method II. But while in methods I and II the bottom steel electrode is insulated from the furnace body itself (only the metal bath being in the

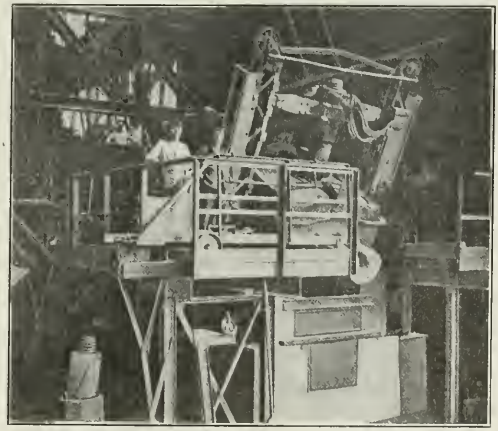


FIG. 4.—OUTSIDE VIEW OF GIROD FURNACE.

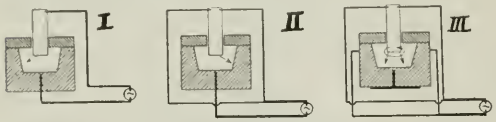
*Translated from *Stahl und Eisen*, July 20 and Aug. 3. Slightly abstracted.

electric circuit), the steel electrodes are here electrically connected with the furnace body. The arrangement of the conductors is symmetrical around the furnace.

With the first two methods the electric arc is deflected towards the side marked with the arrow, which results in a non-uniform heating of the steel bath and a rapid destruction of that side of the furnace which is exposed to the excessive direct heat of the arc. Method III avoids all this.



FIGS. 5, 6, 7.—ARRANGEMENTS OF ELECTRICAL CONNECTIONS TO THE FURNACE.

In view of the currents of high amperage and low voltage which with the Girod furnace is operated, there are considerable energy losses in the low-voltage electric conductors depending both on the resistance and the reactance. Method I, with its short conductors, was originally adopted to make these losses small. But the destruction of the furnace walls and roof on the side to which the arc was blown as indicated by the arrow was so excessive that it was cheaper to incur the

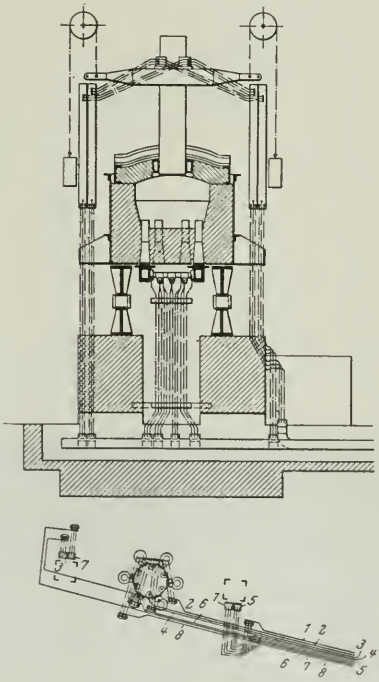


FIG. 8.—OLD ARRANGEMENT.

expense for greater lengths of cables and the losses in the same than the expense for the furnace repair.

It is good practice, therefore, to use as low a frequency of the alternating current as possible, to avoid a material of high permeability for the furnace construction and to try to keep the iron masses as far as possible out of the electric circuit.

The electric arc is forced to distribute its heat uniformly over the bath by arranging the cables symmetrically around the furnace as in Fig. 7, method III. In this way the magnetic fluxes, formed by the iron shell, are reduced to a minimum. The magnetic field around the carbon electrode becomes uniform, the heating effect of the arc becomes uniform, and the current passes through the charge in a more regular order.

The advantages of this arrangement of the cables, from an electrical and metallurgical standpoint, are the following:

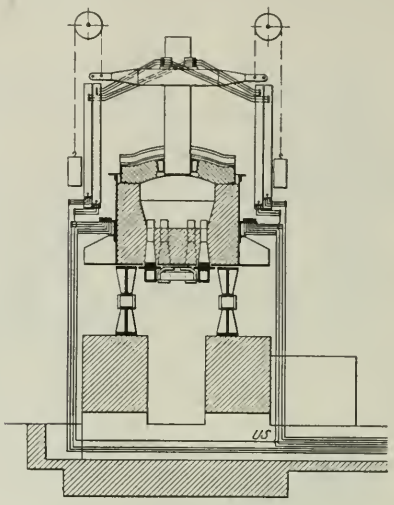

FIG. 9.—NEW ARRANGEMENT.

1. The electric arc circling about the periphery of the carbon electrode causes a strong agitation of slag and metal. This accelerates the speed of reaction between the slag and the iron bath and therefore reduces greatly the time of refining.

2. The arches of the roof as well as the furnace walls receive a more uniform radiation from the electric arc and last longer.

3. The saving in energy consumption is 10 per cent compared with the former arrangement.

4. Copper bus bars can be used instead of cables.

5. The metal bath is heated more uniformly throughout and the resulting product is more uniform.

6. Current interruptions due to the rupture of the arc are avoided, eliminating the resulting rushes of current on the motor-generator set and allowing an easier melting of cold charge than with method II.

7. The consumption of the carbon electrode is more uniform, while with the former arrangement one side of the electrode was consumed more quickly than the other, resulting in greater expense for electrodes.

Fig. 8 shows the older arrangement corresponding to Fig. 6, method II. The current passed in a 23-ft. long circuit through the copper bus bars, marked 8, to the furnace. One half of these bus bars was connected with the bottom electrodes by means of twelve cables, the other half was distributed on both sides of the furnace. With the other electrode connection was made from the conduit both by means of cables and by bus bars. Three cables led on the right side from bus bars 1 and 5, three on the left side of the furnace from bus bars 3 and 7 up to the carbon electrode, while from bus bars 2, 4, 6, 8, three cables each led to the steel electrodes which were electrically connected with each other but insulated from the furnace body.

In the new arrangement (Fig. 9) the six steel electrodes are electrically connected by means of a copper ring and plate with each other and with the furnace body. The entire current is

conducted close to the furnace by eight parallel copper bus bars, and divides at the current distribution point U S in such a way, that opposite currents pass alternately along both sides of the furnace to the pivoting point, where each bus bar is connected by three cables (more recently, by flexible copper bars) either with the furnace body or with the carbon electrode, as clearly shown in Fig. 9. This arrangement with the low voltage of operation overcomes all insulation difficulties and has reduced induction currents considerably. The rotating magnetic fields around the electrode are uniform and very small. This arrangement also permits an easy construction and a saving of cables.

For the first 225 heats the furnace was operated only during the day and in many cases it was possible to tap the furnace five times in 12 hours under favorable conditions (See Fig. 13). In continuous operation it is possible, working day and night, to obtain 25 tons of steel from 8 tappings.

Since the open-hearth furnaces were only tapped every four hours, the electric furnace could not be operated continually. About 3 tons of the metal tapped from the open-hearth was poured into a heated ladle on a weighing scale, and then charged into the electric furnace.

But this method was found to be too expensive, since the temperature drop of the charge from the open-hearth to the electric furnace resulted in a rather high fuel and energy consumption. It was, therefore, finally decided to use a 23-ft. long launder which allows direct charging without any trouble. The weight of a charge can be adjusted with an accuracy of 200 kg. (400 lbs.) by the eye or by a watch.

The operation of the electric furnace is in the main like that of the basic open-hearth furnace, the metallurgical reactions being essentially the same, except the deoxidation. During the charging process, the current is 4000 to 6000 amperes; after the charging launder has been removed from the furnace by a crane, the amount of ore and lime required for the metallurgical reactions is shovelled into the furnace.

The combustion of the phosphorus is now started by a gradual increase in the temperature, while simultaneously the amount of carbon still present is reduced down to a minimum by oxidation. A portion of the sulphur is also removed during this period. This period of refining by oxidation is, of course, the longer the higher the carbon and phosphorus content of the charge.

When this period is over, the oxidation slag is removed by tilting the furnace and the last traces of the slag are carefully scraped off. Then petroleum coke or carbon electrode remnants are added for recarburising and a deoxidation slag is formed by adding lime, fluor-spar, and ferro-silicon. The deoxidation and desulphurisation of the bath now proceed and with proper operation a sulphur-content of 0.01 per cent can be guaranteed. After complete refining, the tap hole is opened, the current cut off, the entire furnace with the carbon electrodes tilted 40° from the horizontal, and the contents poured into a 4-ton ladle.

Lining.

The lining of the furnace must be constructed and maintained with great care. The arches are chiefly subjected to destruction. With the new arrangement of the conductors, which has resulted in greater uniformity of heat radiation from the arc and therefore greater uniformity of the wear and tear of the lining, the silica roof with attached cooling ring will stand 60 or 70 heats. The slightly curved furnace roof of silica brick reinforced by iron bands is insulated from the side walls of the furnace by a thin layer of asbestos and a new roof can be substituted within 20 minutes.

It should be mentioned that the contact areas of the silica roof with its magnesite brick edge resting on the basic walls of the furnace do not reach such a high temperature as to make these materials so-called electrical conductors of the second class, which would result in leakage of the current. Moreover, the carbon electrode usually does not come in contact with the roof-cooling ring so that the insulation is only used as an additional safeguard.

The hearth and walls were at first lined with magnesite, but dolomite is now used.

The ratio of the cross-section of the steel electrodes (Fig. 10) which are embedded in the bottom of the furnace chamber, to the rest of the bottom area is 1 to 16.

A repair of the bottom does not become necessary until it is required to repair the walls. The walls are attacked strongest at the slag line, but the damage can be repaired between charges. After 120 heats the walls must be re-lined. The hearth bottom must also be repaired then and filled up again to the original level, since it has meantime become about 2 in. deeper at the center (where the temperature is highest) than at the periphery.

The cost of an entire dolomite lining is about marks 350 ($87.50), that of an entire magnesite lining marks 700 ($175). Dolomite has proved so efficient that it is now used exclusively. The total maintenance cost for the lining per ton of steel is about marks 1.20 (30 cents.)

Heat Losses Due to Cooling.

Hearth-electrode cooling is still little understood and has even been called a great drawback to the efficient operation of

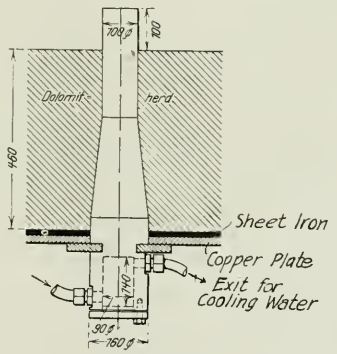

FIG. 10.—WATER-COOLED STEEL ELECTRODE.

the Girod furnace. Fig. 10 shows that only that portion of the soft steel bars which projects below the furnace body, is cooled by water, the bars being connected by a common pipe line.

The difficulties of maintenance of the lining of the Girod hearth are also often exaggerated. The dolomite hearth rammed by compressed-air rammers has lasted through more than 1000 charges and has never given any trouble in spite of different lengths of heats and very different compositions of the charges.

The estimate of the heat losses in the cooling water is often too high, so that the following calorimetric figures should be of interest. The hearth poles were cooled by water running at the rate of 4.9 liters per minute (1.2 gallons per minute), using 637 liters (168 gallons) for a heat of 130 minutes.

The temperature of the water flowing to the bottom electrode was 8° C, that of the water leaving the electrode was 21° C in the first 85 minutes and 23° C in the following 45 minutes.

The heat consumption, due to the cooling of the bottom electrodes was, therefore, $4.9 \times 85 \times (21 - 8) = 5414$ calories (kg), plus $4.9 \times 45 \times (23 - 8) = 3307$ calories (kg), hence the total loss of heat 8721 calories (kg), equivalent to an energy consumption of 10.1 kw hours or 13.7 horse-power hours.

Since according to Joule's law the total energy consumption is equal to $C = 0.2386\ E\ J\ t$ calories, we have in this case with a tension of $E = 55$ volts and a current $J = 4800$ amperes during the total time $t = 7800$ seconds an energy consumption $C =$

$0.2386 \times 55 \times 8400 \times 7800 = 859{,}819$ calories $= 1004$ kw hours (measured by the meter) $= 1364$ hp hours. Hence the loss of heat due to cooling the bottom electrodes is 1.01 per cent of the total energy consumption and when producing 3500 kg (7700 lb) of steel, about 2.9 kw hours or 4 hp hours are consumed per ton of steel for cooling the bottom electrodes.

Let us now calculate the heat loss due to cooling the carbon electrode and the arched roof. 0.2866 liter per second (or 4.5

FIG. 11.—POWER FLUCTUATIONS DURING A HEAT.

(A tapping, B, C, D additions, E carburization, F slagging, G slag readily fluid, H bath boiling, I addition of ore, J slag not fluid, K charging.)

gallons per minute) pass through the cooling ring for the roof, or 2236 liters (590 gallons) for a heat of 130 minutes.

The temperature of the water entering the cooling ring was 9° C, that leaving it was in the first 70 minutes 21° C, and in the following 60 minutes 25.5° C.

This gives a total loss of heat of

$$\frac{2236 \times 70 \times 12}{130} + \frac{2236 \times 60 \times 16.5}{130} = 31.47 \text{ calories, equal to } 36.7$$

kw hours or 49.1 hp hours, so that the loss of heat due to the cooling of the carbon electrode is 3.65 per cent of the total

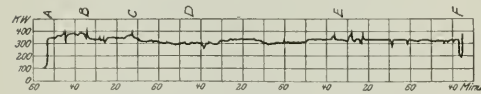

FIG. 12.—FLUCTUATIONS OF CURRENT WITH A HEAT IN THE FURNACE AFTER HAVING BEEN COOLED FOR 12 HOURS.

(F charging, E decarburization, D slagging, A, B, C additions.)

energy supply, 3500 kg. (7700 lbs.) of steel were produced so that 10.5 kw hours or 14.2 hp hours were lost per ton of steel for cooling the carbon electrode.

The Girod furnace with one carbon electrode requires about 0.65 cubic meters of water per ton of steel for cooling the carbon electrode, which is equivalent to 9000 calories. To cool the steel electrodes in the bottom the furnace needs 0.20 cubic meters of water per ton of steel, which is equivalent to 2500 calories. This heat loss is insignificant when compared

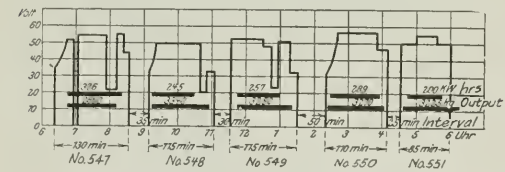

FIG. 13.—FURNACE OPERATION IN 12 HOURS.

(Desulphurization from 0.040 to 0.012%.)

with the radiation losses attendant upon charging, slagging and tapping.

Further, the above figures show that the cooling of the steel electrode requires only one-fourth of the amount of water needed for the cooling of the carbon electrode.

If the water flows at the rate of 5 liters per minute (1.3 gallons per minute), an equilibrium condition is established in the heat exchange as soon as the bottom steel electrodes have melted down to a point which is 20 mm (0.8 in.) below the level of the hearth. These liquid pole points which are gradually solidifying towards the lower end have the composition of the steel bath to be refined. No chemical change is thereby caused in newly charged metal, as they are emptied when the bath is tapped. The pits in the poles are then again filled with newly charged metal. The effect of cooling is a uniform fusing of the pole points, and a homogeneous current density through the same.

On account of the uniform current density and the uniform heating effect of the electric arc, the bath is heated on the hearth surface and the upper layers in such a way that a sticking of steel in the originally cold corners of the hearth is soon eliminated.

Electrical Conditions.

The quiet melting of a cold scrap steel charge has been recognized as a great advantage of the Girod furnace. Figs. 11 and 12 give the fluctuations of the kw consumption as plotted by a recording wattmeter, starting with a liquid charge. The regulation of voltage and current is almost always automatic; hand regulation (with the automatic regulator disconnected) is used only during slagging.

Influence of Temperature and Size of Furnace on Energy Consumption.

The furnace size, the length of intervals between successive heats, the cooling of the furnace during these intervals, the condition of the charge, the desired quality of the end products and other matters can change the energy consumption very considerably.

Fig. 14 shows the influence of the weight of charge in kilograms upon the specific energy consumption in kilowatthours per ton. The results are averages taken from 500 successive

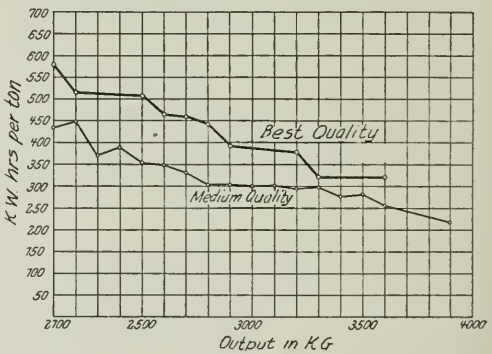

FIG. 14.—SPECIFIC ENERGY CONSUMPTION AS FUNCTION OF WEIGHT OF CHARGE.

heats, including alloy steels. The energy consumption depends a great deal on the weight of the charge and decreases in large furnaces.

The loss of heat through radiation and conduction as also the fluctuations of temperature decrease with increasing size of furnaces. The temperature is much more easily regulated in larger furnaces than in smaller ones.

The minimum economical weight of charge is about 2800 kilograms in Fig. 14, the specific energy consumption not changing materially with increasing weight up to 3300 kilograms.

The specific energy consumption depends still more on the temperature of the furnace and this depends greatly on the length of the intervals between charges. Fig. 15 shows the decrease of the temperature after tapping; this decrease is very rapid compared with that of an open-hearth furnace, the temperature of which sinks down to 1000° C after a 25-hours pause and which cools afterwards at the rate of 20° C per hour. Under such conditions it is possible to get a high thermal effi-

ciency with the Girod furnace only, if it is charged, at the latest, 20 minutes after the last tapping. The interior of the furnace is then still at about 1300° C. The energy consumption per ton is then 188 kw hours for medium-quality steels and 270 for high-quality steels.

Under very favorable conditions it was possible to refine 3654 kg (8039 lbs.) of steel with an energy consumption of 158 kw hours per ton, including refining by oxidation, deoxidation, and desulphurization. Large Girod furnaces are more favorable in this respect, as they can be charged immediately after tapping, i. e. while they are at a temperature 200 degrees higher.

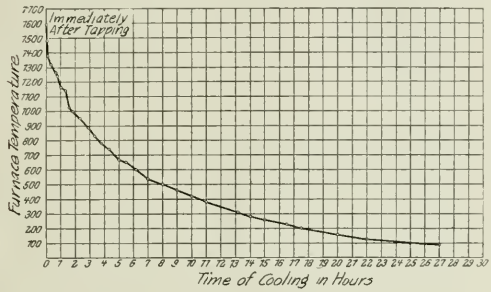

FIG. 15.—COOLING OF GIROD FURNACE.

Metallurgical Reactions.

Fig. 16 is a diagram of the chemical reactions during a heat in the Girod furnace and illustrates the changes of the carbon, manganese, phosphorus, sulphur, and silicon contents.

The results of the analyses of 19 samples are here plotted. Sample 1 is that of the charge, sample 2 was taken after addition of 15 kilograms of ore, sample 3 after addition of 50 kilograms of ore. Sample 4 and 5 were still taken during the period of refining by oxidation, sample 5 just before removing the oxidation slag.

Samples 6 to 19 were taken during the deoxidation period. After addition of 16 kilograms of Girod carbons and 5 kilograms of ferromanganese sample 6 was taken. After addition of 12 kg ferrosilicon (50 per cent Si) and 40 kg refining slag

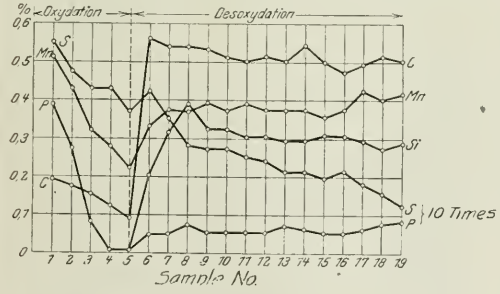

FIG. 16.—ANALYSIS OF C, MN, P, S IN 19 SAMPLES OF METAL DURING ONE HEAT.

sample 7 was taken. After addition of 4 kg ferrosilicon sample 8 was taken; after addition of 20 kg refining slag sample 9; after addition of 3 kg. ferrosilicon sample 10; after addition of 2 kg. powdered petroleum coke sample 11; after addition of 1 kg ferromanganese (80 per cent Mn) sample 12; after addition of 8 kg lime sample 13; nothing was added when sample 14 and 15 were taken; after addition of 10 kg lime and fluorspar and 2 kg powder petroleum coke sample 16 was taken; after addition of 2 kg. ferromanganese sample 17; nothing was added after that, sample 19 being the final sample.

Oxidation Period.

The oxidation period must be preceded in many cases by a melting period of a length corresponding to the interval between charges, as a longer interval will make the steel solidify in parts. During this time ore is gradually added to the bath in the furnace, and carbon, manganese, phosphorus, and sulphur are oxidized.

The carbon oxidizes only slowly, in spite of the high temperature in the furnace. In the heat illustrated in Fig. 16, 0.10 per cent carbon is oxidized in 55 minutes, which is equivalent to 53 per cent of the original carbon content. Although the manganese is present in a more concentrated state than the carbon, only 58 per cent of the original manganese content is oxidized in the same time, which is equal to a decrease in manganese from 0.52 to 0.22 per cent.

Dephosphorization can be carried out to the furthest extent since the concentration of the oxidizing agent can be governed at will and the slag can be maintained very basic. Phosphorus is the easiest to remove of all the impurities in the charge. With progressing decarburization the phosphorus decreases steadily and the original low temperature of the bath favors the oxidation of the phosphorus. Already the third sample taken from the heat in Fig. 16 after a charge of 50 kg. ore, showed only 0.008 per cent phosphorus, against 0.039 at the start, which is a reduction by 80 per cent. Practically all phosphorus is removed before the slagging proceeds.

Sulphur decreases during this period of refining by oxidation, in Fig. 16 from 0.055 per cent to 0.037 per cent, which is a reduction by 33 per cent. Wüst claims that slag containing ferrous oxide dissolves iron sulphide to a certain extent. In stronger concentration it reacts with the ferrous oxide according to the equation:

$$FeS + 2\ FeO = 3\ Fe + SO_2.$$

The sulphur dioxide escapes and can be clearly recognized. But a part of the sulphur may still remain dissolved in the slag together with free ferrous oxide, as is shown by the sulphur of the oxidation slags of table III (p. 587). The figures in table IV (p. 587) show that the average decrease in sulphur during the oxidation period amounts to 26 per cent.

The oxidation slag with its phosphorus is drawn off and the last traces removed by mixing lime with it. This avoids rephosphorization of the bath by the carbon and silicon additions in the following period. One slag is sufficient to remove all phosphorus down to traces.

Deoxidation Period.

Now the deoxidizing slag is produced by adding to the bath about 20 kg. (44 lb.) lime, 3 kg. (6.6 lb.) sand and a like quantity of fluorspar, and also 1 kg. (2.2 lb.) ferrosilicon (50 per cent silicon) per ton of steel. This slag dissolves the ferrous oxide which has meanwhile been formed on the unprotected surface of the metal, and thereby becomes black.

The destruction of the ferrous oxide in the slag is indispensable for the deoxidation and desulphurization of the bath. For the deoxidation the silicon (from the added ferrosilicon) is not sufficient and 1 to 2 kg (2-4 lb) powdered petroleum coke are added to assure complete deoxidation. In this way a slag is obtained which in the air quickly disintegrates into a white powder; this indicates that the ferrous oxide has been reduced down to traces.

With hard charges an amount of petroleum-coke or waste carbon electrode pieces, in a quantity as required for the desired carbon content, are added to the bath for purposes of carburization, prior to the formation of the deoxidation slag. As soon as the slag is readily fluid and free from oxide, the additions are made of ferromanganese, ferrosilicon, etc.

The addition of these alloys which are often impure may increase the phosphorus and sulphur content considerably. Thus in Fig. 16 sample 6 shows that the phophorus has increased from traces to 0.08 per cent, due to the addition of ferromanganese with 0.4 per cent phosphorus.

In following the curve for sulphur in Fig. 16 it will be seen that the amount increases during the carburizing process, showing that the bath has absorbed sulphur from the carburizing agent; this sulphur is then gradually removed from the bath by

Final product, 2985 kg electric steel.
Charge, 3030 kg soft steel.
During the refining period by oxidation sulphur was removed as follows:

3030 kg charge (0.042% S) contain	1273 grams S	
3030 kg (0.033% S) just before slagging contain	1000 "	
Sulphur removed	273 grams S	or 21.4%
After slagging 3000 kg steel (0.033% S) contain	990 grams S	
Absorption of sulphur from 22 kg petroleum coke with 0.60% S	132 "	
Sulphur in metal bath	1122 grams S	
At the end of the desulphurization period (0.014% S)	420 "	
Removed from metal bath	702 grams S	

For the production of a deoxidation slag there were added:

80 kg lime with 0.08% sulphur	64 grams S	
30 kg fluorspar with 0.07% sulphur	21 "	
10 kg sand with traces of sulphur	traces "	
3 kg ferrosilicon with traces of sulphur	traces "	
The deoxidation slag contains	85 grams S	
135 kg final slag with 0.5% S	675 "	
The slag has therefore absorbed from the bath	590 grams S	
There were removed from the bath	702 "	
Missing	112 grams S	or 16%

the refining slag. There is a gradual decrease in the sulphur percentage up to sample 13, but no further decrease from sample 13 to 16. Desulphurization only starts again, after the thick highly basic lime slag has been rendered again effective by the addition of fluorspar (before sample 16).

The chemical reactions between the metal and slag occur only under certain conditions. For example, the reaction:

$$\text{Metallic sulphide} + C + CaO = CaS + \text{Metal} + CO$$

occurs only when the slag becomes white and readily fluid, i. e. after the removal of the metallic oxides down to traces. This is evident from table III (p. 587), which shows that in the slag the increase of sulphur runs parallel to the decrease of ferrous oxide and manganese oxide. It is wrong to assume that when a white slag free from metallic oxide is obtained (as is already the case with sample 12) the bath is completely desulphurized, and an interruption of the smelting process at this time would be a mistake, since the desulphurization has only begun and needs time to be complete.

As long as the bath is covered with an oxide slag it takes up oxide out of the slag and becomes thick and sluggish, which may be the reason for incomplete desulphurization in the presence of an oxide slag. When white slag has been formed on the metal bath, it absorbs the oxide from the bath and the oxide is destroyed by the carbon added and the calcium carbide formed under the electric arc.

The bath becomes more readily liquid through the removal of the ferrous oxide, and now the iron sulphide which is suspended in the bath will rise to the surface of the bath and be absorbed by the slag.

It has been observed that during the hottest period of the process, white vapors rise between the carbon electrode and the cooling ring which vapors deposit on the electrode in form of a mouldy, fibrous crust. As these deposits contain as much as 24 per cent SiO_2, it may be assumed that these vapors consist chiefly of silicon sulphide SiS_2. This gaseous compound is oxidized by the air to SiO_2 and SO_2 and the white deposit of SiO_2 is obtained.

As the final finishing slag has only traces of manganese oxide, and no manganese sulphide in its composition, it is to

This includes the quantities of sulphur absorbed from the carburizing agents, etc., and again removed.

To sum up, the removal of the sulphur takes place in three different ways:

(1) During the oxidation period sulphur is removed through the action of the slag rich in ferrous oxide, whereby sulphur dioxide is formed which escapes.

(2) In the deoxidation period the white slag, free from ferrous oxide, removes sulphur.

(3) The third agent in desulphurization is silicon, forming silicon sulphide.

It is now generally believed that oxides, gases, and slag enclosures have a much more unfavorable influence on the physical properties of steel than phosphorus and sulphur below 0.02 per cent. The electric steel furnace allows the steel bath to rest a long time under the neutral non-oxide slag, which procedure can be carried out in the crucible only with difficulty without chemical changes, and which cannot be carried out at all in the open hearth. The possibility of removing the oxides, gases, and slag enclosure in this way is, therefore, an important advantage of the electric furnace.

As regards deoxidation, it might be said that it is started by introducing carbonaceous materials. The extent and the speed of deoxidation depend on the temperature, the amount and the action in time of the carbon additions. Complete deoxidation of steel with the aid of carbon alone (even with a slag completely free from ferrous oxide) is possible in the electric furnace only, if the refining period is extended for a very considerable time. It is, therefore, advisable to remove the last traces of oxygen by the use of other deoxidation agents like manganese and silicon in order to bring the oxygen into the slag. The oxygen compounds in the slag are reduced by the aid of ferrosilicon or powdered charcoal.

The calcium carbide formed at the greatest heat center under the arc can be increased so much in amount by raising the tension of the electric arc that during the cooling of the slag ladle the acetylene is ignited with explosive violence.

Coussergues (*Revue de Metallurgie*, 1909, p. 589) claims that the calcium carbide causes the formation of acetylene at the contact surface of metal and slag according to the reaction: $CaC_2 + 2H = Ca + C_2H_2$, thus removing hydrogen from the steel and thus rendering electric steel more free from hydrogen than even crucible steel.

The products of the Girod furnace in the Gutehoffnungshütte are carbon steels of various degrees of hardness, also alloy steels, like nickel-steel, chromium steel, nickel-vanadium steel; chromium-vanadium steel, chromium-tungsten steel for high-class machine and engine parts and tools.

Table 5 gives a short synopsis of the results of tests and analyses, and the application of electric steels made in the Girod furnace.

Oberhausen, Rhineland,
Germany.

Cobalt.—The principal uses of cobalt in the United States are in making glass and pottery. A beautiful blue is given to glass by the oxide of cobalt. Sympathetic inks, according to a report of the United States Geological Survey, are made from cobalt acetate, chloride, and nitrate that are colored when heated or colorless when cold. This interesting phenomenon is due to the change in color of the salts on the absorption of water. When dry they are blue and easily seen on paper; when damp they are pink; and when dilute, colorless. A puzzling application of this principle may be in a doll whose dress is blue in dry weather but changes to pink when subjected to dampness, as in wet weather or when the doll is held in the steam of a tea kettle. Artificial flowers are made to show the same effect.

Progress of British Columbia Zinc Investigation.

The status of the investigation into the zinc resources of British Columbia, now being conducted by the Department of Mines, has been outlined in a recent report to the Director of the department by Mr. W. R. Ingalls, consulting engineer to the commission. The gist of the report follows:

Work has been prosecuted in the field of electric smelting at the metallurgical laboratory of McGill University, Montreal, under the immediate direction of Dr. Alfred Stansfield. A large number of experiments have been made with several forms of furnaces, certain of which have rather elaborate construction, and with a variety of material. The early experiments were directed chiefly toward a discovery of the metallurgical conditions which have hitherto prevented a satisfactory condensation of zinc as molten spelter. While I cannot say that these experiments have afforded us a complete explanation of these conditions, they have taught us a good deal; but in spite of the knowledge acquired we have been so far unable to master the difficulties.

We have indeed produced small quantities of spelter, and in some experiments have condensed a fairly large proportion as molten metal, but we have not yet been able to do that at will. Our experiments have thrown light on the principles of furnace design and have led us to condemn several types that we have tried. Our work has indicated that in order to achieve any material improvement over the ordinary practice of zinc smelting it is necessary to abandon certain features of the latter and contemplate continuous charging of the ore and reduction material, and discharging of the residuum without interfering with the process of distillation. These conditions introduce a multitude of perplexing difficulties which can be worked out only by tedious experimentation.

At the request of the secretary of the Canadian Mining Institute I presented at the meeting of the Institute at Quebec in March, 1911, a paper on the problem of mixed sulphide ores, that concisely summarizes the state of the art in the treatment of such ores, and the natural obstacles that block procedure in certain directions. This paper was published in the *Institute Quarterly Bulletin* No. 15, pp. 23-30, June, 1911.

A careful scrutiny of the work on the treatment of such ores that is done by other metallurgists and investigators has been maintained, and I have examined numerous proposals that have been presented with more or less detail, but I have not discovered anything save one that in my opinion holds out any promise of successful adaptation to the conditions existing in British Columbia. I regard the electric work as being of particular interest as an exploration in a virgin field of unknown possibilities. Doubtless with the same idea a great deal of work is being done in this field by numerous investigators in Europe and America. I have been informed within a few weeks that there are now two electrothermic zinc smelters in operation in Scandinavia, viz., one at Trollhättan, Sweden, using about 7000 hp, and one at Sarpsborg, Norway, using about 4000 hp. Operations at these works were inaugurated five or six years ago, but according to my information the results were for several years commercially unsatisfactory, and it is only recently that it has been claimed to have become possible to make spelter from ore upon an industrial scale. The companies operating these works maintain absolute secrecy, and I have not been able to learn any details of their operation.

Apart from the work in Scandinavia, as to the commercial success of which there is no information available, the electric smelting of zinc ore is, in spite of all claims to the contrary, not only still in the experimental stage, but is in the infancy of the experimental stage. Even if the metallurgical difficulties can be overcome, which is possible, I am of the opinion that no one, except perhaps the Scandinavians, is yet in a position to make any reliable estimate of commercial advantage or commercial results in any way. It is, however, worth while to determine the possibilities and publish the results for the general benefit, unveiling so far as possible the secrecy that is likely to be maintained as to the investigations in this field by private interests, having always in mind, of course, the hope that our work may develop a process that will be commercially applicable to the treatment of the zinc ores of Canada.

Cyanide Tailings Disposal in Mexico.

The discharge of cyanide tailings into streams, the waters of which are later used for domestic, industrial or other public purposes, brings up the possibility of legal complications between metallurgical companies and industrial or agricultural communities.

With a view to gathering information on the metallurgical side of the subject, the Instituto Mexicano de Minas y Metalurgia recently propounded a number of questions to leading metallurgical companies. The questions concerned:

(A) the percentage of cyanide contained in material discharged into streams, and the distance down stream at which these percentages persisted;

(B) the chemical or mechanical possibility of eliminating or reducing the quantity of cyanide in discharged tailings;

(C) the cost of conserving or impounding tailings in stacks or dams;

(D) the possible use of tailings for mine filling;

(E) the advisability and cost of purchasing adjoining lands which might be affected by the discharged tailings and cyanide.

From the replies received by the Institute and published in its *Informes y Memorias*, the following are given as representative opinions.

Mr. Hugh Rose, of the Compania Beneficiadora de Pachuca, writes as follows: "(A) and (B)—I have no information of value on these subjects. (C) Where the location of a mill is such that a convenient dumping ground is available at reasonable expense, I consider it by all means advisable to retain the tailings in dumps or dams, according to the condition in which the tailings are discharged from the plant. Where the tailings can be discharged dry, they may be stacked either by belt conveyors or by cars. Where the tailings are discharged with considerable moisture, the South African practice of retaining the tailings by dams built automatically by the discharged tailings is an easy and cheap method. This method may be also used to recover the water in the pond so formed.

"The cost of conserving the tailings by either of the above methods naturally varies to some extent with the special conditions of each plant, but in any case should not be over 2 or 3 centavos per ton, exclusive of the cost of the land." (1 peso or Mexican silver dollar = 100 centavos).

"In a great many instances the conservation of the tailings is a wise policy, not only as a means of avoiding trouble with land holders, but in preserving perhaps for future generations a valuable asset. This applies particularly to the silver mills of Pachuca. There can hardly be any doubt about further advances in milling metallurgy making later economically available the values now discharged in the tailings.

"(D) The difficulties attached to using the tailings for filling stopes underground are increased where the tailings are very fine, as is the case with all sliming plants. It is not likely that this method can be adopted in general, as it requires such special conditions covering the location of mine and mill, method of mining, etc. It is specially applicable where the topograhy is flat or slightly rolling, as is more the case of the Rand, and in some of the flat mineral deposits.

"(E) The purchase of polluted lands would appear to be a very unwise policy, applicable to advantage only in special cases. Not only would it be difficult to secure the land at fair prices, but the adoption of such a policy generally would naturally result in complications to mills so located where the purchase of such lands would not be desirable or necessary.

"In conclusion, I would say that it is the intention of this company to impound its tailings by dams, as discussed in para-

graph C, for the purpose of not only avoiding controversies with land owners, but also of preserving the tailings for later treatment by this company or its successors."

* * *

Mr. D. L. H. FORBES, metallurgical engineer of the Tigre Mining Company, gives the following opinion:

"The cyanide plant of the Tigre Mining Company, which is now about to start operation, will discharge into the Tigre Cañon 250 short tons per day of slime residues containing 40 per cent moisture. These residues will carry the cyanide equivalent of about 50 lb. of potassium cyanide which will be wasted by the displacement of 42 tons of weak barren solution per day.

"The presence of this amount of cyanide with the residues will give the water in the Tigre Cañon a maximum solution strength of 0.025 per cent KCN during the dry season.

"While it is believed that such a weak cyanide solution would have its poisonous properties completely destroyed before flowing a greater distance than two miles, yet the Tigre Mining Company, in order to avoid the possibility of troublesome damage suits, has acquired a strip of land which takes in both sides of the cañon from the mill to the Bavispe River, a distance of ten miles. The writer is informed by Mr. L. R. Budrow, manager of the Tigre Mining Company, that the total cost of protecting the company's interests in this way was approximately 60,000 pesos.

"It is not the present intention of this company to collect the residues from the cyanide treatment in a dry condition, but the plant has been so designed that this may be easily accomplished whenever it shall be thought advisable. I would estimate that the extra operating cost for stacking slime residues which had been previously air-dried on the filter leaves would be 6 to 8 centavos per dry short ton. In the case of this plant it could be accomplished best by means of a 12-in. carrying belt. The initial cost of such a conveyor installation would be about 4000 pesos."

On the subject of filling the mine with tailings the writer is of the opinion that, aside from the inconvenience and expense of handling the tailings in this manner, such a method of disposal would be inadvisable at this property; both because of the method of mining used here, and on account of the timbering expense and danger that would be involved. As the veins of this property all have a nearly vertical pitch and are comparatively narrow, it has been found most economical to mine the ore bodies by a system of overhand stoping.

"Each block of ore is mined in such a manner that the stopes are kept nearly filled with broken ore until the level above the stope is reached. The ore is withdrawn in quantity only sufficient to compensate for its extra volume when broken, and the stopes are never entirely emptied until the section in which they are located is worked out and ready to be abandoned.

"Even if the filling of the mine with tailings were feasible, the fact that practically all precious metal ores are extracted from the upper workings of the mine first makes it obvious that the storage of the large volumes of mud in a pasty condition would have to be above the main roads and passageways and would therefore constitute an element of danger and an extra expense that would seriously handicap any mining enterprise that might adopt it.

"The practice of rendering escaping cyanide mill solution innocuous by special treatment has not been tried at any of the plants with which the writer has been connected. If such a procedure were made obligatory by statute, undoubtedly several methods would at once suggest themselves, the choice of which would depend largely upon local conditions and the spirit of the law.

"The judicious use of any one of the stronger mineral acids, while it would destroy the most active poison present in the solution, would also be adding another impurity to water that would still be unfit for drinking purposes. If, however, the application of the law should require the complete purification of the water escaping from the mill, a special procedure consisting of precipitation of all salts in solution and subsequent filtration would have to be developed. Such an operation as the latter would involve expense that many companies which are now operating on low-grade ore and tailing dumps with small margin of profit could not bear.

"In most instances, however, it will probably be found that sufficient purification takes place in a small running stream. Wood, leaves, fibrous roots of plants and the carbonic acid present in the atmosphere are all well-known agents that decompose cyanide, and as these are always present in the smaller streams of this country it is evident that waste mill solutions mingling with the water of such streams must soon be rendered harmless in so far as their cyanide properties are concerned."

It should be remembered that the practice, which is becoming prevalent in the gold and silver mills of Mexico, of crushing ore in cyanide solution enables the operator to obtain a closed solution circuit, whereby practically no cyanide is run to waste unless "fouling" occurs. Wherever the ore is of such a character that the extraction of values is satisfactory and the decomposition of cyanide while in contact with the raw ore not excessive, crushing in solution is to be recommended, and it has the advantage of lessening the possibility of legal complications from actual or supposed harmful effects of residues escaping from the mill.

* * *

The following compilation of information from the company's several mills was contributed by Mr. GEORGE BRYANT, resident director of the Guanajuato Development Company:

(A).—*Peregrina Mill,* capacity 500 metric tons per day of tailings about one half sand and one half slime are discharged into a large reservoir which is opened once in two years and then during the occurrence of the heaviest rains, so that both the water impregnated with cyanide and the tailings themselves are taken away by flood water and washed a distance of from 20 to 30 km from the mill almost immediately. The superintendent's answer to question (A) is, that "the waters on leaving the mill contain about 0.03 per cent cyanide, and are practically unchanged on reaching the reservoir.

San Prospero Mill (Mexican Milling & Transportation Company), capacity 150 metric tons per day, discharges slimes immediately into the stream, where they join the drainage waters from the city. The sands, comprising one-half of the tailings, are stacked until the rainy season, when they are also carried away by flood waters. The superintendent states as follows, answering question (A): "The water leaving this mill contains on the average 150 grams cyanide to the ton. This proportion is greatly reduced about 400 m below the point of the discharge."

Pingüico Mill, capacity about 300 tons per day tailings about one-half sand and one-half slime. The slimes are discharged directly into a stream below the mill in which there is sufficient water for about one-half of the year to push them along, while during the dry half of the year they collect until the floods of the rainy season push them further down. The sands collect until the rainy season, when portions of them are washed away by the floods. The superintendent states, in answer to question (A): "The solution discharged from this plant with the tailings carries 0.02 per cent KCN. All traces of solution disappear 50 m below the plant."

Jesus Maria Mill, (Guanajuato Amalgamated Gold Mines Company), capacity 450 tons per day of tailings about one-half sand and one-half slime. The sands are stacked and some of them are carried away during the rainy season. The streams flow as long as there is water in the same to push them, which is about nine months in the year. The superintendent answers question (A) as follows: "The water leaving this plant flows down a cañon having very precipitous sides, and for some 4 km (1 km—0.62 mile) the total land contiguous to the stream and used for agricultural purposes does not total one hectare. From that point on there are orchards and more or less cultivated land.

Upon leaving the company's property the solution titrate is, in terms of KCN and CaO

	KCN	CaO
	0.03%	0.31%
1 km down stream	0.03%	0.26%
2 " " "	0.02%	0.19%
3 " " "	0.015%	0.014%

These samples were taken at five-minute intervals over a period of two hours, which represents a complete cycle on our filter, and gives the average solution discharged. It includes the cyanide of sodium, potassium and the simple cyanide of zinc ($ZnCy_2$), usually estimated as free cyanides.

The total cyanides include KCy.KSCy, K_4FeCy_6, K_2ZnCy_4, and the related sodium cyanide compounds are as follows:

Total cyanide in terms of KCN:

At plant	0.05%
2 km down stream	0.04%
4 km down stream	0.025%

(B).—Three of our superintendents answer that they do not know of any practical chemical or mechanical process for further reducing the small proportion of cyanide contained in the discharged water and tailings. A fourth superintendent answers as follows:

"It is doubtful whether sodium cyanide is especially detrimental to water used for agricultural purposes, as the sodium cyanide undergoes slow decomposition, giving off ammonia and urea (both of which are used in the manufacture of artificial fertilizers), and formic acid. Rather the excess of lime is the damaging material, and this could be neutralized by commercial acid, or possibly by our mine waters, should the pumps work continuously.

"Some years ago one plant let its waste solutions percolate through refuse matter from slaughter-houses, manure and sawdust to render them harmless, but with indifferent success. Then, for some years following the introduction of cyaniding milling in many camps, efforts were made to render the effluent solutions harmless, but I am not aware of marked success attending a single effort, and cannot recommend a process to effectively accomplish that result."

(C).—Peregrina answers that the case of discharging dry tailings would increase the milling cost by 1 peso per ton. Pingüico answers that 60 per cent of the tails discharged are perfectly dry and are washed away each year by the rains. Another answers, "About 45 per cent of our tailings are now discharged dry and do not enter the river. It would be impracticable to discharge the balance dry." I quote verbally from a fourth superintendent's answer: "The slime discharge averages 42.5 per cent moisture at present, our sand is dry for practical purposes. Should the tailings be discharged with a lower moisture per cent than our ore carries, the solution would accumulate by reason of this excess moisture until such a time as all storage capacity would be occupied, and then the excess day by day would run to waste. On the other hand, if not drier than the ore, there would be a continuous seepage of solution rather high in KCN from around the lower edge of the dump, and this would gradually find its way into the stream. Thus, while the objectionable elements would be lessened, it would not cause their elimination."

(D).—At all of our plants, mines and mills are so far separated that use of tailings for filling stopes would be certainly out of the question.

(E).—So far as we know, no damage is done by our tailings to agricultural lands, and up to the present time no claims have been suggested for such damage.

In only one case have I taken this matter into consideration. In that case we found that a total outlay of 46,000 pesos would be necessary to accomplish the purpose suggested in question (F), and figuring the ore supply in that property as 720,000 tons, sufficient for five years' work, we calculated that it would increase the milling cost by 6.4 cents, Mexican currency, per ton.

Possible Reduction of the Power Consumption in Electric Steel Refining Furnaces.

By Carl Hering.

The question of the power consumption in electric furnaces for steel refining is, of course, of great importance and is sometimes even the criterion, hence it deserves the most careful consideration. The present article is an attempt to determine from present practice approximately what the maximum economy is which may be expected in a furnace designed with that end in view. Such a figure would show what the limit of economy is beyond which we cannot expect to go and how near present practice is to this best economy. As the deductions are based on data from an actual furnace they, of course, are subject to the same inaccuracies as the original data. But even if these data are not accurate, and the writer assumes no responsibility for them, they are not likely to be far wrong, and the description of the method of making the deductions may itself be of interest, as it can be applied in the future when better data become available. Even if the present data should have been 100 per cent greater (worse) the results deduced would still be surprisingly favorable.

The chief function of a furnace for steel refining is merely to keep the metal at a constant temperature during the process of refining. In the large Chicago furnace the metal is said to even leave at a slightly lower temperature than that at which it entered. Hence the only energy to be considered here is that necessary to keep the temperature constant; if, therefore, there are any chemical reactions which consume energy, or if there is any melting done, or any increase in temperature, the energy necessary for this must be added. Moreover, the heat lost through the doors, electrodes, etc., is also neglected, hence must be added in an actual case.

When the temperature is maintained constant it means that the total energy supplied to the charge is equal to that lost by it. The heat loss from the charge must, of course, all flow through the bounding surfaces of the charge—that is, through the top, sides and bottom; it is lost by radiation from the top and by conduction from the sides and bottom. For want of better data it is here assumed that the loss by radiation from the top is at the same rate per unit surface as that by conduction from the sides and bottom. Though this is no doubt not strictly correct, it is probably sufficiently so for the present purpose of reaching an approximate figure; this figure can be corrected later when better data become available.

It is also assumed in the present deductions that the insulation of the walls in actual practice is uniform for all different sizes of furnaces—that is, that the heat energy passing out of the metal per square foot of its outside surfaces is a constant and is equal to that in the particular furnace from which the data were obtained. If this insulation can be improved the final figures will be lowered accordingly.

Under these circumstances the heat losses through these bounding surfaces for a constant inside temperature are, of course, dependent only on the extent of this surface and not on the quantity of the metal within the walls.

If, therefore, the loss is a constant per square foot of surface of the metal, and is independent of the quantity of metal, it follows that the loss will be least when the metal is in the shape of a sphere. But as this is impracticable it will be assumed here that the ideal form in practice is a hemisphere, leaving a dome of an equal hemisphere above for working space.

The problem therefore is, on the basis of a constant loss per square foot of metal surface,, what will be the total loss when the body of metal has a hemispherical shape?

This constant loss may be deduced from a recent paper by Mr. Albert Hiorth, read at the recent Toronto meeting of the American Electrochemical Society[1], in which he states that by actual test it required 180 kw to keep the steel melted over

[1]See preceding issue of this journal, p. 534.

night in one of his five-ton, two-ring, single-phase induction furnaces for steel refining. As there are no electrodes, this represents the power which is being continuously lost through the walls. When the furnace was running it took somewhat more, but presumably cold slag was then being melted, and probably the covers were frequently removed; there was also presumably an increase in temperature; these doubtless account for the increased input of power. For the present purposes, therefore, it is probably fairest to use the figure for the all-night run. As these measured results were used by him to design a 30-ton furnace, it may be assumed that they are fairly correct.

He also gives all the dimensions of the crucible and body of metal; hence, one is enabled to deduce from them the outside surface of the charge of metal and the total outside surface of the crucible. These deductions have been made by the present writer and the result is that the average continuous loss of heat from the bo nding surfaces of the metal (sides, bottom and top) is equal to about 13 kw per square meter, or

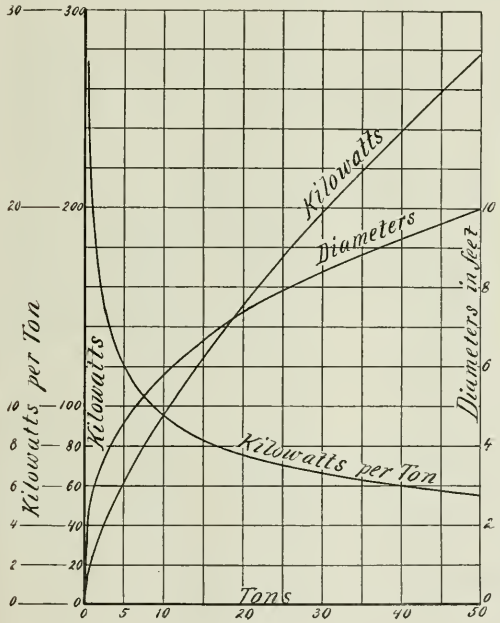

FIG. 1.—MINIMUM KILOWATTS PER TON AS FUNCTION OF SIZE OF FURNACE (CONDITION OF LEAST LOSS).

1.2 kw per square foot. The total surface of the charge was 13.9 sq. m., and the total loss 180 kw. The total exposed outside surface of the crucible was 56 sq. m., or about four times the metal surface.

This average figure, 1.2 kw per square foot of metal surface, is taken as the basis of the following deductions. It is doubtless greater in some parts and less in others, but, as the results are necessarily only approximate, a further refinement is hardly warranted.

In a Roechling-Rodenhauser single-phase, two-ring, induction furnace, the data for which was kindly furnished to the writer for this purpose, the surface of the metal charge was found to be 6.36 sq. meters, and the power necessary to maintain the temperature was given as about 80 kw.; it was a 2-ton furnace, hence considerably smaller than the other one. This reduces to a loss of 12.5 kw. per square meter of metal surface, or 1.17 kw. per square foot. The agreement is herefore confirmatory and is in fact strikingly close.

As these figures can no doubt be improved, an easily remembered rough-and-ready figure for the losses through walls under steel refining conditions is therefore one kilowatt per square foot.

A ton (metric ton equal approximately to a gross ton) of molten iron occupies a volume of about 5.13 cu. ft. From this and the above data the following table has been calculated. It gives the kilowatts which would be required on the above bases to keep steel at the refining temperature, the bottom of the hearth being hemispherical and the metal just filling the hemispherical part. Hence it gives the least number of kilowatts, or kilowatts per ton, required under the best practicable conditions for obtaining the least loss. The curves give the same results graphically.

Capacity.		Diameters		
Gross Tons.	Cubic Feet.	in Feet.	Kilowatts.	Kw. per Ton.
½	2.57	2.14	13.	26.
1	5.13	2.70	20.	20.
2	10.3	3.40	32.	16.
5	25.7	4.61	60.	12.
10	51.3	5.80	95.	9.5
15	77.0	6.65	124.	8.
30	154.	8.38	200.	6.6
50	257.	9.93	278.	5.5

The figures in the last two columns will be found to be far smaller than those of present practice, showing that there is a possibility of very great improvement in reducing the consumption of energy. The actual figure for the Hiorth 5-ton induction furnace was 36 kw per ton as agains a possible 12 kw. In the South Chicago 15-ton furnace it is given as 50 against a possible 8.

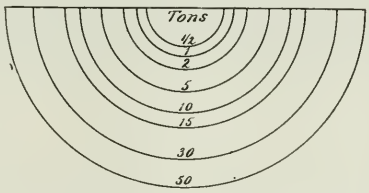

FIG. 2.—INCREASE OF SIZE OF FURNACE WITH INCREASE OF CAPACITY.

The figures in the table are based on the actual results in an induction furnace, but, as the heat insulation per square foot of metal surface of a simple hearth could no doubt be made still higher, the numbers in the last two columns can probably be still further reduced.

These extremely low power consumptions in the table point out the direction in which progress becomes possible if the power consumption is important. They can, of course, be expected to be reached only in those types of furnaces in which it becomes possible to give the hearth its best possible shape and in which the necessary slagging surface is obtained by energetic circulations, as, for instance, in the type of furnace devised by the writer and described in a recent paper read before the American Electrochemical Society[2] and abstracted in the May issue of this journal, p. 277. In other types the results may be approached more or less closely by so designing the hearth or crucible that the bounding surface of the metal is the least possible in that particular type.

The above deductions have nothing to do with the length of time of the refining. If by any improvements, such as rapid circulation, which brings all parts of the metal into repeated contact with the slag, the time of treatment could be reduced, it would, of course, reduce the energy required still more, and in direct proportion; this will reduce the kw-hours, as distinguished from the kilowatts, and it is with the latter only that the above deductions are concerned.

[2]Trans. Amer. Electrochem. Soc. Vol. XIX, 1911, p. 255.

At half a cent per kw-hour it would therefore cost only about 5 cents per hour and per ton of metal to keep it melted for refining purposes in a 10-ton furnace, or 3.3 cents in a 30-ton furnace. As stated above, any power used for melting cold slags, raising the temperature, supplying the losses through open doors, electrodes, etc., must be added hereto. These surprisingly low figures are a good illustration of the improvements which may be expected by a more careful and more rational design, with a view to obtaining the best heat economy.

The following further deductions indicate that even these low figures are probably too high, and that it may be possible to reduce them considerably, possibly to about half these values. In an induction furnace the walls of the crucible which surround the iron cores, are necessarily restricted in thickness; in the one from which these data were taken these surfaces are furthermore water cooled in order to protect the core; moreover, there are 1.65 tons of copper in the primary turns, which are intentionally placed as near as practical above and below the hot metal secondary, to increase the power factor; such a mass of copper will carry off a large quantity of heat. It is likely therefore that the average loss of 1.2 kw per sq. ft. of metal surface in this particular furnace is higher than it would be in one in which the wall thickness is not restricted and in which there is no such mass of copper near the charge. The outside walls of this crucible were about 23 in. thick (60 cm.), the bottom apparently about the same, while the inside ones were only about 14 in. (35 cm.); about one-quarter of the total metal surface was exposed to these thinner walls. The metal charge had about three times the surface exposed to the losses that it would have in a hemispherical hearth.

Taking a five-ton furnace with a hemispherical charge as an illustration, and assuming the wall to be 24 in. thick, the surface on the outside corresponding to 1 sq. ft. on the inside is about 3.5 sq. ft.; hence the flare is about the same as the average (4) in the Hiorth furnace. The mean cross-section of the path of the flow of heat from 1 sq. ft. of the metal surface will then be 1.87 sq. ft., namely, the geometric mean. The thermal resistivity of fire brick deduced from Wologdine's results* is 22.4 thermal ohms for one inch cube. Hence the thermal resistance of such a frustrum of fire brick is $24 \times 22.4/1.87 \times 144 = 2$ thermal ohms; hence if the difference of temperature between the inside and outside is about 1400°C., the flow of heat $W = T/R$, would be $1400/2 = 700$ watts, as compared with 1200 watts deduced from the Hiorth furnace, or only a little over half as much; hence the figures in the table are likely to be nearly double what they should be. Moreover, the Wologdine values for the thermal conductivities are believed to be too high (100 per cent for fire brick, according to Clement & Ely), and if this is true, the flow will be considerably less than 700, perhaps only half as great, in which case the figures in the table would be reduced in the ratio of 1200 to 350, or to less than a third. It is likely, however, that magnesite was used as the lining, and this would increase the flow somewhat, as it conducts far better than fire brick. The rough agreement of the results deduced by these two entirely independent methods shows that the figures are not likely to be far wrong, and are no doubt on the safe side.

An additional check of the order of magnitude of these figures may be obtained from steam heating practice. The amount of heat emitted per square foot of surface of an iron heater, due to radiation and moving air, reduces to about 200 watts when its temperature is about 150°C., and it is said to be about 30 per cent greater from a sandy surface, hence 260 watts. The rate at which the heat would be emitted from the outside surface of the five-ton hemispherical furnace mentioned above is $700/3.5 = 200$ watts per sq. ft., using Wologdine's value, and $1200/4 = 300$, using Hiorth's results, thus again showing very good agreement considering the crudeness of the figures.

*This journal, January, 1911, p. 13.

It, therefore, seems probable that the surprisingly low figures in the table are not only safe, but will in practice turn out to be still lower, and perhaps considerably so, showing the great advantages that may be gained by first finding out what is the best possible design and then approaching it as closely as conditions permit. In an arc furnace the conditions are such that these very high economies can never be expected, owing to the fact that much of the heat of the arc never reaches the metal itself; the above figures refer to the losses of heat from the charge itself, and therefore apply more particularly to resistance furnaces.

Gold, Silver, Copper, Lead and Zinc Production in Western States in 1910.

The United States Geological Survey has recently issued reports showing official estimates of the production of the principal metals in Western States. For convenience the totals have been tabulated as below.

Arizona showed an increased output of gold, but decreased production of silver, copper, lead and zinc. In Colorado the output of lead and zinc increased, but gold, silver and copper showed a decrease. Idaho had an increase in production of silver, lead and zinc, but showed a decrease in gold and copper. In Montana there was an increase in lead and zinc, but a decrease in gold, silver and copper. Nevada had an increase in output of gold, silver and copper, but a decrease in lead and zinc. In Utah there was an increased output of copper and zinc, but a decrease in gold, silver and lead.

	Arizona.	Colorado.	Idaho.
Gold, value	$3,149,366	$20,507,058	$1,096,842
Silver, fine oz	2,566,528	8,509,598	7,369,742
Copper, lb	297,491,151	8,359,535	7,037,292
Lead, lb	2,696,151	76,071,273	228,258,839
Zinc, lb	5,484,899	77,089,648	5,603,114
Total value	$42,731,519	$33,673,879	$16,316,196
Tons mined	3,914,969	2,434,664	1,786,174

	Montana.	Nevada.	Utah.
Gold, value	$3,730,486	$18,878,864	$4,032,085
Silver, fine oz	12,162,857	12,479,871	10,466,971
Copper, lb	284,808,553	64,359,398	127,597,072
Lead, lb	4,106,292	4,871,130	123,597,072
Zinc, lb	31,638,184	2,707,071	16,367,104
Total value	$48,358,253	$34,152,148	$32,199,185
Tons mined	5,079,446	3,655,775	6,380,398

Sixth Congress of the International Association for Testing Materials.

The sixth congress of the International Association for Testing Materials will be held under the patronage of the President of the United States at the Engineering Societies' Building, New York City, during the week beginning September 2, 1912.

The nature of the work for which the congress will meet is concisely described in section 2 of the by-laws of the association as "the development and unification of standard methods of testing; the examination of the technically important properties of materials of construction and other materials of practical value, and the perfecting of apparatus used for this purpose."

Another of the most important functions of the association is the establishment of standard specifications for materials used in manufacture and construction. As these specifications are of greatest value to engineers, it is to be hoped that many American engineers will join the association in order to attend the congress and aid in establishing these specifications.

Prof. Henry M. Howe is the president of the American

Society for Testing Materials and acting president of the International Association for Testing Materials. Prof. Edgar Marburg, of the University of Pennsylvania, Philadelphia, Pa., is the secretary of the American society.

Mr. H. F. J. Porter, 1 Madison Avenue, New York City, is the secretary of the organizing committee of the congress, and all communications concerning the congress should be addressed to him.

An Historical Note on Ore Treatment in San Juan County, Colorado

By Warren C. Prosser.

It is often stated that milling practice in San Juan County is far behind the times, which is probably true. Pressure has, however, been brought to bear within the past few years, by adverse circumstances, which has created the incentive to do better work, improve conditions and institute the best methods of ore treatment. This will no doubt result in successful modern practice at no distant future time.

In picking out the flaws of past and present methods the main fact discovered is that instead of having one problem to solve in arriving at successful extraction of the metallic values, such as might confront a camp mining one general character of ore, there are here a dozen to solve for each character of ore mined.

The early discoveries made in 1861 were abandoned necessarily on account of the violation of treaties with the Indians and it was not until 1873, when the Brunot Treaty was made, that mining operations started in earnest.

The year previous the Little Giant Company was organized in Chicago, anticipating the signing of this treaty, and they immediately took steps to replace their arrastres by stamps and amalgamation plates. Their ore was a brown quartz carrying free gold in quantity.

In these early days silver was high in value, ranging around $1.29 per oz. and ores were mainly sought which carried high silver values. Gray copper and galena ores were found abundantly as snperficial ores.

Mineral Point, where outcrop some of the largest and most extensive veins to be found anywhere, received much attention during 1874 and the year following. The pay streaks were large and some of the ore carried silver in hundreds and thousands of ounces to the ton. Gray copper ores were found in many properties and some rich pockets were opened. The Bill Young mine, for instance, produced $50,000 in one pocke- The Old Lout produced an ore carrying bismuth and associated with a pyrite of botrioidal crystallization which ran $3,000 per ton. The Alaskan mine produced $100,000 in one pocket of this same character of ore.

Early Silver Processes.

The most enterprising of these Mineral Point mines, however, was the San Juan Chief. It was early discovered that much of the value of the ore was being dissipated in excessive freight and treatment charges, and regretting that they did not know of some method of saving the gold, copper, lead and zinc, they decided to institute a method of treatment for silver alone. Before this some of the ore had been treated in a custom mill at Animas Forks with crusher, rolls, jigs and tables but the ore was slimed and great losses resulted. A buddle was put in but this too proved a failure.

Kempton and Thatcher finally built a small testing plant near Mineral Point, where they worked up a leaching process, supposed now to have been designed after the Augustin process, and then they built a larger mill which is now the San Juan Chief mill. Here were placed a Blake crusher, rolls, stamps, roasters and vats. The material from the mine, after being crushed and stamped, was dried in one of the roasters and then given a chloridizing roast in the other. It was then fed hot into a vat of sulphuric and nitric acid solution where it was leached for thirty or forty hours. The solution was then drawn off and run through granulated copper suspended on a cloth screen immersed in water just below the top of another tank. The silver was precipitated by the copper which in turn was recovered by being precipitated on iron sheets hung in the tank below. The silver remaining on the screens was then filter-pressed, melted in large graphite crucibles and cast into bricks. Later it was attempted to crush and roll dry, and still later to concentrate on Cammett tables and canvas.

At Gladstone where the high grade gold-silver ore of Poughkeepsie Gulch was being delivered, and at Crookes mill, two miles north of Silverton, operating on the gray copper ore of the North Star mine on King Solomon Mountain, lixiviation works of the same character were installed a short time following the San Juan Chief operations. It is clearly evident that the method was designed to treat the gray copper ores, tetrahedrite, freibergite and perhaps stromeyerite, which were subject to excessive sliming by ordinary wet concentration.

SILVER LAKE MILL AND TERMINAL EQUIPMENT TWO MILES ABOVE SILVERTON, COLO.

The causes of the failure to treat the Mineral Point and Poughkeepsie gulch ores were varied. The freight on acid and salt was extremely high; the exact figures are not now available but one of the operators of the San Juan Chief tells that it was cheaper to buy a four horse team and wagon in Denver and haul it in. It was thought that the railroad considered the acid so dangerous that in case of a wreck the rails for miles around and the two nearest stations would be entirely destroyed. Again the failure to receive payment for gold and the absolute waste of the copper and lead values worked another hardship. Then, too, the presence of much zinc mineral interfered with successful concentration and reduction.

Smelting.

In 1874 the Green smelter, just north of Silverton, was erected and it was blown in the following year, treating principally the sulphide ores of Arastra Gulch and Hazelton Mountain. This is reported to be the first successful water-jacket furnace in Colorado.

Crooke and Company erected a smelter at Lake City in 1875, and drew sulphide ore from the mines in the northern part of the county around California, Mastodon and Poughkeepsie Gulches and Mineral Point. Mather and Geist of Pueblo also bought ore around the county in competition with the Crooke smelter.

In 1876 a concentrating mill was erected at Animas Forks to treat the ores of the Red Cloud mine near Mineral Point, but this was not successful.

Jas. Cherry built the Eclipse smelter at the mouth of Grouse Gulch in 1880, at a cost of $65,000 and worked only a few tons of lead ore from the Mountain Queen mine.

The Green Smelter about this time was moved to Durango, where it became successively the New York and San Juan Smelting Company, The Durango Smelting Company, The San Juan Smelting and Mining Company, until 1895, when it became the Durango Plant of the American Smelting and Refining Company, now operating under that name.

In 1883 sampling works were operating in Silverton, under the management of E. T. Sweet, T. B. Comstock and Company, and Stoiber Bros. Two years previously the rich copper-silver deposits of the Red Mountain district had been discovered and a smelter was built by Thos. Walsh at Silverton on the site of the Martha Rose smelter ostensibly to handle these ores.

The samplers assisted in securing the production of great quantities of sulphide ores and a large tonnage of low grade ore of this character was developed. Their concentration was attempted by Edward G. Stoiber and Judge J. H. Terry.

Concentration.

Stoiber erected the first Silver Lake mill in Silver Lake Basin where forty stamps were followed by concentration tables. In 1893, a Bleichert tramway was built from this mill to the railroad and in a short time a 100-ton mill was built at the lower terminal, to which milling operations were then removed. In this latter mill were used rolls, jigs, vanners, tables, and later, canvas tables. The mill was burned in 1905, and in 1907 the present modern mill was built on the same ground.

J. H. Terry's operations were first carried on with a ten-stamp mill near Lake Em and the Sunnyside mine. Later a larger mill was built at the forks of Eureka Creek, two miles below and still later a forty-stamp mill was built at Eureka on the railroad, aerial tramways being run to the mine. This mill has been in continuous operation for many years.

The successes achieved by Judge Terry and J. H. Stoiber were emulated by many, some being fairly successful in concentrating and reducing their ores and others using the opportunity thus presented to secure the erection of mills on their properties with no ore in sight. The Gold King, an eighty-stamp mill; North star, twenty stamps; Hercules, twenty stamps; and the Iowa, a roll mill, were highly successful.

The year 1906 witnessed a mill building boom in San Juan County. The Old Hundred mill was built at enormous cost, using 1350 lb. stamps, plates, Card tables, and Sperry slimers. The slimers were soon discarded and amalgamation became their chief effort. Successful concentration was defeated through lack of classification, principally. At the Mogul mill the character of the ore, carrying high percentages of zinc, was the sticking point and the mill closed down after some very expensive work including the installation of Blake machines. The problem here remains to be solved to-day.

In 1905 and 1906 the Gold Prince mill was built at Animas Forks. This is a 500-ton mill of 100 stamps. It was built at a cost of half a million dollars, of steel and reinforced concrete and is a very modern building. It is hard to state just why its operation was not continuous but it is maintained that the ore reserves in the mine were not adequate to meet the enormous tonnage required. It was operated under receivership during 1909-10 and is now awaiting the outcome of litigation.

Very little data is available covering the milling of the sulphide ores. The savings were poor as a general rule. Several factors crept in to render the extraction difficult. A desire to stamp for purposes of amalgamation and to produce concentrates simultaneously, met with a loss of lead and other values in the tailings on account of the fine grinding. The presence of zinc, for many years a bugbear on account of the penalty inflicted by the smelters for its presence, induced further losses of included values upon being eliminated. A rhodonite gangue introduced a waste mineral of high specific gravity, which crept up on the table and interfered with the separation. The Sunnyside mine has had all these factors to contend with. Here an attempt was made to produce a zinc product with Blake machines, which was partially successful, up to the time that the zinc plant was burned.

Prospects for Cyanidation.

The treatment of the siliceous ores of the county, carrying values principally in gold and silver, is to-day presenting a broad field for operation in which past efforts have been mainly experimental. In Ice Lake Basin an attempt was made to treat the dry ores of the overlying volcanics by amalgamation. The gold is coarse and rusty, however, and a saving of about 40 per cent was all that could be obtained. Cyanide tests on these ores gave an extraction of 92 per cent of the gold and 66 per cent of the silver, in eight hours, using compressed air for agitation and aeration. Only a small loss in cyanide was experienced.

On the Eastern Range, including a rather large area, the siliceous ores containing values in free gold associated with argentite were overlooked for many years save for an occasional shipment of high grade ore. The Intersection five-stamp mill is the pioneer in this field and this was built solely for experimental purposes. By amalgamation and the production of a pyrite concentrate on an Overstrom table a saving of 86 per cent of the combined values has been made. That it is a cyaniding field is unquestionably the case. The Esmeralda, Little Maud, Intersection, Ridgeway, Buffalo Boy and Crystal Lake properties have all had highly successful tests showing a good extraction with a small loss in cyanide.

If the reports concerning the extraction of values in some of the mills are true it is not surprising that few reliable records have been kept; but at the same time it must be borne in mind that a great complexity and diversity of ores exists in this district which has tried the skill of many good mill men. Moreover they had at their disposal very little machinery which could do the work, up to a very recent time.

The introduction of electrostatic machines has been the most important step that has been attempted for many years, and that it will be successful in the production of high grade products has already been proved by exhaustive tests, chiefly on zinc-bearing ores. The success of mining operations in the San Juan is now largely dependent on ore treatment, and the backwardness of milling operations has constituted unwittingly a conservation of a greatly diversified mineral wealth.

Silverton, Colo.

Reinforced concrete jigs have been decided upon to replace wooden jigs at the mill of the Cananea Consolidated Copper Company, Cananea, Mexico. They were designed by F. J. Strachan, superintendent of concentrators, and are described in detail in the *Engineering and Mining Journal*, Oct. 7. The inside of the structure is coated with a mixture of lye, alum, cement and water.

The so-called bicarbonating process of treating oxidized or carbonate ores is carried out by dissolving the minerals in a water solution of CO_2 under pressure, forming bicarbonates of the metals. The water solution is separated from the gangue, and the different mineral salts are caused to precipitate by successively reducing the pressure to the critical points at which the various carbonates are claimed to separate out of the solution. It is claimed, for example, that with copper and zinc in solution as bicarbonates under pressure, if the pressure is gradually reduced copper will precipitate before zinc, and that this means of separation can be made quantitative. The whole process is carried out in the cold, and consists of a system of agitating and pumping, with recovery of the CO_2 when the pressure is released from the bicarbonate solutions and when the precipitated carbonates are calcined. The idea has never been carried out commercially, but has been the subject of experimentation by H. D. Rankin and E. H. Westling.

The "Paragon" Electric Furnace and Recent Developments in Metallurgy.*

BY JOH. HÄRDÉN.

Recent developments in the art of steel refining in the electric furnace have called for certain modifications in the design calculated to meet the requirements of the metallurgist.

A retrospective view of the electrometallurgy of recent years will make this clear.

When the late Dr. Kjellin, whose untimely decease we all had to lament on last New Year's eve, designed his induction furnace, about 1894, to 1898, his primary object was to create an efficient melting machine for high-class crucible steel, pure and simple, without any consideration of refining possibilities which were deemed unnecessary with the high-class raw material employed in the manufacture of such steel.

That this furnace has filled this demand, in capacities up to 4 tons and more, has in course of time been amply verified.

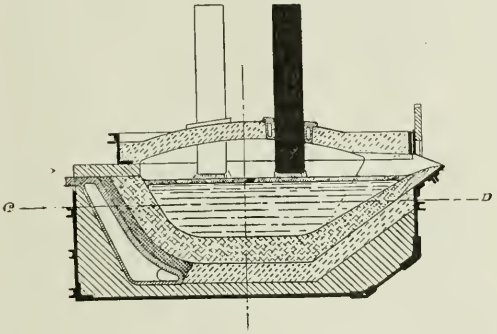

FIG. 1.—VERTICAL SECTION OF PARAGON FURNACE.

though the progress, the author regrets to state, has been very much retarded in England, chiefly on account of the power question, as "surplus" power is scarce in most steel plants and is considered more necessary for other purposes, though it has been repeatedly proved that a clear saving of from £1.10.0 to £2.0.0 ($7.50 to $10) per ton of steel, in the melting, can be effected with this furnace.

It is well known that very little refining as regards sulphur and phosphorus can be effected in the induction furnace on account of its small slag surface, and the comparatively low temperature of the slag (though degasifying is daily carried out in a large Kjellin furnace by a prominent Continental European firm, the Poldihütte A. G. in Bohemia).

The reason for this behavior is quite obvious, but a crude analogy may serve as an illustration. Imagine there are two cups of water on the table, one containing hot and the other cold water, and let us drop a lump of hard crystal sugar into both; as is well known, the sugar will dissolve much more rapidly in the hot water, also if some special salt is added, it may be found to dissolve quite readily in the hot, but not at all in the cold water.

The impurities in the steel may be considered to act precisely in the same way; they dissolve readily in a super-heated slag blanket of a temperature considerably higher than that of the steel, while a slag of the same or lower temperature than the steel may dissolve but little or none of the impurities.

As to the gases, another crude analogy may be taken for comparison. Take, for instance, a vessel containing soda-water, or any other liquid in which gases are occluded. If the flame of a burner is applied over the surface of the liquid, some of the gases may be made to escape somewhat quicker especially if the liquid is stirred, either by the action of the heat or otherwise) but if the flame is applied from beneath the liquid, the degasifying is undoubtedly carried on much more quickly, as at the same time the lower portion of the liquid is rapidly brought to the surface and the gas expanded by the heat.

These considerations, among others, brought the author to work out the design known as the "Paragon" furnace, illustrations of which are herewith reproduced.

In this furnace, the bath is heated, as is easily seen (Figs. 1 and 2), both from the surface of the slag by means of suitably arranged arcs, and also at the same time from the sides and beneath the bath, by means of side plates of "second-class conductors," similar to those which have been used for some four to five years in the Roechling-Rodenhauser furnace. In this manner the metallurgist has it in his hands to apply the maximum heat exactly where he wishes to have it, since both circuits are made to be regulated at will. Thus, during the desulphurization and dephosphorization the slag is heated to a temperature higher than that of the steel, while during the period of degasifying, the bulk of the power is conveyed to the bath through the bottom and sides.

This design brings in other important improvements, viz.: It is quite easy to start the furnace from cold by means of the arcs, which obviates the necessity of filling in liquid charge as a means of starting the non-electrode furnaces. Furthermore, the electrode question in plain arc furnaces may in many cases become a serious one, as large electrodes for furnaces

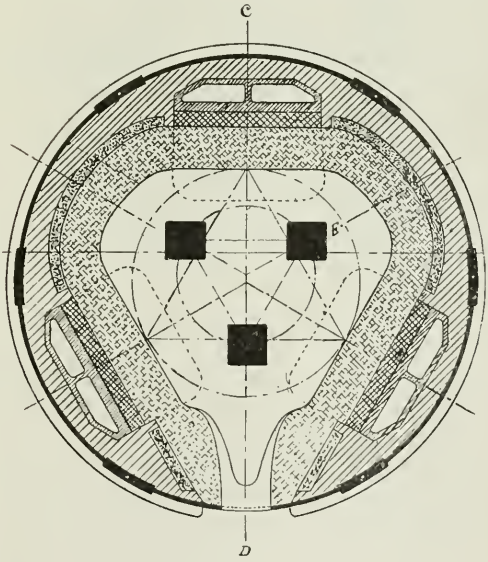

FIG. 2.—PLAN OF PARAGON FURNACE.

of greater capacities are exceedingly difficult to obtain, and always expensive, especially if the losses are considered.

Owing to the nature of the Paragon furnace, where only a smaller part of the power enters the furnace through the electrodes this drawback is considerably reduced. If, for instance, the upper limit of a plain arc furnace is, say 20 tons, on account of the difficulty in obtaining large enough electrodes, it will be found that this capacity can be doubled with the Paragon type, as only about half of the power is required to pass through the electrodes. It is true that with some designs of furnaces the electrodes may be coupled in parallel, but this is also possible in the Paragon, and this statement therefore holds good in this case also.

*A paper read before the Faraday Society on October 2, 1911.

The electrodes for a 30-ton three-phase Paragon furnace should have a cross section of 16-in. x 16-in., or 255 square inches, and in a 50-ton furnace the electrodes should be 24 in. x 24 in., or 576 square inches, which would still only give a maximum of 24.5 to 26 amp. per square inch, which, as experience has proved, is well within reasonable limits, both from an electrical and manufacturing point of view. This would correspond to plain arc furnaces having a capacity of only 12 to 14 tons and 18 to 22 tons. In fact, it may safely be said that as far as the electrodes are concerned any capacity possible with the plain arc furnace may be doubled with the Paragon design.

A further advantage in this design is the greater durability of the roof. It is well known that the roof is the part of an arc furnace which is most rapidly destroyed by the action of

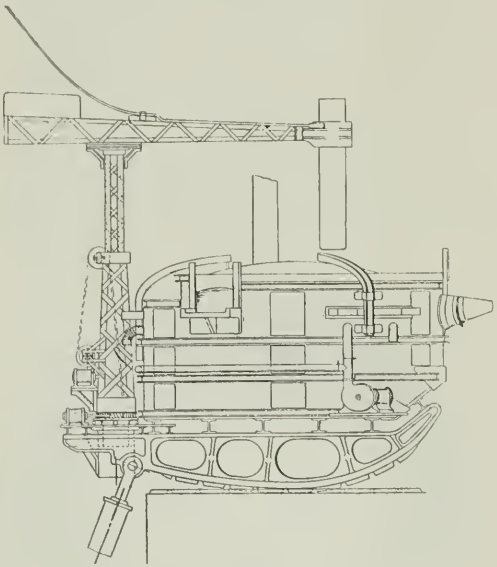

FIG. 3.—30-TON PARAGON FURNACE.

the hot gases. In the Paragon furnace the destructive action is minimized, as only a smaller part of the power is acting on the slag.

In cases where electrodes are more or less unobtainable, the same design may still be used with advantage, when gas firing is used as a substitute for the electrodes, while the electric power is applied only through the side plates. One may perhaps remark that in this case the gas firing alone will be sufficient, but it will be seen on closer consideration that the electric heating is still of great advantage, if the analogy with the liquid containing occluded gas, is remembered, which should be driven out.

Besides, the desulphurization and deoxidation require a considerable temperature, and in order to obtain this one has to blow in a sufficient quantity of air with the gas, which easily renders the flame slightly oxidizing, thus making the deoxidation of the steel difficult.

If electric heating is applied as described, the desired temperature can easily be obtained in the right direction by maintaining a reducing atmosphere, and a more thorough refining should be possible without incurring a higher cost.

Finally, the melting down of cold material with gas should be more economical in this particular case than with the electric furnace proper, since no very high temperature is required to liquefy low-grade iron; but it is the subsequent refining, apart from the dephosphorisation, which demands the higher heat energy, and this can be applied in a more efficient way by means of the side plates conducting the electric power to the furnace.

These furnaces have been patented by the author and the Gröndal-Kjellin Co., Ltd.

A trial furnace is just being built in Germany and designed by Mr. Rodenhauser and the Roechling Iron and Steel Works, where the side plates only are provided for. Experiments have proved that sufficient power can be converted to the bath in this way to give the steel the temperature required. The construction of this furnace has progressed so far that the author hoped to give here some figures of the results obtained; certain delays in the delivery of the electrical parts have, however, frustrated this, but the results are expected to be ready for publication shortly.

It is expected that this design will enable the constructors to provide furnaces up to 50 tons capacity.

Having now broached the question of very large furnaces, in fact of the largest size possible under present conditions, the author wishes to mention a few words about a new furnace of the smallest size, suitable for laboratory purposes, etc.

It is a long-felt want of the steel-maker, to be able to carry out trial melts on a small scale, especially for alloys, before making up a proper charge. This is of great importance in the case of such alloy steels in which expensive ferroalloys are a prominent constituent.

The old method of making a trial in a pot in the crucible furnace is both time-robbing and very uncertain. This new furnace should be a real boon to the crucible steel maker, as it enables him to make melts from a few pounds in weight up to several hundred pounds in a most easy and controllable way.

The furnace is known as the "Helberger" furnace. It consists of an electrically heated ordinary plumbago crucible, lined in such a way as not to react upon the charge. Any form of electric current may be used, but alternating current of from 25 to 60 cycles is preferable.

The furnace and the crucible are open at the top, so that the contents can easily be watched and additions made. The temperature is very easily regulated by means of a handle; temperatures of 3000° C. have been obtained in these furnaces, which will even permit the melting of platinum and other very refractory metals.

The furnaces are made either to be tilted or else with detachable crucible for direct pouring; they are delivered complete, ready for use, at quite reasonable prices.

The melting cost compares very favorably with other methods for small capacities; a few figures will show this:

100 kg.	steel	requires	75	kilowatthours	
100 kg.	copper	"	30	"	
1 kg.	platinum	"	10	"	

The following temperatures of the crucible were obtained:

In 8	minutes	1000°	C.	with	90	amperes,	104	volts.
" 15	"	1470	"	"	160	"	101	"
" 25	"	2150	"	"	165	"	100	"
" 45	"	2750	"	"	248	"	93	"

The temperature was still higher after the last reading, but the pyrometer used did not enable any higher readings.

From this it will be seen that any temperature required for trial purposes in steel-making may be easily obtainable.

With regard to accessories for steel-making, it may be stated that such ferroalloys as ferrotungsten are now being made in the electric furnace on a commercial scale in England by Electric Furnaces & Smelters, Ltd. in their new works at Luton. Three furnaces are in use alternatively, and alloys are produced in considerable quantities. Ferrotungsten, as low as 0.25% in carbon has been made, though 0.5% is more usual.

The power supply is 500 volts direct current which is being converted into alternating current, 25 cycles, 50 to 90 volts, by means of a motor generator.

London, England.

Iron and Steel Institute Meeting.

The autumn meeting of the Iron and Steel Institute was held in London on Oct. 5.

The Duke of Devonshire, President of the Institute, occupied the chair and was supported by two past-presidents, Sir Hugh Bell and Sir Robert Hadfield.

In his introductory address the president expressed great regret that it had been necessary to give up the original intention to hold this meeting in Italy. This was the more regrettable in view of the extensive preparations which had been made in Italy for the entertainment of the Institute. A resolution was adopted "that this meeting desires to place on record an expression of its most sincere regret that circumstances have arisen to deprive the Institute of the honor and privilege of holding the autumn meeting at Turin, under the auspices of its kindred organization, the Association for the Italian Metallurgical Industry."

There were a long list of papers of all of which printed advance copies were available. But only three of them came up for discussion. The others were read by title.

Transformation of Steel by Heat Treatment.

A paper by L. GRENET, of Paris, on "The transformations of steel within the limits of the temperatures employed in heat treatment" was read, in the absence of the author, by the secretary.

The chief conclusions of the author are as follows:

"The iron-carbon alloys partake of the general category of alloys, and no complications due to allotropic transformation of the element iron need be taken into consideration.

"It is quite easy to represent by simple diagrams the mode of influence of the special elements on the temperature of transformation on cooling.

"Quenching (rapid cooling from a temperature sufficiently high that the constituents of an alloy should not be the same as at the ordinary temperature) may, as compared with annealing (slow cooling), act as follows:—

"(*a*) By changing the nature of the constituents and, notably, by preventing wholly or partly the transformation on cooling. In this case, which is rare, so far, that is, as steels are concerned, the quenched state and the annealed state are physico-chemically different states, and their properties cannot be foreseen. It may, however, be said that in the few instances in which such quenchings are known the quenched state is often softer than the annealed state.

"(*b*) Quenching may also act by lowering the temperature of the transformation on cooling. In this, which is the most usual case, the quenched metal is always harder than the annealed metal.

"The following very general law, which satisfactorily groups the facts which have been observed as to steels of the most varied description, and appears to agree with what is known as to alloys, may be formulated. An alloy is the harder in proportion as the transformation which has given birth to its constituents at the time has taken place at a lower temperature, has been more rapid, and as the maximum temperature reached since the last transformation has been at a lower temperature and has been maintained for a shorter period of time.

"The pure metals are alloys in which one of the constituents is in the proportion of nil, and the law applies in this extreme instance, in which there is but one constituent (pure, or nearly pure, iron).

"When it is distinctly higher than the temperature of transformation, the action of the maximum temperature reached since the last transformation preponderates, and it is this which should serve as a guide in the treatment of steel.

"It would appear that the law enunciated above applies equally when the constituents for the time being result from a transformation which causes the metal to pass from the liquid state to the solid state (influence of the method of casting), as, for example, in sand or in a chill: and when they result from a transformation of the metal to the solid state either before or after transformation (as in the quenching of steels).

"The phenomena relating to the hardening of a steel by quenching belong, therefore, to the exceedingly common category.

"So far as the real cause of hardening is concerned, it cannot be said to be known. We are thus led to the conclusion that hardening produced by quenching is due solely to the fineness of the structure. The comparison of the quenching of a solid solution to the quenching of a liquid solution (cast in chills) appears, therefore, to the author to be nearly perfect. In some instances the constituents of a metal vary with the rate of cooling (white or grey pig iron, austenitic steels); but, generally speaking, the constituents of the metal are independent of the rate of cooling, and the law connecting the hardness of the metal with the conditions under which the transformation has been effected applies. Annealing is liquation within a solid, and this liquation would appear to be limited only to the extent of the complete separation of the constituents. Exceedingly slow cooling isolates the constituents in steels or in alloys.

"Between the quenching of metal in a state of solid solution and the quenching of a liquid metal there are naturally enormous differences from the practical point of view. The cooling of a solid solution takes place without the intervention of a mold, and may be very rapid; the constituents separating from the liquid solution are more readily able to segregate by the intervention of the liquid solution not as yet decomposed than the constituents separating from the solid solution. The quenching of a solid solution is therefore more energetic than the quenching of a liquid solution.

"Further, while a liquid solution presents no discontinuity, a solid solution is divided into grains like the metals formed of a single constituent; the grains are larger in proportion as the metal has been heated longer and at a higher temperature. At the time of the formation of the 'cold stable state,' the texture of this state may depend partly on the texture on the 'hot stable state' which has preceded the state at the time being.

"What is important to remember as a guide in the treatment of alloys is the relation—independent of any special conceptions as to the metal iron—which connects the hardness of an alloy with the conditions under which the transformation on cooling is produced, and, in particular, with the maximum temperature to which the alloy has been raised since the setting at liberty of its constituents at the time being."

The paper was discussed at considerable length. Sir Robert Hadfield referred to the author's statement that if quenching acts by preventing wholly or partly the transformation in cooling, the quenched state is often softer than the annealed state. He could confirm this peculiar fact from observations on manganese steel.

Prof. I. O. Arnold said the paper showed that the rival schools of thought were now getting nearer together. He was especially glad that the author had come to the conclusion reached by the Sheffield school of metallographists long ago that the so-called martensite was not a constituent at all, but a structure.

Dr. J. E. Stead criticized the terminology employed by the author as differing in various respects from the usual one.

Dr. W. Rosenhain remarked that the author's opinion on the cause of hardening differed very much from that usually accepted in France or England. The usual view was that the hardening effect in quenching arose from the possible prevention of transformations which would occur on slow cooling. According to Grenet, however, hardness resulted from transformation occurring very rapidly and their products being present in extremely fine division. But this view would require experimental evidence to establish it.

Iron-Manganese Alloys.

Prof. J. O. Arnold, of the University of Sheffield, then presented a paper by himself and F. K. Knowles on "the mechanical influence of carbon on alloys of iron and manganese."

Arnold and Read had formerly expressed the opinion that "the influence of carbon is very considerable, but is by no means the dominating factor, which without doubt is the manganese."

The object of the present paper is to prove the truth of the foregoing enunciation.

Two series of steels were made, in both of which the manganese ranged from 1 to 20 per cent. In one series, however, the carbon was about 0.85 per cent, while in the other it was kept under 0.1 per cent. The results are given of tests of the turning properties, static mechanical (tensile) tests, and dynamical stress-strain tests (alternations induced). Microphotographs of the structure of four typical nearly carbonless alloys are given.

Sir Robert Hadfield, in discussing the paper, gave hardness figures of the manganese steels, obtained by the Brinel method of testing hardness, which he said should find much wider applications, as very valuable practical conclusions could be drawn from it.

Dr. J. E. Stead urged that the investigation should be extended to other properties of the manganese steels.

Temperature Influences on Carbon and Iron.

Mr. E. Adamson, of Sheffield, in his paper on "temperature influences on carbon and iron" endeavored to show that the determination of silicon alone is not sufficient in the chemical grading of iron.

The author gives facts to show that carbon is precipitated as free carbon virtually in the absence of silicon, and in the author's opinion this precipitation in the case of the manufacture of pig iron, primarily depends upon the original temperature to which the iron is raised in the blast furnaec.

The higher the temperature in the blast furnace the higher the carbon in the product—within limits—for it is well known that cold-blast iron is lower in total carbon than hot-blast iron, although the full force of this fact has perhaps been overlooked. What this amounts to is that the temperature of the furnace decides the fracture of grey iron as well as of the lower grades, regardless of the contents of silicon, sulphur, phosphorus and manganese.

The author distinguishes between three different varieties of free carbons and discusses under what conditions they appear. Analyses are given to show that under no conditions can it be said that the percentage of silicon controls the percentage of combined carbon or the graphite or the ratio of one form to the other. Under precisely the same conditions of temperature and time, additions of silicon may show fairly regular variations in the carbons, but under the same constant conditions phosphorus and manganese would do the same.

"The facts stated in this paper are of vital importance in considering the question of the grading of pig iron, and to a large extent explain the objections of many in this country to complete change in the methods used at present to one of grading by practically silicon contents only. The author has shown on several occasions that it is not possible to regulate tests by silicon only, and has no hesitation in saying that the fracture indication is quite as satisfactory as varying the silicon, if the user is fully conversant with fracture indications.

"Continual experience in the use of pig irons in the foundry shows that the same tests can be obtained within very wide ranges of silicon contents. Of course, if it is a question of commerce, there should be no objections to selling irons by silicon contents if this is demanded, and full responsibility is taken by the purchaser: but when it becomes a question as to whether such a method of grading is the best, so as to be of the greatest use to the greatest number, the reply must be an emphatic negative, for it would appear that carbon and its various conditions, due, as shown, to influences entirely outside of analyses, is of primary importance."

In the discussion Dr. J. E. Stead said that the paper was an attack upon analysis and also an attack upon those who depended upon the determination of silicon for pig iron. He thought that all those who had anything to do with foundry work understood thoroughly that the determination of silicon was most important.

Mr. Adamson replied that he was not attacking the chemist, who was a very valuable man as he enabled the iron founder to use grades of iron which he would otherwise not be able to employ. But he attacked grading by analysis pure and simple, and this meant in fact grading by the silicon content.

The other papers were read by title. Nine of them were from the pens of Italian engineers an gave very interesting data on metallurgy in Italy. On account of limitations of space only the two papers on case-hardening are abstracted in this issue. Abstracts of the other papers are reserved for our next issue.

Case Hardening of Steel by Carbon Monoxide and Carbon

Dr. F. Giolitti's paper gives first a summary of the facts established in recent years by the author in co-operation with others on the theory of case-hardening (the original papers having appeared in *Gazzetta Chim. Ital.*, vol. 38, No. 2, 1908; vol. 39, No. 2, 1909; vol. 40, No. 1, 1910; *Rendiconti della Soc. Chim. di Roma*, vol. 6, No. 17, 1908; *Atti della Reali Accad. delle Scienze di Torino*, vol 45, 1910; vol. 46, 1911; *Rassegna Miner., Metall. e Chim.*, vol. 34, No. 18, 1911, and September, 1911; *La Metall. Ital.*, August, 1911, and September, 1911.) These principal facts are as follows:

Where case-hardening is carried out with solid cementing agents having a carbon base, the carburizing effect of the free carbon on the iron, the materials being in simple contact and without the intervention of gaseous carbon compounds, is exceedingly weak, and in any case is entirely negligible in industrial practice.

Where case-hardening is effected with the solid case-hardening agents ordinarily employed in the industry, the specific effect of the nitrogen is very weak. Only with the cementing agents containing a high proportion of the cyanogen compounds (alkaline cyanides, ferrocyanides, etc.), does the direct action of volatile nitrogen comopunds have any marked effect.

As compared with the cementing effect of the solid agents ordinarily employed in the industry, the specific direct carburizing effect of carbon monoxide preponderates enormously over every other carburizing effect.

Pure carbon monoxide carburizes iron at all temperatures within the range (700 deg. to 1300 deg. C.), at which the process of case-hardening can be performed by means of any other medium whatever. Moreover, the rate of case-hardening (by which is understood the depth of carburization which can be obtained in a given time) when working under suitable conditions is greatest when carbon monoxide, or a mixture in which the carbon monoxide can efficaciously exercise its specific carburizing effect, is used as the agent.

This specific carburizing effect exerted by the carbon monoxide on the iron at high temperature is due to a series of chemical reactions, the course and state of equilibrium of which has been actually observed with precision. Moreover, the conditions of equilibrium of the systems in which these reactions take place are in general comprised within the ranges of temperature and pressures ordinarily employed in practice. It is, therefore, possible to obtain with certainty a predetermined result using case-hardening agents whose activity is due, if not exclusively at least very largely, to the specific carburizing action of the carbon monoxide. More particularly is it possible to obtain with such agents carburized zones in which the concentration of the carbon does not exceed a predetermined maximum limit and varies in a well-defined degree toward the inside of the carburized zone. Such definite results, variable at all within sufficiently wide limits, are obtained by varying, in accordance

with fixed rules, the temperature at which the case-hardening is performed, the pressure of the carburizing gas, and the amount of carbon monoxide which, in a given time, comes in contact with the unit surface of the steel to be carburized.

The results obtained by the use of carbon monoxide as an agent vary regularly, other conditions being equal, as the chemical composition of the steel to be carburized is varied.

It is possible to vary regularly and within fairly wide limits the characteristics of the desired product by subjecting the steel to the action of substances along with carbon monoxide which are capable of modifying the conditions of equilibrium of the chemical systems under which the reactions due to the specific carburizing effect of the carbon monoxide are completed. Such substances may be gases, such as hydrocarbons or nitrogen, or they may be solids such as carbon in various forms, and their actions can proceed simultaneously with that of the carbon monoxide throughout the whole cementation period or during a portion only of it.

In particular, by means of the agents, the activity of which is due to the specific carburizing effect of carbon monoxide, it is possible to obtain with ease and certainty—whatever kind of steel is being operated upon—soft case-hardenings and graduated case-hardenings; that is to say, carburized zones in which the concentration of the carbon without being excessive in the outer layers, diminishes slowly and with regularity in the succeeding deeper layers. This is the essential condition for the avoidance of the dangerous phenomena of brittleness and peeling, which defects manifest themselves so frequently in steel pieces case-hardened by the processes ordinarily used in the industry.

The chemical reactions produced by agents in which cyanogen is the active element, are at present but imperfectly understood, particularly as regards their condition of equilibrium upon which depends the concentration of carbon in the carburized zones. It is, however, certain in the conditions under which case-hardening should be performed in practice that the conditions of equilibrium just now alluded to should closely correspond to the strength of the very high concentration of carbon passing into solution in the iron. Thus it happens that the cyanides, ferro-cyanides, and other derivatives of cyanogen, if used alone as case-hardening agents, always give rise to too rapid (energetic) a case-hardening. That is, carburized zones are produced in which the concentration of the carbon is excessively high in the outer layer up to a certain depth and is then suddenly lowered in the succeeding layers. Zones of that type produce brittleness and peeling.

Further, gaseous or volatile hydrocarbons, when used alone as agents, also give rise to too rapid case-hardening, the causes being identical with those referred to in the case of cyanogen and its compounds.

In the light of the facts recited in the foregoing, the great advantage of the use of agents, the activity of which is due, if not exclusively, at least principally, to the specific carburizing action of carbon monoxide, is clear. In order to obtain the best results with such an agent, it is necessary to satisfy the following fundamental conditions:

1. The chemical composition of the agent should be absolutely definite, and should be accurately known.

2. The compounds should be as simple as possible.

3. The reactions which take place during the case-hardening process between the various constituents of the agent and those of the steel should be simple, and should proceed rapidly—under the conditions most easily obtaining in practice—to a well-defined state of equilibrium corresponding to definite concentrations of carbon in the carburized zones.

If pure carbon monoxide alone is used, the concentrations of carbon in the carburized zones are generally too low. It is, therefore, preferable to use along with the carbon monoxide small quantities of hydrocarbons of known composition, or to use along with the carbon monoxide solid carbon in a properly divided state. It is the latter method—the combination of carbon monoxide with free carbon—which is advocated by the author.

Among the numerous advantages claimed for this method by the author are great speed of penetration of the carburized zone; great uniformity in the distribution of carbon in the carburized zone; possibility and ease of regulation of carbon concentration so as to get maximum hardness with minimum brittleness; absolute security against the introduction of foreign substances into the steel; a minimum of deformation and change of volume of the steel pieces.

While the process may be carried out in the ordinary horizontal muffle generally used for case-hardening, the following special furnace offers decided advantages.

As shown in the illustration on p. 600, it consists of cylindrical muffles arranged vertically and heated by producer gas. It is a double-muffle furnace provided with regenerators, of the kind constructed by Messrs. C. M. Stein, of Paris, for the Sampierdarena Engineering Works of Messrs. G. Ansaldo, Armstrong & Co.

The parts of the apparatus particularly applied to the case-hardening process are represented in the illustration which shows a section through the center of the vertical muffles of the furnace with the accessory apparatus completely mounted.

Inside each of the muffles of refractory material is placed a cylindrical retort of mild steel, A, the external diameter of which is about 10 to 20 millimeters less than the internal diameter of the muffle. Mannesmann seamless tubes serve very well for making the retorts, as they are easily obtainable in stock sizes up to 35 centimeters diameter. For retorts of larger diameter, as in the case of the furnace here represented, tubes welded by the autogenous process are used. The retort is supported on a bottom flange attached to a frame fixed to the brickwork of the furnace. The arrangement which serves to hold the retort, whether it is being supported by the bottom flange or by the upper flange, H, intended to receive the cover, is such as to enable one retort to be replaced by another in a few minutes. To the bottom flange is attached a cast-iron funnel B, closed at the bottom by a non-return valve Q.

The steel nozzle C, admitting the carburizing gas, passes through an opening in the side of the funnel, provided with a good-sized boss. The gas is introduced through the screwed tube D, and through the nozzle C. This latter is connected to the hollow cast-steel dish E, intended to support the pieces to be case-hardened by means of the disc F, consisting of a steel plate covered with refractory material.

The carbon monoxide, after passing through the hole bored axially in the nozzle C, is delivered into a small distributing device placed inside the dish E, from which it passes to the case-hardening chamber G, through a number of holes provided in the disc F. During case-hardening the dish E is supported upon a series of projections on the same lower flange to which the funnel B is attached. This ring has thus to sustain the entire weight of the dish E, the disc F and any articles to be case-hardened which may be resting directly or indirectly on the disc. The section shows exactly the position of the various parts during case-hardening.

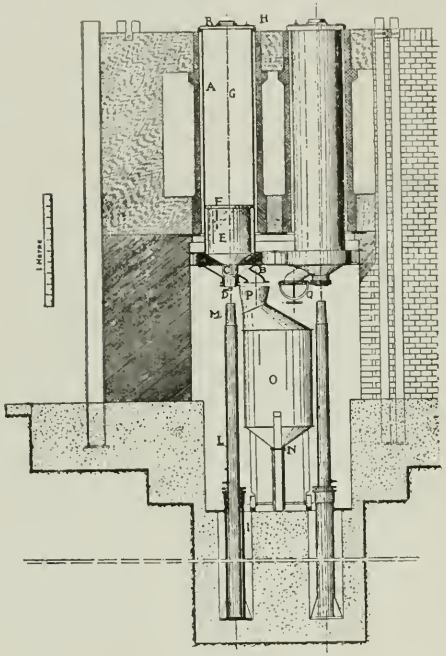
In the case of spur wheels, the maximum diameter of which might be 100 to 150 mm less than the internal diameter of the retort, the first thing to be done is to unscrew the tube D; then by means of the plunger L, actuated by the hydraulic cylinder I, the whole of the parts C, E and F are lifted together, the blunt conical end of the plunger M engaging with these as it rises. The plunger LM is cooled internally with water circulation, so as to avoid the heating of it in case it should accidentally remain raised inside the retort for too long a period.

When the piston L has reached the end of its stroke the upper surface of the disc F being now only about 30 cm below the cover of the retort; the cover is removed, and the wheels to be case-hardened are piled horizontally one on top of the other upon the disc F. As the wheels are inserted

one by one, the apparatus carrying the weighed portions C, E and F gradually sinks, and the charge is complete when the apparatus has reached the lowest position indicated in the figure. In that position the last wheel charged should be at least 30 cm below the upper edge of the retort.

Generally, the articles to be case-hardened are charged hot at a temperature of about 800 to 900°C, this being a matter of prime importance, as it affects most favorably both the quality of the product and the economy and regularity of the operation.

For the preliminary heating of the pieces a small coal-fired muffle will serve, since the uniformity of temperature which



CASE-HARDENING FURNACE.

can be obtained in such a furnace is quite sufficient for the purpose. If, however, the case-hardening furnace is not being worked to its fullest capacity, one of the vertical muffles may be used for the preliminary heating of the articles, while the case-hardening of the charge is proceeding in the other. In this case the best method of working the furnace is to use the muffles alternately, the one for case-hardening and the other for preheating the pieces.

As soon as the articles to be case-hardened have been inserted as described, the cover is placed on the retort and the bottom discharge pipe N, leading from the iron box O, is passed through the central opening in the cover. This box is full of the granular carbon still hot (generally at about 900°C.) which was discharged from the retort after use during the last case-hardening operation just concluded. The box is easily swung above the muffles, being suspended by a tackle from a swinging arm.

The outer walls of the box, notwithstanding that its contents of granular carbon are at a temperature of nearly 1000°C., do not become heated above 200° to 250°C. during the time required for the loading and unloading of the retort, even when working under the most unfavorable conditions. This is due to the small thermic capacity and the very low conductivity of the mass of granular carbon, which, although at a high temperature, can only impart to the walls of the box containing it a small proportion of its heat in a unit of time. The heat is quickly dissipated simply by the cooling action of the air currents passing around it.

The box O having been adjusted as indicated, the butterfly valve which closes the low end of the opening N is gradually opened, and in a few seconds the whole of the free space in the retort surrounding the pieces is filled with glowing granular carbon. The hot granular carbon employed by the author for case-hardening with his mixed medium constitutes a mass which, particularly at high temperatures, is endowed with a mobility comparable to that of a liquid. On this account it is able to penetrate simply by its own weight into all crevices among the articles to be case-hardened, and between these and the walls of the retort. The filling up may be further assisted by means of open rods introduced through holes in the cover and manipulated by the operator who stands on the furnace.

When the granular carbon has been filled in up to a level of 2 cm or 3 cm below the upper edge of the retort, the butterfly valve of the tube N is closed, the box O is lifted, the central opening of the cover is closed, the plunger L is lowered right down and the tube D is screwed into the nozzle C, through which the carbon monoxide or dioxide, pure or mixed with air, is admitted gradually to the distributor E and then into the retort. In order to regulate the current of carbon monoxide, an ordinary gas meter of the dry type is used. The case-hardening then proceeds without further trouble, the only thing that is necessary to be watched and regulated being the current of gas and the temperature.

For the observation of the temperature, an operation which, with the type of furnace described and when adjusted properly, does not often require to be made, an ordinary thermoelectric pyrometer is used by passing it through any one of the holes in the cover from time to time and inserting it into various parts of the mass of granular carbon. The temperature should be maintained quite constantly at a fixed point between 900° and 1100° C., chosen in accordance with the rules laid down by the author in the reports previously referred to.

The gas issuing from the retort through the pipe fixed in the cover can be collected in a gasometer, and after suitable regeneration it will serve for further heats. The necessary length of the heating period can be determined with the greatest precision, and is dependent on the result which it is required to obtain. When the heating has proceeded long enough, the current of carbon monoxide is shut off, the tube D is removed and the discharge of the retort is undertaken.

Where results of a very special nature are not aimed at, the discharging operation begins by withdrawing the whole of the granular carbon at once, and removing it through the non-return valve Q in the box O, now placed underneath.

Where, however, exceptionally graduated case-hardening is required, the specific action of the carbon monoxide is isolated during the last phase of the case-hardening from the direct action of the granular carbon. In that case the box O is placed so that the neck of the funnel B is inserted into the open end of the tube P, the box for this purpose being placed in the chamber below the muffle, where it can be maneuvered on a small bogie.

The non-return valve is then opened gradually and a quantity of the granulated carbon is drawn out from the retort.[1] Only those parts of the case-hardened pieces are uncovered in which a well-graduated case-hardening is required. Sufficient solid carbon is retained in the retort to ensure the desired chemical equilibrium of the gas. The remainder of the carbon is removed from the retort after the second phase of the case-hardening with isolated carbon monoxide has proceeded long enough to attain the desired results.

In either case as soon as the whole of the granular carbon

[1]The carbon contained in the retort falls out from below, passing first through a series of holes in the bottom flange upon which the apparatus C, E, F rest. It was, however, not possible to show all these holes in the accompanying sectional view of the furnace.

has been evacuated from the retort, the cover of the latter is lifted. In performing that operation the operator must be careful to remain at some distance from the upper open end, because the air which enters forms, with the carbon monoxide contained in it, a mixture which explodes suddenly at the high temperature of the retort. The explosion, which in any case is light and not at all dangerous, may be avoided by rapidly scouring the muffle with a little carbon dioxide after the removal of all the solid carbon. Care must be exercised, however, to perform this operation as quickly as possible, in order to prevent the carbon dioxide causing a superficial decarburization of the case-hardened pieces.

When the pieces rest direct on the disc F, as in the present supposed case, they may be lifted by means of the appliances C, E, F, up to the open top of the muffle without first discharging all the granular carbon from the retort. In that manner the light explosion just referred to is avoided, but the picking up of the pieces for quenching is made more difficult, and a considerable quantity of the solid carbon is apt to get burnt in the retort.

At all events, whether the carbon is removed from the retort or not, as soon as the cover R is removed the plunger L is raised until its conical head beds itself in the recess provided for it in the part C. The hydraulic ram then continues to move slowly, gently lifting the weight-supports, C, E, F, with the case-hardened pieces resting on them. It only remains then for the operator standing above the furnace near the open muffle to pick up the case-hardened pieces one by one as they come within reach and quench them in the tank, also placed above the furnace (in case double quenching is desired), or bury them in hot ashes. When all the pieces have been removed, the furnace is ready for a fresh charge.

The method of loading the pieces to be case-hardened into the retort varies greatly according to their shape or size. Pieces of cylindrical shape can be piled on one another as in the foregoing example. If the pieces are of small diameter, such as pinions, cutters, cups and rings for ball bearings, several columns can be built up for one heat; but in that case it is desirable to keep the pieces in position by threading them on iron rods, assuming that the external surfaces only require to be case-hardened.

For cylindrical pieces to be case-hardened internally, such as rings for ball bearings, the rods are placed outside the columns. Pieces of great length or of irregular shape have also been suitably supported in the retort. Finally, very small pieces are placed in cages formed of iron framework held together with iron wire netting. Such pieces can also be laid free on successive layers of granular carbon.

The operation of charging the retort may vary from 4½ to 6 minutes and may be increased to 10 or 12 minutes. The time required for the complete discharge of the retort is 3½ to 5½ minutes, though it may extend to 13 or 14 minutes.

Further, in the case of the process described and in almost all cases occurring in the practical production of case-hardened pieces for machine construction, in which the carburized zone is seldom required to exceed 2 mm in thickness, the period of case-hardening never exceeds 2 hours, and may even be reduced to one hour, the time being reckoned from the moment of completing the charging operation to that at which discharging begins. It, therefore, includes the time necessary for bringing the temperature up to working point, which requires not more than 10 minutes, owing to the fact that both the solid carbon and the pieces are already hot when charged.

The foregoing particulars show that in practice, under ordinary working conditions, the time for a complete heat is less than 2½ hours, and since the weight of the charge, which retorts of the size shown in the accompanying sketch can conveniently hold, varies from a minimum of 100 kg in exceptionally unfavorable cases to a maximum of over 500 kg, it will be seen that the productive capacity of each retort ranges from a minimum of 1 ton to a maximum of 5 tons of case-hardened steel pieces during a working day of 24 hours.

The chief advantages of the furnace described over horizontal muffles are greater speed of working, greater simplicity of operating, and increased uniformity of the treatment of all the pieces forming the charge in the muffle.

The author finally gives two examples which show what can be done in practice with this process, and especially how the distribution of the carbon in the carburized zones can be graduated by isolating the action of the carbon monoxide during a part of the carburizing period.

The following data refer to case-hardenings of medium depth from 5 mm to 10 mm) in which the application of the process in question presents the greatest technical interest, particularly in the case of very deep case-hardening. The tables give the contents of carbon in successive layers of a thickness of 0.5 mm, obtained by case-hardening with the mixed agent, followed by exposure to the action of carbon monoxide isolated in the manner previously described.

First Case.—The material used was an ordinary mild steel containing 0.12 per cent C, 0.06 Si, 0.47 Mn, 0.02S, 0.03 P.

The figures in the column marked *a* give the amount of carbon in the different layers after case-hardening for ten hours at 1100°C. with the mixed agent; *b* gives the amount of carbon after reheating the same carburized zone for five hours at 1100° C. in isolated carbon monoxide; *c* gives the amount of carbon after reheating the same zone for another five hours (altogether ten hours of reheating) at 1100° C. in isolated carbon monoxide

No. of range of single layers analyzed.	Distance of layer analyzed from surface.	Amount of carbon. *a*	*b*	*c*
1	0.5 mm	1.17	0.85	0.70
5	2.5	0.81	0.78	0.67
10	5.0	0.34	0.46	0.53
15	7.5	(0.12)	0.25	0.39

Second Case.—The material used was a chromium-nickel steel of the kind ordinarily used for Krupp armor-plates. On this account the data here given relative to case-hardening at moderate depth are of peculiar interest. The steel contained 0.33 per cent C, 0.06 Si, 1.15 Mn, 0.02 S, 0.015 P, 1.50 Cr, 3.17 Ni.

The results after each single phase of treatment were as follows The figures under *a* give the amount of carbon after case-hardening for ten hours at 1100°C. with the mixed agent, *b* the amount of carbon after reheating the same carburized zone for five hours at 1100°C. in isolated carbon monoxide, *c* the amount of carbon after reheating the same zones for a further five hours (total reheating period ten hours) at 1100°C. is isolated carbon monoxide.

No. of range of single layers analyzed.	Distance of layer analyzed from surface.	Amount of carbon. *a*	*b*	*c*
1	0.5 mm	1.16	0.80	0.86
5	2.5	0.81	0.77	0.87
10	5.0	0.50	0.58	0.75
15	7.5	(0.33)	0.45	0.59

The author concludes that his process permits to obtain carburized zones in which are eliminated the principal causes of brittleness and peeling which always occur, in a greater or less degree, in steels case-hardened by the ordinary process. The principal causes of these defects are excessive concentration of carbon in superficial zones of the case-hardened pieces, and the rapid diminution of the carbon in passing to the deeper layers. It is also worthy of note that this rapid diminution contributes in a high degree to render more intense the phenomenon of liquation of the cementite or of the corresponding complex carbides of the various special steels, and of the ferrite. These phenomena in their turn are productive of the sudden local variations of the concentration of carbon in the carburized zones to which is due the peeling off of the carburized and quenched zones.

Finally the ability to alter the form of the curves of case-hardening, as shown in the two examples, suggests that case-hardening can also be successfully applied to those special steels on the exterior of which the ordinary process of case-hardening yields carburized zones, which are practically useless on account of their excessive brittleness.

Case-Hardening by Means of Compressed Gases.

A paper by F. Giolitti and F. Carnevali, both of Turin, Italy, deals with the effect of gaseous pressure in case-hardening by means of compressed gases, especially by the method (described in the preceding paper in detail) employing the "mixed agent" of carbon monoxide gas and free carbon.

The authors have formerly found that the characteristics of cementation zones vary in notable fashion concurrently with the variation in pressure of the carburizing gas, in the sense that an increase of pressure produces (all other conditions remaining unchanged) an increase in the depth of the cementation zone obtained within a given time and an increased concentration of carbon within the zone itself.

The authors have investigated this phenomenon quite carefully. The arrangement of their experiments is described in detail in the paper and the results of the treatment of six different steels are given. The case-hardening was accomplished by means of a mass of wood charcoal traversed by a slow current of carbon dioxide. This gas supplies with great rapidity and without any possible excess of carbon monoxide, a mixture of carbon dioxide and carbon monoxide of a concentration exactly corresponding to the equilibrium with free carbon, under the conditions of temperature and pressure employed in the operation.

The tests tabulated in the paper show clearly that an increase in pressure of the carburizing gas increases the depth of the case-hardening and the concentration of the carbon in the carburized zone as stated before.

A secondary effect observed is that an increase in the velocity of the current of carbon dioxide tends to cause a diminution in the intensity of case-hardening to such an extent as to eliminate the effects of increase of pressure. This is due to the fact that, on account of the high speed of the carbon dioxide, the carbon monoxide gas does not reach a concentration corresponding to equilibrium.

A third effect which occurs frequently in the course of case-hardening operations carried out under high pressure by means of a case-hardening mixture based on carbon monoxide is the superficial oxidation of the case-hardened steel. This effect is made the subject of a long discussion of the theory of the process.

Finally the authors remark that an understanding of the theory of the process permits to draw valuable practical conclusions.

One example is the fact that the case-hardening of steels with rather high percentages of chromium (more than 4 or 5 per cent) with "mixed cement" at a temperature not higher than 1000 deg. C. (a limit which in many cases cannot be exceeded) is accompanied by considerable oxidation of the metal, even when the process is conducted below ordinary atmospheric pressure.

Now, the results of the tests of the authors suggest immediately a method of avoiding this oxidation; it will suffice, indeed, to reduce the pressure of the carburizing gaseous mixture ($CO + CO_2$) below the minimum pressure of oxidation characteristic of the particular metal at the temperature at which it is being case-hardened. This can be in many cases easily accomplished by "diluting" with air the carbon dioxide which is circulating through the mass of granular carbon. In this way the carburizing gaseous mixture acts under partly reduced pressure, since it is "diluted" by the nitrogen of the atmosphere.

Experience has abundantly confirmed the efficacy of this method.

Abstracts of the other papers presented at the meeting will be given in our next issue.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

The Institute of Metals.

The autumn meeting of the Institute of Metals took place on the 20th, 21st and 22nd of September at Newcastle-on-Tyne. It is noteworthy that the whole of the papers dealt with non-ferrous metals and alloys, and that the subject of corrosion in connection with such metals and alloys received a considerable share of attention. Abstracts of the papers presented were given in the October issue, page 515. In the following we give an account of the discussions:

Non-Ferrous Metals in Railway Practices.

Mr. George Hughes, of the Lancashire & Yorkshire Railway, read a paper on "Non-ferrous Metals in Railway Work" (abstracted in the October issue, p. 516.) The paper extended only to the use of non-ferrous metals in the locomotive and rolling-stock departments, and was peculiarly valuable on account of the author's description of the means of overcoming difficulties liable to occur in course of manufacture. The chief metals dealt with were copper and copper alloys and aluminium.

The discussion was opened by Mr. A. V. Hussey who said that the successful soldering of aluminium yet remained to be achieved; but the autogenous welding process was being largely used with satisfactory results.

Dr. G. H. Desch said that the statement that copper containing 0.3 per cent of arsenic was preferable for fire-box stays was not in accordance with usual experience.

Mr. H. Woore remarked that with phosphor-bronze slide valves running on cast-iron faces, he had found the wear to vary very widely, and he was inclined to ascribe this variation to differences in the cast iron.

Prof. Huntington, with regard to the use of bronze slide valves working with super-heated steam, said that the Lancashire and Yorkshire Railway seemed to have had very good fortune, but as the employment of super-heated steam in locomotives increased it was certain that the discussion of the subject would be revived.

Mr. L. Boeddecker desired to point out that the author had neglected the good points of copper-nickel alloys. The alloy containing 2 per cent of nickel possessed the remarkable property of increasing its tensile strength, after long annealing, from 15.2 to 16.1 tons; and there was a further improvement to 17.1 tons per square inch after five hours' heating in the fire-box of a locomotive.

Prof. H. Louis said that, although the paper compared copper with steel fire-box plates, no comparative figures were given for best Yorkshire iron, and he thought figures for that material were desirable.

Prof. Carpenter pointed out that the specification for copper boiler tubes especially directed that the ends should not be annealed; but this was quite contrary to the proposition of Dr. Beilby that all copper which was to be used for superheating should be annealed at 300° to 350°C.

Sir Gerard Muntz said it was gratifying to know that copper nickel alloys were being experimented with, and it was probable that they would displace the alloys of copper with arsenic. The alloy containing 2 per cent of nickel was stated to retain a tensile strength of 14 tons up to a temperature of 700°C. Pure copper, under the same conditions, gave only six tons; and the usual arsenical copper about ten tons per square inch. There was one point which frequently appeared to be lost sight of in the practical use of copper, and that was the very great influence of the oxygen content on the qualities of the copper.

Hard-Drawn Copper.

A paper on "The Mechanical Qualities of Hard-drawn Copper" was contributed by Mr. D. R. Pye, who directed attention to the want of any satisfactory standard specification for

the properties of hard-drawn copper and the consequent variation of metals so described when obtained from different manufacturers (in October issue, p. 516). He suggested as a satisfactory definition of hard-drawn copper, "Hard-drawn copper, when in the form of circular wires, should have a tensile strength not less than that given by the formula $T = 30 - 20\ D$, and an extension per cent on a marked 10 in. length including the point of fracture, of not less than that given by the formula $e = 5\ D$, where T = tensile strength in tons per square inch of original section, e = extension per cent, and D = diameter of the circular rod in inches."

Mr. A. P. Trotter said that further tests were clearly necessary, as tests of material furnished by one manufacturer only did not constitute a satisfactory basis for action; and manufacturers were chary of making their results public property. They would not give any description of their processes; and users of hard-drawn copper had to be content with what they could get.

Sir Gerard Muntz said it was curious that the amount of work put upon the metals was not taken into account in drawing up specifications. It was his experience that the same specifications were received repeatedly both for 16-gauge wire and for ½-in. wire, and of course the differences of diameter should be allowed for.

Conductivity and Constitution of Alloys.

Dr. W. M. GUERTLER read a paper on "The Electrical Conductivity and Constitution of Alloys" in which he discussed the determination of the constitution of alloys from their conductivity (abstracted in the October issue, p. 517).

Dr. W. Rosenhain opened the discussion and said that the paper was useful in that it directed attention to the limitations of the methods habitually employed by metallurgists in ascertaining the composition of alloys, especially the limitations of thermal analyses. All would welcome the additional method of investigation, but that method also had its limitations. He did not intend to depreciate the value of electrical methods, and thought that metallurgists had unduly neglected those methods in giving preference to thermal results and microstructure.

Dr. C. H. Desch considered that the author had furnished distinct evidence of the existence of inter-metallic compounds in solid solution; and that had recently been extended to the region above the liquidus curve. There was thus proof of the existence of compounds in a liquid state such as had hardly been obtained before with aqueous solutions.

Prof. T. Turner said he was glad that the author had indicated the inutility of expecting to get good conductance in an alloy. Metallurgists seemed to be unable to solve the problem; and it remained to work for the improvement of the mechanical properties of the alloy to a greater extent than the conductivity decreased.

Copper-Tin Alloys.

"Volume Changes in the Alloys of Copper with Tin" was the title of a paper by Mr. J. L. HAUGHTON and Prof. T. TURNER, from which the following conclusions were drawn: (1) the expansion during solidification is closely related to the crystallization interval, except in two regions, but the nature of the relationship is not clear; (2) allotropic changes, during and after solidification, cause variations in the coefficient of expansion; (3) accurate determination of the densities of copper-rich bars on original castings is rendered impossible by blow-holes; and (4) the hardness curve does not fit in with Kurnakow and Shemtschusny's theory, probably owing to the metastable condition in which the bars exist. (See also October issue, p. 515.)

In the course of a brief discussion Dr. Rosenhain remarked that the method described in the paper was suitable for rough analysis, but not for ascertaining the composition of the complicated alloys of the copper-zinc series.

Dr. Desch said that the effect of crystal thrust complicated the interpretation of the results.

Prof. T. Turner, in reply, claimed that the experimental methods adopted were duly adequate; and that the volume changes measured corresponded exactly with those obtained in practice. The results arrived at had moreover been corroborated by the researches of Keep and Wüst.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the eight months ended on the 31st August, put the value of imports of iron and steel, including manufactures, at £7,369,674, and exports at £28,605,040, the respective increases being £1,615,364 and £307,944 as compared with the corresponding period of last year. The imports of other metals, including manufactures, were £18,160,533, and exports £7,071,749; increases of £2,701,540 and £397,887. Imports of electrical goods reached £887,215, with exports of £1,781,520, a decrease in imports of £89,404 and a decrease in exports of £821,516. The value of imported machinery was £3,984,669, and of exports £20,417,462; increases of £986,015 and £1,352,224 respectively. Imports of new ships amounted to £56,796 and exports to £3,703,481, an increase in imports of £39,063 and a decrease in exports of £3,349,499. Taking the month of August only, during which the strikes had a considerable effect on trade, all the exports except those of machinery were materially lower than in August, 1910. Iron and steel fell by £177,452; other metals dropped £75,735; electrical goods fell £400,960; while the value of ships declined by £1,713,224. In imports for August, iron and steel show an increase of £104,314; other metals rose by £3,763, and machinery by £29,339, but electrical goods dropped £43,378 and new ships £1,793.

Electric Steel.

An article entitled "Electric Steel: Its Position and Requirements," which appeared in the *Times* of the 9th August, has given rise to a prolonged and decidedly interesting controversy in the columns of that newspaper, from which it would appear that the views of the writer of the article are widely shared by steel users in England, and to some extent in other countries too.

One correspondent points out that a power consumption of 540 kw per ton in a two and a half ton Héroult furnace, would mean the extraordinarily high furnace efficiency of 79.25, but would only effect the melting of scrap, and not the making of steel or the killing of the metal. Another questions the lasting or fatigue properties of electric steel giving the same analysis and having the same tensile strength and elongation as basic hearth steel. But, without going into the various points discussed, it may be stated that unless and until much greater uniformity of quality and properties than are at present obtainable in electric steel can be secured there is little prospect of the new product making much headway here, especially among tool makers.

A flood of light is thrown on the subject by the remark of a certain German file manufacturer, who after using electric steel for a time handed an order to a Sheffield steel traveller, saying "Thank goodness I am going to have a steel again from which I can get more than two files alike out of a bar."

On the other hand, English steel-makers recognize the possibilities of electric steel; and although the number of furnaces now running is small, it is slowly increasing. The "Electro-Flex Steel Company" is putting down an initial installation of two one-ton Stassano arc furnaces at Dunston-on-Tyne for the production of steel by exclusively electrical methods.

A New Process of Electroplating

Plant has been erected in London for the demonstration of improved methods of electroplating, adopted by Mr. Q. Marino, which are apparently applicable to the deposition of all the ordinary metals and alloys on almost any metal and on non-metallic substances. It is noteworthy that aluminium

receives perfectly adherent coatings either of pure metals or alloys after a special preparatory treatment of brief duration—while for protecting iron with zinc the deposit obtained by the new process has obvious points of superiority over the coating obtained by the ordinary galvanizing. Tin-plate of very superior quality is said to be produced more economically than by the method in general use.

After certain chemical treatment which makes the surface conducting, without employing varnish and plumbago or other similar means, china and glass are coated with a film of adherent metal which can be polished, burnished and subjected to heat treatment.

Market Prices.

September, 1911.

Copper has remained fairly steady on the whole. On August 30th it was £56, and remained at this price till the 8th, then fell off, touching £54.7.0 by the 20th, but since recovered to £55 at which it closed.

Tin has been as erratic as usual. Starting at £192.10.0, it fell rapidly to £186.0.0 by the 5th, to £179.0.0 by the 14th, £176 on the 19th, and £171 on the 25th, closing, however, at £179.10.0, a recovery of nearly £9 in 5 days.

Lead fairly steady, and strong, opened at £14.12.6, rose to £15 by the 14th, and continued rising to the close, at £15.10.0.

Haematite has been flat, with a rise towards the end of the month, opened at 61/-, rose to 62/3 and remained at this price till the 21st, closing at 61/9.

Scotch Pig has been rather lower, opening at 53/-, dropping to 52/9 by the 14th, and closing at 52/6.

Cleveland has also been depressed, opening at 46/10 by the 14th, it ultimately closed at 46/6.

India Rubber (Para fine) has fallen off, opening at 4/9½, it was 4/½ on the 14th and closes 4/8.

	£ s. d.

Carbolic Acid, gal.	1
Platinum	12. 6
Fall	
Copper Ore, unit	4½
Sulphate of Ammonia, ton	7. 6
Tin Ore, ton	8. 0. 0

The Braden Copper Company, operating in Chile, has recently completed the first unit of its new concentrating plant. The complete mill will have a capacity of 3000 tons per day, and the first unit of 1000 tons capacity is probably now in operation. The ore is low grade, averaging 2.7 per cent copper.

Synopsis of Metallurgical and Chemical Literature.

Gold and Silver.

Economics of Tube Milling.—The tube mill was first introduced into the metallurgical industry by Dr. Diehl in Kalgoorlie in 1892, but it was not until 1905 that the machine assumed any importance in metallurgy. About the latter year it was extensively introduced on the Rand, where it has continued to grow in favor. The latest reports from the Rand show that 218 tube mills were in use there in June 1911, compared with 178 in the same month in 1910. In spite of the wide use of these machines the most efficient manner of their operation has not been a matter of settled conviction, and consequently the tests made by H. Stanbish Ball at McGill University, Montreal, Canada, are very interesting and valuable. The full results of Mr. Ball's work have been printed in *Bulletin* No. 83, Inst. of Min. and Met. The paper is replete with tabulations and curves which cannot be reproduced here, but the following gives a concise summary of the main points established.

Four series of investigations were carried out to determine the most efficient feed, moisture, pebble load and speed. In each series one of these factors was varied while the other three remained constant. Stadler's proposal for estimating crushing efficiency, based on Kick's law, was adopted in the calculations, and standard screen of the I. M. M. were used in the grading analyses. A general summary of all tests is given in the accompanying table.

*Most efficient test of series.

Series I.—Tests to determine the most efficient rate of feed. From the results obtained it was found that a feed of 18 tons per 24 hours is the most efficient one for the laboratory mill, any larger feed apparently causing the crushing efficiency as well as the relative mechanical efficiency to decrease. (The tube used in the experiments had outside dimensions as follows: 4 ft. 8 in. by 3 ft. 5 in. The lining was silex brick set in cement.)

This is a most interesting point, as a critical feed is indicated, above which it seems probable that the fine grinding properties of the mill decrease in proportion approximately to the increase of feed. The theory of a critical feed may have an important bearing in modern practice, as it would seem that more efficient working, with a greater output of slimes would be obtained if a smaller feed were used. In South Africa the tendency at present is to increase the feed in the 5½ by 22 ft. mills, and although they are now feeding at the rate of 400 tons per 24 hours, the belief is held that even heavier feeds would result in increased grinding. The results of the present investigation show the danger of carrying this too far. Comparing the South African mills with the laboratory machine, it appears that the former would give better results if fed with about 300 tons per day instead of 400.

Series II.—Tests to determine the most efficient percentage of moisture in the feed.

The outstanding feature of these tests is the great efficiency of 37.7 per cent moisture over all others. This fact coincides with tests carried on in other parts of the world. In those conducted by Mr. Walter Neal the ideal dilution was determined to be in the neighborhood of 39 per cent moisture, although he believes that the critical point will vary with the size and nature of the mill. The results of the author's tests tend to disprove this belief. Sherrod found that the mill efficiency rose when the moisture was present to the extent of 40 to 45 per cent. G. O. Smart found the best moisture to be 38.5 per cent, while H. W. Fox discovered that, taking the power consumption in conjunction with the fine grinding, the most efficient moisture would be 39.6 per cent. Prof. J. W. Bell suggests that the critical moisture point depends on the percentage of voids in the sand, and that in all probability when the percentage of moisture is numerically equal to the percentage of voids in the sands inside the mill, the moisture is critical.

In connection with the tests on moisture, some novel work was done. From the first series of tests, on the variation in feed, it had been determined that the mill assumed uniform conditions after a period of about 35 minutes from the start of the test. This fact gave rise to the following idea, viz., if the mill was run for a given time at a certain fixed moisture until the conditions had become uniform and the moisture was then suddenly raised to another fixed point without stopping the mill, but allowing it to run for the same period, would not one be justified in assuming that the samples and power readings taken during the transition period of the mill from one state of normal conditions to the next, are representative of its product caused by the amount of moisture in it at that exact moment at which the sample was taken.

To test this theory, samples and power readings were taken at intervals of five minutes throughout three tests and were most satisfactory. It was found that whereas the mill took 30 minutes to adjust itself after the moisture had been changed from 30 to 50 per cent, it took only 12 minutes to assume uniform conditions from a change of 50 to 58 per cent, thus indicating that the time of change was proportional to the amount of change of moisture. With this fact so clearly demonstrated it was a simple matter to calculate what percentage of moisture the mill contained at the precise moment when a transition sample was taken, e. g., since the first transition period was 30 minutes and five samples were taken, the corresponding percentages of moisture would be 33 1/3 per cent, 36 2/3 per cent, 40 per cent, 43 1/3 per cent, 46 2/3 per cent. In the curves plotted by the author, the points obtained for these transition samples coincided with remarkable regularity with the curve drawn through the main points obtained for the actual tests. Hence the adoption of this method was more than justified, as it saved considerable time, material and labor, and gave a number of moisture efficiencies which otherwise would have been impossible to obtain.

Series III.—Tests to determine the most efficient pebble load. The result of this test indicated that the most efficient pebble load is about 7/16 of the volume of the mill, whereas, disregarding power, the most effectual crushing load is about 0.6 of the volume which corresponds to present Rand practice. Whether it would pay to sacrifice power and gain fine grinding, of vice versa, would of course depend upon the conditions of the plant.

Series IV.—Tests to determine the most efficient speed of mill. These tests were most interesting as they proved rather conclusively that 37 r. p. m., at a peripheral speed of 333 ft. per minute, was the most efficient, both in relative mechanical efficiency and grinding efficiency; thus demonstrating that at that speed the grinding was decidedly better and the power required less. If this speed is exceeded or decreased the crushing effect of the pebbles is much reduced, while the power required is increased. The efficient speed determined by the tests, viz., 37 r. p. m., compares with other determinations as follows: Davidson, 34; White, 39; Richards, 38.

General Conclusions.—In connection with the curves obtained from the different tests it is the author's belief that there is a possibility of deducing from them the probable results that would be derived by running the mill under different conditions. It seems that if one complete series of tests was run with a constant feed, the other factors being varied and the respective curves obtained, one would be able to deduce from them all the necessary information regarding any feed, provided that one test at that particular feed had been carried out.

Factors in Mexico's Progress.—Twenty years ago the bulk of Mexican silver ore was treated by the Patio process. Attempts were made frequently to introduce the American pan system, but for various reasons it was not successful. The non-adaptability of the ore; its irregular supply and the lack of mechanical knowledge stood in the way of progress. Changing conditions, however, forced new methods into Mexican metallurgy and have made it what it is to-day. In the *Informes y Memorias* of the Mexican Institute of Mining and Metallurgy, VICTOR M. BRASCHI discusses the influence of some of the factors in Mexican progress. He regards the smelter, electricity and the cyanide process as the three most important of these.

The smelter first proved a benefactor in eliminating the long time usually required for recovery of the value from ore. Instead of the thirty days required for treating the torta, the smelter bought and paid for the ore on delivery. This resulted in abandoning to a large degree the Patio process, and most of the ores were diverted to the smelter. To quote Mr. Braschi's words, "The smelter began by helping the Mexican industry, but it was ending by throttling its very life." It had not only established a monopoly in ore treatment, but it had bought many large mines, and was making the lion's share of the profit.

About this time the cyanide industry was firmly established in the old mining district of Guanajuato, and the development of hydroelectric power in Michoacan combined with the cyanide process to point the way to freedom of the miner from the smelting process. Both of these improvements made much ore available that formerly could not stand the freight and treatment charges of the smelter. Not only ore in place, but much that was in the stopes and on the dump was treated at a profit.

It is Mr. Braschi's opinion that a modern school of mines and metallurgy will be the next step in the development of Mexico's wonderful mineral resources, and that chemical engineering also will be a great aid in utilizing many nonmetallic resources.

Continuous Cyaniding at Natividad, Mexico.—In a paper read at the Wilkes-Barre meeting of the American Institute of Mining Engineers, in June, 1911, Mr. HUNTINGTON ADAMS presented the results of continuous agitation in Pachuca tanks at Natividad, Mexico.

The difficulties encountered in intermittent filling and agitating in tall tanks of the Pachuca type are principally those due to the accumulation of pulp in the cone of the tank. Therefore a continuous flow of pulp from tank to tank has been devised and put in operation in several places. In this way the time of agitation of all the pulp is longer than by intermittent filling, and all particles of ore have the best opportunity to come in contact with the circulating solution.

The main point to be observed in continuous flow is that the composition of the pulp as regards ore and solution shall be maintained as uniform as possible. Otherwise a classification will result and in some tanks heavier particles will accumulate while the lighter particles pass on through the system. The only sure method of obtaining a uniform flow through the system is by arranging the overflow connections from tank to tank so that they will sample the overflow of the air lift pipe. This sampling should make a clean cut of the whole thickness of the air lift discharge. Some previous installations have not ob-

served this point, their connections being placed in the sides of the tank.

At the Natividad mine the concentrate is cyanided with the rest of the pulp after being ground very fine. Johnston vanners concentrate the slime overflow from Dorr classifiers, the concentrate being returned to the tube mill and reground until too fine to be caught on the vanners.

The arrangement of tank connections is as follows: A drop of 4 in. is used from tank to tank, and the central air lift tubes are cut down or added to in order to give this drop. Wooden boxes 7 in. wide, 10 in. long and 6 in. deep are fixed against the central tubes with their tops flush with those of the tubes, and 4 in. pipes placed horizontally pass from the bottom of each box to the next tank in series. Bypass pipes fitted with valves, join each pipe connection with the next in the series, and the 4 in. drop from tank to tank is made in the by passes. Since the level of the inflow pipe in each tank is 2 in. below the tops of the air-lift tube and of the overflow box connected with the outflow pipe, but is slightly above the pulp level in the tank, no part of the pulp entering can pass out of the tank without first gravitating to the bottom, and risen through the air-lift tube, thoroughly mixed with the whole content of the tank.

On the tops of the overflow boxes are sliding iron covers which open at right angles to the direction of the overflowing stream. The regulation of the flow from tank to tank is done entirely by means of these covers, and the valves are used only when it is desired to bypass the tanks. The boxes are sufficiently large for the tonnage passing through agitation, so that the covers need be opened only an inch or two. The openings which sample the pulp stream are thus rectangular, with their long axes parallel to the radial overflow at these points; and while theoretically this is not so correct a shape as would be a sector of a circular ring, in practice it has been found to offer no difficulties.

As the last tank in the series discharges to the pulp tank of a Moore filter, where an intermittent feed is important, it is arranged with two pairs of sliding doors on the central air-lift tube so as to permit agitation at various levels. The pulp is drawn off intermittently to the filter through the bottom discharge openings of the tank, either by hydrostatic pressure in the tank if full enough, or by centrifugal pumps. All the tanks retain their bottom discharge connections with the pumps which lift to the filter, so that whenever it is necessary to empty any of them they may be cut out of the series and discharged to the filter.

The advantages of the Natividad installation over those of Grothe and Kuryla seem to be: Greater simplicity of installation; greater accessibility for handling and supervision; no plugging of the pipe connections can occur and no compressed air connections are necessary to free them; no classification is likely to occur as the boxes by which the flow from tank to tank is regulated provide convenient means of accurately sampling the mixed pulp as it overflows the air-lift tube, and the proportion of solution to slime remains the same throughout the whole system.

Physical Chemistry.

The Specific Heat of Solids at Extreme Low Temperatures.—In 1905 Dewar published a series of interesting results on calorimetric measurements carried out at temperatures of solid carbon dioxide and liquid air. (See *Chemical News*, 92, 181). Recently Herman Barschall reconstructed the Dewar apparatus so as to ensure greater accuracy in the determinations. It consists essentially of three Dewar vessels, one inside of the other. Details and cuts are given in *Zeitschrift für Elektrochemie* of May 1. Only a few grams of the substance, whose specific heat is to be measured, are required to obtain very accurate results. The author found the following values for the specific heat at 183 C; lead, 0.0294; silver, 0.0402; cadmium, 0.0503; sulphur, 0.119; mercury, 0.0316; bromine, 0.073; mercuric iodide, 0.0375; lead iodide, 0.0377; lead bromide, 0.0463.

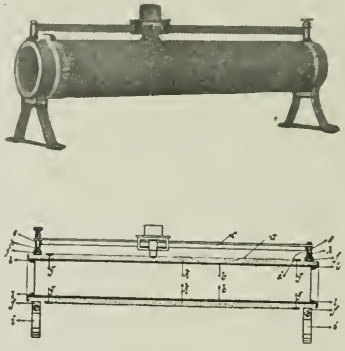
The Heat of Evaporation of Oxygen.—H. Barschall has made a new determination of the heat of evaporation of oxygen (*Zeitschrift f. Elektrochemie*, May 1.) The average of six experiments is 51.30 calories per gram of oxygen boiling at ordinary atmospheric pressure. This value approaches that of Alt 50.97 rather closely, but is considerably smaller than the figure 61.0, published by Shearer in 1903.

Improved Laboratory Rheostat.—A German firm has recently put on the market a new porcelain tube resistance unit particularly adapted for laboratory purposes. As is shown in the accompanying figure the porcelain tube k is lined inside with a metal tube, the contact between metal and porcelain being the best possible. The resistance wire, wound on the outside of the porcelain tube, can be kept at temperatures approaching red heat without serious effects on the tube. The rheostats may be had in lengths of 10 to 100 centimeters. (*Zeitschrift für Elektrochemie*, June 1.)

Chemical Engineering.

Wislicenus Smokestack for Fume Dilution.—Investigation has pretty clearly established the maximum quantity of noxious gas which vegetation can successfully withstand. For SO_2 in relation to sensitive trees such as the spruce, this density is one part of gas in 500,000 parts of air. This is a small percentage, but is not much less than exists in some of our industrial towns other than smelting centers. In the latter the percentage rises much higher, and the necessity of diluting the gases in some manner becomes more important. To this end Dr. Wislicenus, of Germany, has invented a smokestack designed to aid in rapid dilution of discharged gases. The full description appears in the *Zeitschrift* Ver. Deutscher Ing., June 10.

If stack gases are to be diluted so that they will not be injurious they must mix with large volumes of air at the time of their discharge from the stack, as it is well known that from



RHEOSTAT.

high stacks especially the smoke will persist in density for long distances. It is Dr. Wislicenus' idea that if the upper part of the stack were built in lattice form, with a large number of apertures for escape of the gases, a more rapid dilution would occur. Eddies would be formed which are most favorable to dilution. Consequently he has experimented with models and on a large scale, and has designed several forms of lattice structure which break up the dense smoke and mix it immediately with larger volumes of air than would be the case if the dense smoke issued in the ordinary way. One form of lattice consists simply of radial openings, another of tangential openings, and still another with projecting and enlarged vents for steel stacks. Correct construction is necessary to obtain the best effect.

Removing Oil from Return Feed Water.—The presence of any considerable quantity of oil in return feed water is injurious to boiler tubes and plates, reduces the evaporative efficiency and aids in the deposition of scale. Various schemes have been proposed to overcome this, such as submitting the water to an electrical discharge between iron electrodes for the purpose of

coagulating the oil. This scheme, however, has been found to cause deterioration by corrosion, probably due to electrolysis.

A successful plan is described by C. E. CROCKER in the July 1911 *Journal* of the Chamber of Mines of Western Australia. It consists in treating the oily water with alum and common soda in the proportions of 0.35 lb. of alum and 0.30 lb. of soda per thousand gallons of water, for water containing 3.5 grains of oil per gallon. The quantities of chemicals used are, of course, proportioned to the quantity of oil contained in the water. The apparatus should have sufficient capacity to allow the chemicals ample time to act. In the plant referred to the capacity is 50,000 gallons per 24 hours, and the tanks and filters are arranged so that five hours are required for the water to pass through.

The alum and soda are mixed in tanks and allowed to drip into the incoming oily water. The precipitated water is filtered through coke, charcoal, shavings, or any open porous bed. The filters are cleaned as often as necessary. The cost is about 2.3 cents per 1,000 gallons. The plant has been in operation for two years, and the boilers require less cleaning than formerly.

Ozone.

Ozone Generators.—Prof. C. HARRIES, of Kiel University, reports in the *Zeitschrift für Elektrochemie* of August 1, results of experiments made with a Siemens and Halske ozone generator. When using pure oxygen a maximum output of 18 per cent to 19 per cent ozone was obtained at a potential of 7400 volts alternating current, and frequency of 100 at 20° C. The ten glass tubes of the generator were mounted in a wooden instead of the usual metallic frame, and as a consequence an appreciable increase in efficiency was obtained. For parallel connected tubes the most favorable gas velocity was 60 liters per hour and for series connected, 8.6 liters per hour.

The efficiency of the generator increases after repeated using. When air or pure nitrogen was passed through the tubes an intensive blue luminescence appeared which was absent, however, when pure oxygen was used. This blue luminescence is not to be confused with the blue color of highly concentrated ozone gas; it is not due to the presence of traces of oxides of nitrogen, as Warburg and Leithaeuser had assumed, but is the inherent color of the gas. Ozone will react fairly readily with unsaturated hydrocarbons resulting in addition products, such as ethylen ozonide and propylenoxozonide, that are highly explosive. The study of these compounds lead to the assumption that ozone gas contains quadri-atomic oxygen besides the tri-atomic. By careful fractional distillation and analysis the author succeeded in verifying his assumption. The formula of oxozone is either O_4 or O_5.

GIDEON LECHNER has investigated the efficiency of a Berthelot ozonizer. With direct current he finds that the ozone output is directly proportional to the frequency of the interrupter. Increasing the closed-circuit interval of the interrupter increases the mean current intensity and at the same time almost proportionately the ozone output. An alternating current of 42 cycles is more efficient than a direct current of frequency 42 owing to the flatter form of the wave and consequent greater mean current intensity. (*Zeitschrift für Elektrochemie*, June 1.)

Minimum Potential of Silent Discharge.—Prof. E. H. RIESENFELD, of Stockholm, investigated the behavior of a large number of gases when passed through a generator tube of the Jannasch type. The results are recorded in the *Zeitschrift für Elektrochemie*, September 1. The author found that the relative minimum potential necessary to bring about the silent discharge is well defined for every gas and independent of the size or shape of the generator tube, of the velocity of the gas and of the frequency of the current. The relative potential is defined as the potential expressed in terms of the oxygen potential taken as unity. The minimum potential of a gas is proportional to its continuous potential or potential required to effect a steady continuous discharge. The author's values for the relative minimum potential are: Hydrogen, 0.77; nitrous oxide, 0.85; ammonia, 0.97; oxygen, 1.00; carbon dioxide, 1.03; carbon monoxide, 1.032; acetylene, 1.11; ethylene, 1.11; nitrogen, 1.16; hydrogen sulphide, 1.27; hydrochloric acid gas, 1.27; chlorine, 2.42. The luminescence color of each gas is very distinct and different from that of any other. Hydrogen shows a pale blue, oxygen a deep greenish blue, nitrogen a decided purple, and chlorine a very intense green luminescence. There does not seem to be any direct relation between the phenomena of spark discharge and those of the silent discharge.

Electrolytic Production of Ozone.—The electrolytic production of ozone was recently investigated by E. H. ARCHIBALD and H. VON WARTENBERG (see *Zeitschrift f r Elektrochemie*, September 15.) Dilute solutions of sulphuric acid were electrolyzed with direct current and with alternating current superimposed. Owing to the depolarizing effect of the alternating current the output of ozone was greatly increased over that obtained with direct current alone. In some cases the increase was three hundred fold. Platinum electrodes were used. By keeping the intensity of the direct current constant and increasing the alternating current step by step the amount of ozone rose steadily. The maximum output was obtained at about 6 amperes, alternating current, for all values of direct current between 0.25 and 1.00 amperes. An increase in the frequency of the current was accompanied by an increase in the ozone output. The principle involved is commercially utilized by the Norddeutsche Affinerie in their gold-silver parting process (Wohlwill process.) Formerly, when using merely direct current, a considerable part of the chlorine escaped the bath as gas instead of combining with the silver; this loss, however, is now entirely avoided by superimposing an alternating current. (See our vol. viii, p. 82).

Recent Metallurgical Patents.

Iron and Steel.

Nodulizing and Desulphurizing Kilns.—For the purpose of desulphurizing and nodulizing iron ores in one rotary furnace, Mr. DAVID BAKER, of Philadelphia, Pa., has patented a furnace. The invention consists primarily in constructing the furnace in two sections, in one of which desulphurizing takes place, and in the other nodulizing or sintering. Invention also lies in combining with a rotary furnace a scraper or cleaning device to prevent the accumulation of rings in the hottest part.

The desulphurizing end of the kiln consists of a cylindrical furnace, having a slight pitch so that the ore will travel through the furnace as it revolves. The nodulizing portion consists of an extension of the kiln in the form of a truncated cone, which is relatively shorter than the cylindrical portion. The smaller end of the truncated cone encircles the end of the cylindrical portion so as to receive the ore discharged therefrom. Different speeds are imparted to the two parts of the furnace, so that the desulphurizing end runs slower than the nodulizing portion, there being less heat and longer time required for desulphurizing and higher heat and shorter time for nodulizing. A satisfactory speed is 1 r.p.m. for the cylindrical portion and 4 r.p.m. for the truncated cone. The scraper is a bar sustained in such a position that it is in close proximity to the side of the nodulizing kiln. It is cooled. (1,004,340, Sept. 26, 1911.)

Still another means for preventing the formation of rings in sintering furnaces has been patented by Mr. HARTLEY C. WOLLE, of Westmont Borough, Pa. It consists in embedding cooling pipes in the interior walls of the kiln. The object of the cooling pipes is to so cool the furnace in their vicinity that a continuous ring can never form. Sintered accumulations may form, but they will be in the form of an arch without a keystone, and in the natural revolutions of the furnace they will tend to fall off. One or more of these cooling pipes may be embedded in the furnace wall, thus causing one or more breaks in the continuity of any ring which might form. The coolers are cooled by circulating air or water through them. (1,005,396, Oct. 10, 1911.)

A similar effect is obtained by Lewis P. Ross, of Standish, N. Y., by supporting a T-bar in the furnace to detach material adhering in the form of a ring or annulus. The bar is suspended so that it is not rigid, and is cooled by water pipes running its length. (1,004,085, Sept. 26, 1911.)

Electric Steel Furnace.—Among the more recent combination furnaces for electric steel refining is that of Hans Nathusius, which has been employed in commercial tests at Friedrichshütte, Germany. (our vol. viii, p. 490 and 546). It combines heating from the top by means of arcs from vertical electrodes with heating from the bottom by means of

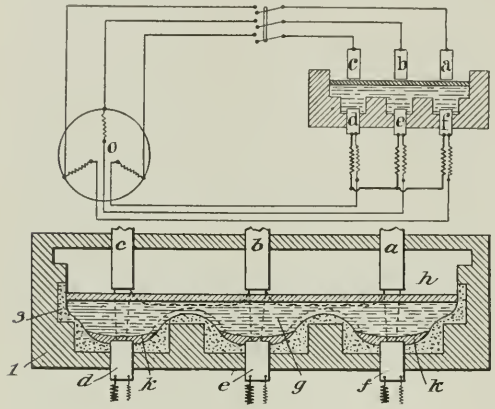


FIG. 1. ELECTRIC STEEL FURNACE.

metallic electrodes embedded in the bottom and separated from the furnace charge by a socalled conductor of the second class, as in the Roechling-Rodenhauser furnace. The object is to heat from the top when the refining depends on a very high temperature of the slag and to heat from the bottom at other periods when this may seem desirable. To increase the heating effect from the bottom, the arrangement shown in Fig. 1 is employed. With three-phase currents, as shown in the upper diagram, this is accomplished "by dissolving the nodal point of the machine and connecting the three inner ends which otherwise form the neutral point, to the bottom electrodes, while the outer ends are connected in the usual manner to the three surface electrodes. By means of this connection the point is transferred into the metal bath itself."

"This heating action in the metal bath, or the increase of heating action due to resistance heating in the metal bath or in the hearth role, by increasing the current, can also be advantageously obtained by connecting in front of the bottom electrodes a transformer which transforms the current from the main furnace source of current to a very high strength of current with a correspondingly small pressure, so that in addition to the primary current a current of any desired strength is supplied by the bottom electrodes direct to the metal bath or to the hearth sole." The lower diagram shows a lining *k* formed of a conductor of the second class disposed around and over the inner extremities of the bottom electrodes *d e f*. The upper electrodes are *a b c*, the hearth is *g* and the slag layer *h*. The refractory lining 3, which is rammed between the bottom electrodes and which, when the furnace is in operation, is traversed by the current, consists of ordinary burned dolomite, being mixed with tar as binding agent. This is the so-called "black mass" which serves in a similar manner for the preparation of basic open-hearths.

The transformer is best built directly under the electric furnace as a part of it to permit easy bottom connection. (1,000,838, August 15, 1911.)

Gold and Silver.

Improved Method of Forming a Halogen Cyanide.—In cyanidation it has been found advisable in some cases to make use of bromocyanide, or similar halogen compound. The usual method of forming this compound has been by mixing sulphuric acid, potassium cyanide and an alkali bromide and bromate. The mixture usually is made only when it is needed, and the procedure is one requiring care. It is the aim of Dr. Hans Foersterling, of the Roessler & Hasslacher Chemical Company, of Perth Amboy, N. J., to provide a better means of forming halogen cyanides by melting an alkali halogen with an alkali cyanide in the proportion of one molecule each and permitting them to solidify. No decomposition takes place in this process and the double salt is used instead of making the mixture above referred to. In order to liberate bromocyanide, for example, from a mixture of sodium bromide and sodium cyanide, an oxidizing agent such as an acid solution of hydrogen peroxide is used. The reaction follows:

$$NaBr + NaCN + H_2O_2 + H_2SO_4 = BrCN + Na_2SO_4 + 2H_2O.$$

By this method it is possible to provide cyanide mills with a correctly proportioned mixture ready for use when dissolved and mixed with an oxidizer. (999,215, Aug. 1, 1911.)

Precipitation of Gold and Silver Prior to Filtration.—The use of aluminium as a precipitant for gold and silver from cyanide solutions has been proposed before, the aluminium being merely a substitute for zinc. Mr. James E. Porter, of Syracuse, N. Y., proposes to use aluminium or its suitable alloys to precipitate gold and silver from cyanide solutions without filtering the solution from the ore pulp.

The ore is finely ground and agitated for a short time with caustic soda to neutralize cyanides and to give the ore a protective alkalinity. Cyanide is then added and the mixture agitated, preferably with aeration and by the use of so-called silica sponge, until all the gold and silver are in solution. If the agitation and aeration are well done the inventor states that sulphides can be effectively treated in the raw state.

Strips of aluminium are then immersed in the plup while the agitation is continued; the immersion being accomplshed in any suitable manner. The dissolved metals will precipitate on the aluminium, which is periodically removed and cleaned by wiping or scraping. As long as any precipitate forms the operation is repeated. The precipitation of gold liberates potassium cyanide and cyanogen; some of the aluminium goes into solution as potassium aluminate with liberation of hydrogen, and the cyanogen and hydrogen combine with the alkali present to form potassium cyanide, thus regenerating the cyanide combined with the precious metals. (1,002,446, Sept. 5, 1911.)

Direct Cyanidation of Sulphides.—In cyaniding sulphide ores containing silver, or gold and silver, with the latter usually predominating, silver sulphide goes into solution in potassium cyanide, forming potassium silver cyanide and potassium sulphide. The solvent action is, however, limited to the state of equilibrium which soon occurs, and after that point has been reached the reaction is reversible and silver again goes into solution. This phase will occur before all the silver has been dissolved. It is the object of an invention of James E. Porter, of Syracuse, N. Y., to provide means whereby the sulphide of potassium formed may be oxidized to thiosulphate, thereby avoiding reprecipitation and aiding in the extraction.

Mr. Porter shows that some form of oxidation is necessary to accomplish this, and proposes to obtain it by energetic and prolonged agitation with air. The conditions of success which he imposes are (1) fine grinding of the ore; (2) suspension of the ore in cyanide solution; (3) thorough permeation of the mass by minute bubbles of air which will remain in the liquid for some time and not rise quickly to its surface, and (4) operation at a temperature of about 180 deg. Fahr. to 190 deg. Fahr. Under these conditions he claims that it will be impossible for soluble sulphides to remain as such, their oxidation following

closely upon their formation, and equilibrium between dissolved silver and dissolved sulphide cannot exist. In this process the inventor prefers to use silica sponge as the medium for atomizing the air. (1,002,447, Sept. 5, 1911.)

Impact Filter.—A filter utilizing centrifugal force in the separation of cyanide solution and ore pulp has been patented by THOMAS H. NEIKIRK, of Midas, Nev. As shown in Fig. 2 the filter consists of a revoluble drum in the shape of a truncated cone, suitably mounted on a hollow shaft and driven from a pulley at 4. Within the drum is a filtering medium against which the incoming pulp is thrown from a number of radial members mounted on the hollow shaft. The filter is designed to work continuously as regards the formation and discharge of cake, and with the minimum of attendance.

The operation of the machine is as follows: Slime, barren solution or wash water are introduced into the filter through the pipes 18, 19 and 20, respectively, each being properly controlled by valves as shown. When the valve on the slime line is open slime enters from pipe 18 to the hollow shaft 3, and is distributed by centrifugal force through connecting radial arms

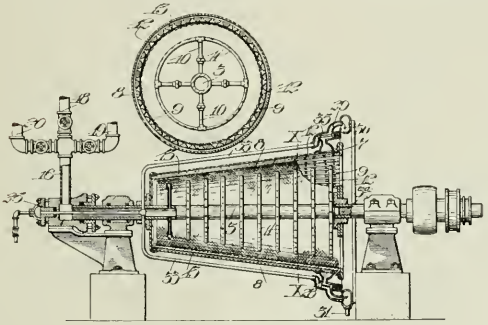

FIG. 2. IMPACT FILTER.

10 to perforated rings 11. The pulp issues from the ring perforations and is forced against the surrounding filtering medium 9, which is supported on a grooved surface 8. The liquid is thus separated from the solids and passes by perforations 12 into an annular channel 13, from which it is eventually discharged into an annular collector 28, which is fastened to the outside of the shell at its larger end. From this collector the solution is finally directed into a drain pipe 31, from which it is conducted to the zinc boxes. The solids accumulate on the filter, and when a cake of sufficient thickness is formed, the valve controlling the incoming slime is closed and barren solution and wash water introduced in a similar manner. The cake having been washed, it is now dislodged from the filter surface by means of a fluid introduced under pressure through the pipes 26 and 33, which connect with the annular channel beneath the filter. Automatic valves 35 prevent the pressure water from finding its way into the collectors which were used for discharging the filtered gold-cyanide solution. The pressure water and filtered pulp thus mix in the cone and are discharged at the lower end of the drum, after which the cycle is repeated.

The impact of the slime pulp against the filtering medium is designed to increase the efficiency and capacity per unit of filtering area. Another important feature is the relative size of the machine to the common filtering apparatus now used. (1,000,540, Aug. 15, 1911.)

Zinc, Lead and Copper

Zinc Furnace.—In the accompanying illustration, Fig. 3, is shown a cross-sectional view of a furnace for the distillation of zinc ores, designed and patented by FRANK LAURENT CLERC, of Boulder, Colo. The novelty of the invention lies in the means used for applying heat to the charge of zinc oxide and reducing substance, and in the proposed manner of introducing the charge. The furnace consists of a retort *a* and heating chamber *b*. The retort has a port *d* for the exit of zinc vapors, and a feeding spout *e* for supplying the charge to be smelted. The bottom of the retort consists of a body of molten metal *f*, such as copper or an alloy of copper and zinc, or a

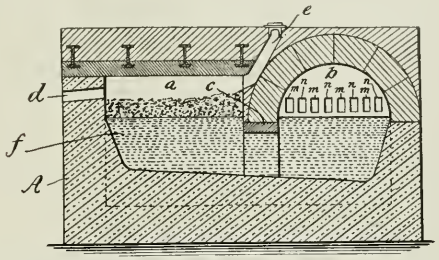

FIG. 3. ZINC FURNACE.

ternary compound which has a melting point higher than the temperature at which zinc is reduced from its oxide by carbon, and which has a high heat conductivity. This body of metal is kept in a molten condition by hot gases from a suitable source of combustion, and the heat is thus conducted through the molten metal to the charge of ore and fuel as shown on the hearth. The reduced zinc vapors pass out through the port *d* and are condensed in a suitable manner. The accompanying carbon monoxide can be collected and burned for any useful purpose. (1,002,037, Aug. 29, 1911.)

Precipitating Copper from Solutions.—The usual manner of recovering copper from dilute solutions such as mine water or water flowing over old copper dumps, is to precipitate the red metal on scrap iron. As is well known, the quantity of iron required is several times that indicated by theory, and the precipitate is not high grade. Mr. E. E. SLAUGHTER, of Clifton, Ariz., has patented an improvement in this method, having assigned the same to W. L. Austin, of Riverside, Calif. Mr. Slaughter prefers to precipitate copper by using a mixture of iron and carbon in the form of small pieces of coke. He thus gains the advantage of an electrolytic action, and states that the precipitated copper is free from basic iron salts and of higher grade than that obtained by precipitation on iron alone. (1,001,466, Aug. 22, 1911.)

Refining and Desilverizing Lead.—The crystallization process used in the refining of lead bullion carrying gold and silver are based on the fact that when such bullion is melted and cooled down to nearly the solidifying point and stirred by hand or otherwise crystals of lead form which are freer from silver and other impurities than the liquid which permeates the mass of crystals. It is customary in this process to draw off the fluid from the crystallized lead, and repeat the process. Usually twelve treatments are required to give commercial lead as one product and a high-grade bullion suitable for cupeling as the other.

Mr. GEORGE P. HULST, of Omaha, Neb., has patented means for handling the semicrystallized mass in a press, by means of which the liquid is squeezed from the crystals, rendering the latter drier and concentrating the impurities in the liquid. By this procedure the number of crystallizations is reduced to six, as compared with twelve as usual. (1,001,525, Aug. 22.)

Cyanidation of Silver Ores at Cobalt.—At the Nova Scotia mill in the Cobalt, Canada, district cyanidation is in use, as noted in the *Mining Magazine* for September, 1911. The ore is crushed in stamps in cyanide solution, and concentrated without classification on Deister No. 2 tables to remove the metallics and rich sulphides. The table tailings are classified, reground in tube mills, thickened in Dorr thickeners, agitated in Trent agitators, and filtered by the Moore process. Precipitation of silver is by the Merrill zinc dust method.

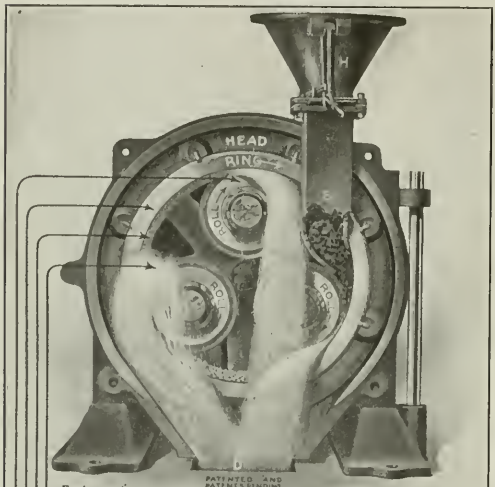
Combination of Ring Roll Mills and Tube Mills in the Grinding of Cement Clinker.

One of the most important problems in many branches of metallurgical and chemical engineering is the proper combination of different grinding machines so as to grind a given material at the lowest cost. Under different conditions the best combination will differ, but in many cases it will be found advantageous to subdivide the whole grinding operations into a series of different ones, carried out in different machines, instead of trying to finish the whole job in one machine.

A case in point is the grinding of cement clinker, and in this respect some tests made by Sturtevant mills are of considerable interest.

The usual practice in reducing Portland cement clinker is to grind the clinker in one ring-roll mill to 20 mesh and finish in three tube mills.

The alternative method, which was compared with that just



HEAD

RING ROLL MILL.

mentioned, is to grind the clinker in two ring-roll mills to 80 mesh and finish in one tube mill to 83 per cent—200 mesh.

In each case the ground product of the ring-roll mill was raised by means of an elevator to Newaygo screen separators to separate the fine material, which then underwent finishing treatment in the tube mill.

The comparison between the two methods extended to the establishment of comparative figures, firstly, for wear and tear of the machinery, and secondly for power consumption. Of course, the following figures are only comparative, using the same hard clinker.

As to the *cost of maintenance*, the wear and tear of the one ring-roll mill grinding 45 bbl. to 20 mesh per hour represents an expense of 0.076 cent per bbl. The wear and tear of the Newaygo separator, handling 45 bbl. per hour, was 0.022 cent per bbl. The wear and tear of the three tube mills was 0.266 cent per bbl. Hence the total wear and tear of the ring-roll mill, separator and the tube mills (not including elevator) was 0.364 cent per bbl.

On the other hand the wear and tear of the two ring-roll mills, grinding 45 bbls. to 80 mesh per hour, was 0.152 cent per bbl. The wear and tear of the two separator screens was 0.044 cent per bbl. The wear and tear of the one tube mill was 0.089 cent per bbl. Hence the total cost of wear and tear of the two ring-roll mills, separators and the one tube mill was 0.285 cent per bbl. This method, compared with the first one, exhibited a saving of 0.08 cent per bbl. in the maintenance cost of the grinding machinery.

As to the *power consumption*, the one ring-roll mill in the first case requires 0.777 hp per bbl., the Newaygo separator 0.022 hp per bbl. and the three tube mills 5.666 hp per bbl. Hence the total power consumption of ring-roll mill, separator and tube mills is 6.465 hp per bbl.

In the second case the two ring-roll mills require 1.555 hp per bbl., the Newaygo separator 0.044 hp per bbl. and the tube mill 1.888 hp per bbl. Hence the total power consumption of ring-roll mills, separator and tube mill was 3.487 hp per bbl. This represents a saving of 2.987 hp per bbl.

Both with respect to maintenance cost and power consumption the second method turned out to be considerably more economical.

In this comparison the elevator has not been considered since its wear and tear as well as power consumption was taken as the same in both cases.

It is clear from the above comparative figures that the decisive item in the results of the tests was the decidedly high economy of the ring-roll mills and for this reason a description of the Sturtevant ring-roll mill to which the above figures relate should be of interest.

The adjoining illustration shows the construction. A heavy steel anvil ring is secured in a head supported by a horizontal shaft. Against the inner face of this ring hammer rolls are elastically pressed with great force and revolved by frictional contact with material on the ring.

Substances to be ground are fed (up to 1¼ in.) to the inner face of the rotating ring which holds them thereon by centrifugal force to be crushed as drawn under the rolls by ring rotations and discharged on both sides thereof.

The face of the ring is concave and the roll faces convex.

The roll mountings are on the massive door that forms one side of the mill casing, and they are swung away from the ring with the door when it is opened. Thus the whole grinding outfit is made accessible by opening the door. The roll shafts are as large as those of the driving wheels of a locomotive, and crushing pressures are greater. One adjusting screw on the outside of the door regulates the roll forces and gives the rolls an absolutely equal pressure. No rock can withstand these pressures.

When at work, the concave of the revolving ring is always covered with a thick layer of material fed thereto. A naked track is never exposed to the roll faces. They cannot damage one another. Rock is crushed down upon itself (between anvil ring and hammer roll) producing a maximum of fines, with least wear.

As there is a constant feed, while the mill is at work, of coarse and partly reduced material, so there is a constant drop of material crushed off to both sides of the ring by the rolls. This escapes, as in all mills of this class, from the bottom of the case, and is taken to a Newaygo screen to remove the finished product *as soon as made*. The tailings, separated by this screen, are returned to the ring (with fresh feed) for further reduction.

Thus the mill is always breaking down coarse rock *upon* tailings, producing a maximum output and forcing the rocks to crush one another.

It should be emphasized again that in the Sturtevant ring-roll mill the ring drives the rolls. They run like those of an automobile's roller bearing. No roll drives are used nor do the rolls support the ring.

The Absorption of Hydrochloric Acid and Other Gases.

By Percy C. Kingsbury.

Practically all of the muriatic acid made in this country is obtained from the decomposition of common salt by means of sulphuric acid or bisulphate of soda.

The hydrochloric acid gas evolved during the reaction is

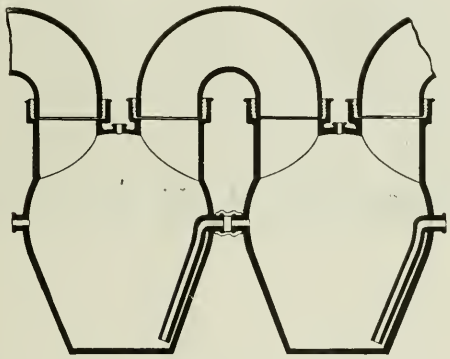

FIG. 1.—STANDARD FORM OF TOURILL.

first cooled and afterward dissolved by water. The cooling of the gas is effected by passing it through large pipes exposed to the air. The pipes are usually of fire clay and on account of the porosity of this material are boiled in tar before being installed.

The plant commonly employed for the absorption consists of a system of stoneware "tourills" connected in series by stoneware piping. A current of water or dilute acid passes through these vessels over the surface of which liquid the cooled gas circulates. One or two small wash towers usually complete the absorption equipment.

For many years little consideration was given to the design of an effective type of tourill for this purpose, chemical manu-

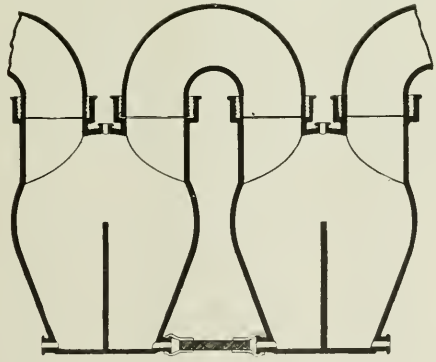

FIG. 2.—ANOTHER STANDARD FORM OF TOURILL.

facturers being content to use the standard form of vessel supplied by the stoneware manufacturers.

This form, illustrated in various modifications in Figs. 1, 2 and 3, has the advantage of being easy to manufacture, and, on account of its symmetrical shape, of resisting the expansion and contraction due to variations in the temperature to which it is subjected.

The principal function of the tourill is to dissipate the heat evolved during absorption as the amount of gas that can be absorbed, or, in other words, the strength of the acid obtainable, decreases very materially with rise in temperature of the absorbing liquid.

An efficient type of tourill should, therefore, offer as large a cooling surface as possible compared with the volume of acid it contains. Those illustrated in Figs. 1, 2 and 3 are for all practical purposes spherical, and therefore from the above point of view of efficiency the least desirable, as of all geometrical forms the sphere has the least surface in relation to its volume.

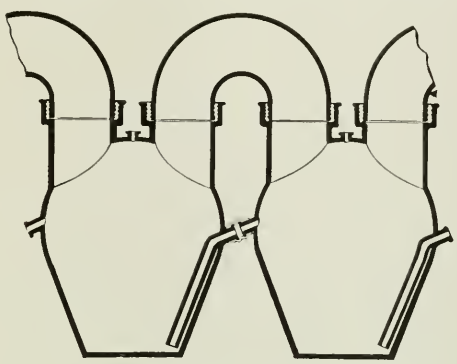

FIG. 3.—ANOTHER STANDARD FORM OF TOURILL.

This tourill has, moreover, several other disadvantages. The acid contained presents a comparatively small surface of contact with the gas to be absorbed, the vessel is difficult to clean out and cannot conveniently be water-cooled. The latter is an important consideration, as artificial cooling is necessary in working for acid of the highest possible strength, especially during the summer months.

These considerations led some acid manufacturers to replace the spherical tourills by vessels of more or less fanciful shapes, most of which proved unsatisfactory on account of the designers not taking into consideration the limitations of the material of which such articles have to be made.

The first practical improvement on the old-fashioned type is the Cellarius tourill illustrated in Fig. 4. Several of the advantages of this vessel are obvious. It can be completely immersed in water, offers a much larger cooling surface in comparison with the volume of acid it contains and also exposes a larger surface of the absorbing liquid to the action of the gas.

By connecting successive tourills in the manner shown in Fig. 5 the vessel can immediately be emptied and flushed out by simply reversing the glass "T" piece. It will be noted that the acid enters the tourill by one of the projecting tubulures and before leaving by the other must flow through twice the entire length of the vessel, passing in a shallow stream over

FIG. 4.—CELLARIUS TOURILL.

the arch at the back of the tourill. This insures an efficient cooling of the liquid and a progressive increase in the strength of the acid as it passes through the vessel.

The tourill withstands variations in temperature very well, as the form of a double arch enables it to take up considerable strain due to expansion and contraction of the material. This form is also advantageous from the point of view of mechanical strength.

One other practical advantage of this vessel is that the acid

connections are under the surface of the liquid, thus preventing the possibility of stoppage of the flow due to the formation of air locks, a matter of frequent annoyance in the old type of vessel.

The many advantages of the Cellarius tourill have received prompt recognition in Europe, where it is rapidly replacing the spherical vessel. Where such substitution has been made it has been found that one Cellarius tourill can replace two or three of the old-fashioned type.

No difficulty is experienced in connecting both kinds of vessel to the same battery. The advantages of the new tourill can, therefore, be realized practically at little expense or disturbance of operation by substituting or adding a few Cellarius tourills at the beginning or end of a series.

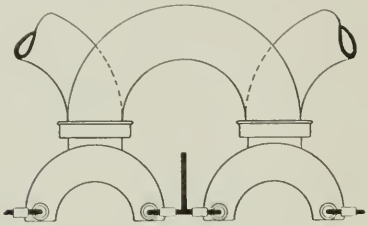

FIG. 5.—CONNECTION OF SUCCESSIVE TOURILLS.

The success of the Cellarius tourill for absorption purposes has led to the design of a modification of this vessel for the cooling and condensation of gases. This pattern is illustrated in Fig. 6 and it will be noted is merely an inversion of the type used for absorption, the advantages of which are retained. It has been employed for the pre-cooling of hydrochloric acid gas before it enters the absorption battery and for the condensation of nitric acid and is a practical and efficient vessel for all purposes where acid gases are to be cooled or condensed to the liquid state.

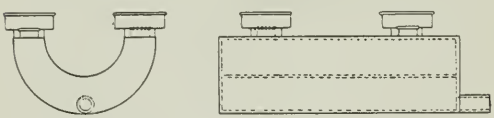

FIG. 6.—MODIFICATION FOR COOLING AND CONDENSATION OF GASES.

The Cellarius tourill was exhibited at the Pittsburgh meeting of the American Institute of Chemical Engineers, December, 1908 (this journal, Vol. 7, page 89), by the Didier-March Company, New York, who are the manufacturers of these vessels in this country.

The Oxygen-Gasoline System of Lead Burning.

While in the old familiar system of "lead burning" hydrogen and air are employed, the new Howard system involves the use of oxygen gas saturated with gasoline. With this new system much more perfect combustion and higher temperatures can be obtained and it is claimed to combine the advantages of superior results with respect to quality of work, with greater economy, greater speed of operation and greater convenience in use.

The adjoining illustration shows the Howard apparatus in operation. It will be seen that there are only two principal parts, namely the gasoline saturator, weighing about 28 lb., and the oxygen cylinder weighing about 68 lb.

To the valve on the oxygen cylinder the oxygen regulator is attached. One outlet of the oxygen regulator is connected by a rubber hose to the blowpipe, while from the other outlet of the oxygen regulator another rubber hose leads to the inlet of the gasoline saturator. The exit gas from the gasoline saturator passes through a hydraulic trap which serves as a safety device in the case of a back-fire, and is then conducted through a rubber hose to the other nipple on the blowpipe. A proper burning mixture is produced at the blowpipe by manipulation of the gas and oxygen cocks.

There is nothing difficult about the operation. In fact, any workman conversant with the hydrogen-air system of lead burning will experience no difficulty in operating the Howard lead burning system.

HOWARD LEAD BURNING APARATUS IN OPERATION.

The advantages of the Howard system are essentially due to the simple apparatus required, as described. As compared with the old hydrogen-air system, the hydrogen generator is dispensed with. The air bellows or pump is dispensed with and consequently the services of a boy are not required. The apparatus is portable and may be carried anywhere, thus doing away with the very troublesome necessity of moving a heavy hydrogen generator and bellows from one job to another.

There is no apparatus to get out of order, involving expense, delays and repairs. No acid or corrosive substance is employed. As neither zinc nor sulphuric acid is used, there is no deleterious matter to be carried through the blowpipe to act injuriously on the lead seam.

The flame produced is absolutely clean and does not blacken nor tarnish lead, brass or copper. This is of special advantage in soldering the two latter metals, and also in repairing old lead work that is thin, as very little shaving is necessary.

A much better, hotter flame is produced than with hydrogen and air and much superior and faster work can be accomplished. The flame is so hot that even heavy lead in wet and cold positions can be burned "in situ" without preheating. A general idea of the comparative speed of lead burning by means of the Howard apparatus and the hydrogen and air method respectively may be gathered from the figures in the following table, in which the approximate foot run burnt per hour is given for various weights of lead sheet.

		Gasoline-Oxygen	Hydrogen-Air
Flat seam	20 lb. lead	20 ft. per hour	15 ft. per hour
" "	12 " "	48 " " "	27 " " "
" "	8 " "	60 " " "	40 " " "
" "	6 " "	108 " " "	90 " " "
Upright "	20 " "	5 " " "	4½ " " "

No gas is generated when the blowpipe is not in use, and consequently there is no waste of gas and no charge to withdraw overnight.

The apparatus can be recharged in about three minutes. This will appeal to lead burners who are familiar with the time taken to recharge the hydrogen apparatus.

The Howard system of lead burning is being introduced by the Linde Air Products Company, of Buffalo, N. Y., which firm has been so successful in the last years in developing new uses for oxygen and especially in popularizing the oxy-acetylene system of welding. It is hardly necessary to add that this company makes the oxygen from liquid air by the Linde process.

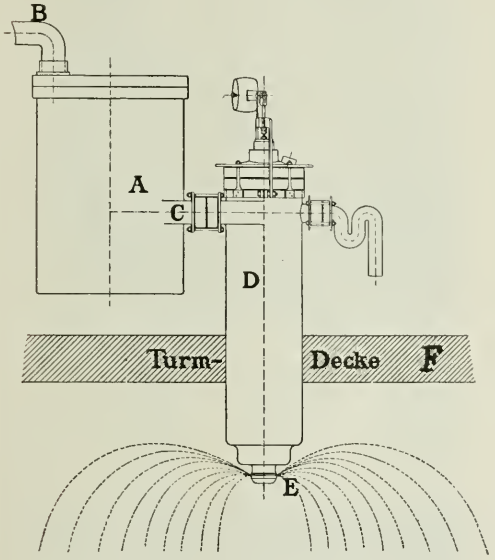
Novel Feeding Device for Glover and Gay Lussac Towers.

The adjoining illustration shows the "effecter distributor" for tower liquid, *i. e.*, a new feeding device for Glover and Gay Lussac towers, built by the Deutsche Steinzeugwaarenfabrik für Canalisation und Chemische Industrie in Friedrichsfeld.

Its chief advantages are that there are no valves nor other movable parts in it, that the liquid is distributed absolutely uniformly over the whole cross-section of the tower, and that only one opening in the top of the tower is required. Neither variations within rather wide limits of the liquid supplied to the tower per hour nor considerable impurities in the liquid are detrimental to the proper operation of the apparatus.

The "effector distributor" is especially suitable for the sulphuric acid industry, since on account of its simplicity and robustness of construction it permits a perfect and uniform distribution of the liquid over the whole tower cross-section in Gay Lussac and Glover towers under all conditions.

The vessel *D* is supplied with the liquid from the filling device



FEEDING DEVICE FOR GLOVER AND GAY LUSSAC TOWERS.

A which operates at periodical intervals. The liquid is gradually given off from *D* to the tower through the spray nozzle *E* in form of a veil of spray of conical form, or rather of umbrella shape. A syphon connected with the interior of the tower conducts any excess of liquid directly into the tower.

The filling device *A* and the spray nozzle *E* are so designed in relation to each other that when the spraying begins the circle which is being sprayed with liquid (or the solid angle of the spray cone) becomes gradually wider while the level of the liquid in the vessel *D* rises. When the liquid in the vessel *D* has reached its highest level and begins to fall again the solid angle of the spray becomes smaller again.

The apparatus is adjustable in such a way that between each period of action there is a shorter or longer interval, or it may be so adjusted that in the moment when the vessel *D* is completely emptied the vessel *A* gives off to *D* the liquid which had accumulated in it in the meantime, so that the spraying process begins anew. In this way the liquid spray changes its conical form continually as though an umbrella was opened and closed successively at regular intervals.

The liquid passes from a reservoir to the filling device *A* through the pipe *B* in a continuous stream. After a certain quantity of liquid has accumulated it is suddenly given off through *C* to the vessel *D*, which then begins to spray through *E* as described before.

This apparatus can be designed for any hourly quantity of liquid and for any tower cross-section, but for the present 5 cu. m. of liquid per hour and a tower diameter of 5 m are the maximum values for which it is built.

Mr. J. W. Sittig, Temple Court Building, New York City, is the sole American agent of this as well as the many other products of the Friedrichsfeld chemical stoneware factory.

Carborundum Refractories.

"Carborundum firesand," one of the by-products of the manufacture of carborundum in the electric furnace, has found very extended use in the last years as a refractory. From a bulletin, entitled "Carborundum Refractories" and issued by the Carborundum Company, of Niagara Falls, N. Y., the following information is extracted.

Chemically carborundum firesand consists of several silicocarbides of compositions ranging from Si_2C_2O to Si_4C_3O, representing the partial reduction of silica by carbon at the intense heat of the electric furnace. This is furnished in the form of finely ground sand and is mixed before using with a binding material such as silicate of soda or fire clay to give it proper cohesion when brought up to heat. A silicate of soda of 52 deg. Baumé is best adapted for this purpose; it must be diluted with a certain quantity of water before being added to the firesand. When clays are used, a crude Jersey fire clay or one of equal purity should be taken. Kaolin may also be used with good results. Prepared fire clay, such as is furnished for laying up fire brick, is generally mixed with ground calcined clay or powdered fire brick, and is not suitable for the purpose.

In estimating the amount of material required for a lining of given dimensions, the weight of the carborundum firesand mixture may be computed as 85 lb. per cubic foot.

Lining of Crucible Brass Furnaces.—For linings of crucible brass furnaces a mixture is used consisting of 70 per cent carborundum firesand, 15 ground fire clay, 8 silicate of soda of 52 deg. Baumé and 7 water.

The silicate of soda is first added to the water and thoroughly dissolved. This solution is then mixed with the clay and firesand until the material acquires the consistency of molding sand. The constituents when thoroughly incorporated form a plastic mixture which is easily molded and has sufficient cohesion when tamped into place to retain its shape until fired. A sheet-iron form is provided of the same diameter as the interior of the furnace, consisting of a sheet of iron bent in cylindrical form, so that after use it can be sprung inward and be easily withdrawn. The center may also be constructed of wood and in such case should be well greased so that it can be drawn without the lining adhering to it.

The mixture is rammed up solidly between the center and the outside shell of the furnace, after which the center may be at once removed and the lining dried out with a slow wood fire. It can then be immediately put in service. In cold weather it is well to warm all the materials before mixing.

It is the practice in some foundries to provide channels or vents to assist in drying out the lining. This is done by placing four or five wooden strips about 2 in. by 1 in., spaced equally around the furnace inside and against the shell. These are withdrawn after tapping in lining.

This same mixture is used for lining ladles for brass, copper or iron.

Linings of Tilting and Rotary Oil-Burning Furnaces.—For tilting and rotary brass furnaces, in which the linings are subjected to the severest possible conditions, a mixture of 86 per cent carborundum firesand, 7 silicate of soda at 52 deg.

Baume and 7 water is recommended. In many cases it is found advantageous to replace about 15 per cent of the firesand with an equivalent amount of kaolin.

This mixture is thoroughly incorporated and tamped between the shell of the furnace and a strong center provided for the purpose. When completed the center is carefully removed and the lining dried out at once with a slow wood fire. It is then gradually brought up to heat by means of the oil flame and can at once be put in service.

Many users of this style of furnace have found it practicable to throw in a small quantity of broken glass when first heating up the lining. This glass, when melted down, can be evenly distributed over the surface of the lining by tilting the furnace, and the interior thus acquires a smoother glazed surface which adds to the durability of the lining.

Patches can easily be made in places where the lining becomes broken or worn. It is best to cut out the broken parts entirely through to the shell, undercutting the old lining, in order that the new portion may be keyed into the old lining. For the purpose of repairs the same mixture is used as when putting in a new lining.

Repair of Firebrick Linings.—A mixture consisting of equal parts of carborundum firesand and fireclay or kaolin is extensively used for patching holes or broken parts of fire brick linings and for filling open joints in furnace walls. It is used to good advantage in ordinary crucible furnaces for brass and steel, also in copper reverberatory furnaces for keeping the side walls in repair. By its careful use it is possible to double the life of any firebrick lining. The mixture is largely used in repairing the Schwartz down-draft furnace, and also as a wash applied daily after the melting. Another efficient mixture for this purpose is the one recommended for crucible brass furnace linings given above.

A mixture of equal parts of firesand and fireclay is used successfully in repairing the brick linings of Tropenas converters, which are subjected to extreme corrosion by the flame.

Carborundum Furnace Paint.—Carborundum firesand may be made up in form of a paint or furnace wash by mixing 65 per cent carborundum firesand with 20 ground fine clay and 15 silicate of soda of 52 deg. Baumé and adding sufficient water to bring it to the consistency of a thick paint, which is applied to the surface of the lining with a broom or stiff brush. Two or three applications gave a proper coating. This makes an excellent protective coating for furnaces subjected to intense flame action and high temperature. It is preferably applied to new brick work, as it does not adhere so efficiently after the linings have become glazed over or covered with slag.

Special applications of carborundum paint are in arch and bridge walls of boiler furnaces which are subjected to severe flame action, in potters' kilns, welding furnaces and malleable iron furnaces. It is of great value in oil furnaces in protecting the brick from the well-known pitting and eating action of the high-pressure oil flame. Carborundum paint is used with good results as a cupola wash in protecting the melting zone of foundry cupolas.

Carborundum mortar is made from a mixture of equal parts of carborundum firesand and fireclay. It is used in laying up firebrick, in patching open joints and holes in brickwork and in general repairs. The life of a firebrick structure is generally limited by the life of the joints. A mortar of carborundum firesand is found to effectively stop the slagging and corroding at the joints.

Carborundum firebrick are furnished in the regular size, 9 in. × 4½ in. × 2½ in., and also in many of the special arch and key shapes. Many special shapes and forms are also made according to specifications and drawings. Carborundum brick have shown great economy in oil furnace work of all descriptions, in connection with the melting of crucible steel in forging and welding furnaces, in electric furnaces and in brass furnaces. They are, moreover, the only brick which will stand the intense heat generated in furnaces using powdered coal fuel.

A New Electric Recording Instrument.

A new type of electric recording instrument, particularly adaptable for use as a recording electric pyrometer, recording voltmeter or ammeter has been designed by the Brown Instrument Company, of Philadelphia.

Recognizing the necessity of a recording instrument which

FIG. 1.—VIEW OF ELECTRIC RECORDING PYROMETER.

is both accurate in operation and simple in construction the Brown Instrument Company has spent much time in designing a recording instrument which can be mounted on the wall or switchboard and used by the most inexperienced workman.

In the common form of recording instruments no means are provided for shifting the recording pen arm out of the way when the chart which receives the record is changed, conse-

FIG. 2.—RECORDER OPEN.

quently there is serious danger of bending the pen in removing the chart. In this respect the new Brown recording instrument is most novel in construction, in that the essential parts of the instruments are mounted on the door instead of in the case. The clock mechanism and chart alone remain in the case when the door is opened. Consequently there is no possibility of

bending the pen because there is no occasion to handle it for any reason whatever. As soon as the door is thrown open the entire voltmeter system and the inking device is swung aside automatically, permitting the old chart to be easily removed and a new one substituted.

Fig. 1 (page 614) illustrates this recorder in operation with the door closed, while Fig. 2 shows the instrument with the door thrown open ready to have a new record chart installed.

The millivoltmeter system which is used in this new recording instrument is a simplified form of the D'Arsonval system which is the only system used in electrical instruments of precision. Also the recording pen comes in contact with the paper momentarily only for the purpose of making a dot, thereby eliminating all friction between the pen and the chart.

An inking pad is placed immediately beside the pen carrying sufficient ink for a week's supply, and this inking pad touches the pen point frequently, keeping the point damp. When the door is closed the arm seen at the left of Fig. 2 and operated by the clock mechanism, comes in contact automatically with the inking device, and every half minute, or quarter minute if preferred, it pushes the inking pad away from the pen, permitting it to swing freely. It then falls, allowing the inking pad by its own weight to press the pen against the paper.

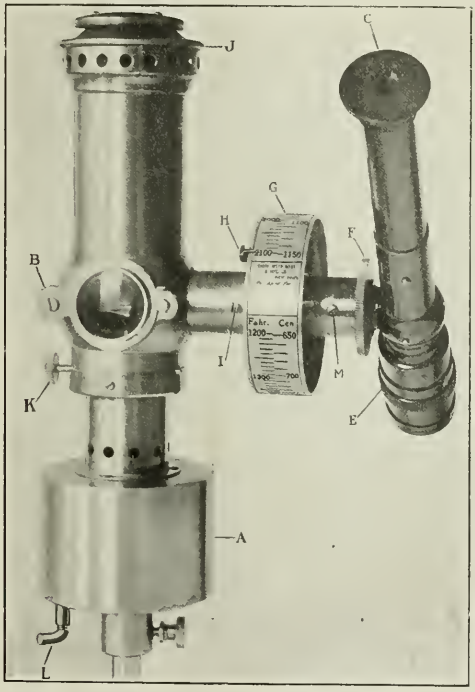


FIG. 1.—PYROSCOPE.

This extraordinary simplicity of construction, the freedom from unnecessary parts, as well as the frictionless operation on the paper, will strongly appeal to those who understand the value or rather necessity of simple design for recording instruments.

Filter Papers.—We have received price list and samples of filter papers in sheets, rolls, circels, and folded-filters, made by Messrs. Carl Schlaicher & Schüll, filter-paper manufacturers of Düren, Rhenish Prussia. Messrs. Eimer & Amend of New York City are the sole agents for the United States.

A New Optical Pyrometer.

In many fields of metallurgy it is now clearly recognized that exact heat treatment is all-important and that the skilled eye of the most experienced attendant is not able to judge temperatures always correctly on account of the considerable variations of the illumination of the room with the weather, etc. This explains the rapid development of the pyrometer industry and the ready introduction of the pyrometer into commercial practice in recent years. Naturally the tendency in the design of various pyrometer types has been to develop robust fool-proof shop instruments from what were originally laboratory instruments requiring careful handling.

FIG. 2.—MEASUREMENT OF THE TEMPERATURE OF A TOOL BY PYROSCOPE.

This same tendency is manifest in the latest design of an optical pyrometer, called the pyroscope and built by the Shore Instrument & Manufacturing Company of 555 West Twenty-second St., New York City. There is no necessity to deal here again with the underlying principle of all optical pyrometers. The chief points of the Shore pyroscope are its simple design, strong and rugged construction and comparative inexpensiveness. It is a little less accurate than a first-class and perfectly calibrated pyrometer, but is stated to give correct readings within 10 deg. Fahr.

The standard lamp used for comparison is a miniature kerosene flame. Ordinary kerosene is filled in the tank *A*, Fig. 1, the wick is lighted as in any ordinary lamp and the flame is adjusted to normal height (about ¾ in.) by the knob *K*. By now looking through eye-piece *C* at the hot tool, etc., which undergoes heat treatment, one gets a clear view as through any telescope. After focusing by turning the knurled ring *E*, the knob *F* is turned, which works the colored diaphragm and

controls the light intensity of the comparison reflector *R* shown in the special diagram in the upper left-hand corner of Fig. 2, which shows the image seen through the pyroscope. Knob *F* is turned until practically no difference can be seen between the redness of the reflector *R* and the tool under treatment. This can best be tested by going a shade higher or lower until balanced. The indicator *H* on the graduated drum *G* then gives directly the temperature reading.

By means of locking by the set screw *M* it is possible to set the instrument at a given temperature so that the work can all be heated up to a certain degree. The telescope can be used in any desired position on its pivot.

Recording Pressure Gauges.

The use of recorders has rapidly increased in recent years in connection with all kinds of measuring instruments, since a continuous record, furnished by a recording instrument, represents the best and most reliable control of the operation of a plant and the work of the attendants.

The Columbia pressure recording gauge, made by the Schaeffer & Budenberg Manufacturing Company, of Brooklyn, N. Y., and shown in the illustration, is noteworthy especially for

RECORDING PRESSURE GAUGE.

some special features of the record chart, namely uniform graduations, large effective record space and the division of the border into a black and a white section, denoting the day and night record respectively.

Columbia recording gauges are made in two sizes, suitable for 8-in. and 12-in. charts respectively and for pressures ranging from 4 in. water pressure up to the highest working pressure met with in practice.

Some of the applications of these gages are the recording of steam, air, gas, water and ammonia pressures. These gauges may be had in dust and air-tight or moisture-proof case, and for temporary installations or field service portable gauges are provided.

The recording chart shows maximum and minimum pressure carried, the rate of rise or fall in pressure, in brief it is a complete log of the operation as indicated by the pressure at any time. A file of charts in the office of the superintendent enables him to compare the work done in the plant hour by hour and day by day and to study in detail how the plant economy is affected by the pressure.

On the other hand the workman likes the recording gauge as it relieves him from the time-consuming and inconvenient writing down of the pressure gauge readings on the report sheet.

On the whole, the installation of pressure recording gauges leads to more conscientious operation and should prove a great incentive to improvements in all chemical works where gases or liquids are carried under pressure.

Titanium Steel.

The American Iron and Steel Association published recently the following statistics of the tonnage of various alloy steels during 1910.

Titanium steel	326,316	gross tons
Nickel steel	106,707	" "
Nickel-chrome steel	52,021	" "
Chrome steel	23,550	" "
Manganese steel	19,360	" "
Vanadium steel	9,049	" "
Other Alloys steel	30,816	" "
Total	567,819	

As is pointed out in a recent circular of the Titanium Alloy Manufacturing Company of Pittsburgh, Pa., these statistics show that the output of titanium steel for 1910 was not only 300 per cent greater than the next largest nickel, but it was greater by 84,813 gross tons than the output of all the other alloy steels combined.

It is, of course, a question whether titanium steel can be considered as an alloy steel in the same sense as, for instance, nickel steel or chrome steel. In the case of the latter two, the nickel and the chromium are alloyed in certain proportions with the steel and give it certain valuable properties.

On the other hand, titanium was originally introduced in the steel industry as a cleaner. Titanium is an excellent deoxidizer and has also a very high affinity for nitrogen. It acts as a purifier of the steel, removing the gases from it, and improves greatly the structure of the steel. When acting in this way the titanium passes into the slag and if no excess of titanium is used, no titanium is contained later in the steel. Such titanium-treated steel is, therefore, not an alloy steel like nickel steel or chrome steel, but the results obtained by the purifying titanium treatment are so remarkable that they alone would explain the enormous increase of the use of ferrotitanium in the steel industry in the last few years.

However, more recently several investigators have found that the beneficial effects of titanium are not restricted to its action as a purifier but that titanium may give valuable properties to steel when the titanium is used in excess over that needed for purification alone. Facts illustrating this action have been cited to us from different investigators working quite independently of each other. It is to be hoped that exact information concerning this most interesting subject will soon become available.

The Non-Ferrous Metal Market.

Prices have fluctuated somewhat since our last report owing to conditions on the Stock Exchange and in foreign markets. The report of the Copper Producers' Association depressed the domestic copper market, as it seemed to indicate a contraction of business abroad. Tin fluctuated considerably as a result of both foreign and domestic conditions. Lead has eased off somewhat, while spelter has advanced.

Copper.—The latest quotations on this metal show a tendency toward lower prices, and there has been a large of-

fering on the part of Lake producers who wish to dispose of stocks before navigation closes. The quotation for Lake copper is 12⅛ to 12⅜ cents, with electrolytic at 12.05 to 12.10 cents.

Tin.—At the close of September tin could be bought at about 35⅝ cents in New York, but as a result of the activity of the Syndicate abroad prices rose, and at present October tin is quoted at 41 cents.

Lead.—As a result of two successive reductions by the principal seller, this metal has fallen off about ¼ cent per pound, and there is little demand in view of the unsettled conditions. New York lead is quoted at 4.20 to 4.25 cents; St. Louis at 4.05 to 4.10 cents.

Spelter.—Prices have steadily advanced in view of large exportations and shortage in the domestic supply. Business has been on a heavier scale and consumers are buying in such quantities as can be supplied. Latest quotations were firm at 6 to 6.15 cents, New York, and 5.85 to 6 cents, St. Louis.

Other Metals.—Business in aluminium is somewhat improved, but prices are no higher. The metal is quoted at 18.5 to 19 cents, New York. Antimony is weaker and prices are reduced to 7 to 8.25 cents for various grades. Prices have fallen slightly in quicksilver; New York prices being $45 per flask of 75 lb.; San Francisco, $44.50.

Notes.

The **Kestner Evaporator Company,** which for a number of years has been located at 333 Walnut Street, Philadelphia, has recently removed its business to the Commonwealth Trust Building, Twelfth and Walnut Streets, in the same city.

Monel Metal Casting.—An interesting feat in the casting of Monel metal was recently accomplished in the foundry of the Bayonne Casting Company, Bayonne, N. J., where a four-blade propeller wheel, 16 feet in diameter, was cast in somewhat less than an hour. Fully 18,000 pounds of the metal were required to allow for gates and finish, the melting temperature being about 2500 Fahr. and the finished weight about 14,000 pounds. The wheel, because of its greater strength and freedom from corrosion, is to take the place of a steel wheel on the S. S. Madison, of the Old Dominion Line.

Mr. **H. M. Hirschberg,** 30 East Twentieth Street, has recently been appointed American representative of the Planiawerke, Ratibor, Silesia, Germany, manufacturers of the well-known carbon electrodes bearing their name. There is such a big demand for products of this factory, that contracts are now being made for the latter part of 1912 and 1913 deliveries, Mr. Hirschberg already having closed for almost the entire output of the factory available for this market. These electrodes are being made in sizes up to 600 millimeters (2 feet) square cross section for rectangular electrodes or 600 millimeters (2 feet) diameter for round electrodes and in lengths up to 2000 millimeters (6 feet 7 inches). It is especially noteworthy that these electrodes are provided with a screw end so that new length can be added when required, thus doing away with all waste of carbon ends.

A New Departure in Handling Gritty Water.—For many years the pulsometer has found favor for dredging work, coal mining, sand suction, etc., because it has no rubbing surfaces so that no difficulty is experienced in handling gritty water. To overcome the terrific cutting action of high velocity water containing very hard flinty matter, the Pulsometer Steam Pump Company, of 17 Battery Place, New York City, announces that pulsometers are now being cast by a special patented process wherein the shell, while of the usual cast iron construction to give ample rigidity, is completely lined on the inside with a surface of carborundum. Sand blast and other abrasive tests would seem to indicate that this lining will stand almost indefinitely the wear of water moving at high velocity and containing anywhere from 40 to 60 per cent of hardest material.

The International Institute of Technography, an association of patent experts and technical bibliographers, has been organized to make comprehensive prior art examinations of patents and literature by a carefully organized system. A careful compilation of any single prior art from all the records, by an individual, requires weeks or months. Such laborious and expensive compilations have already been made, however, in comparatively every art, covering each to at least a comparatively recent period. The association has made it its business to know of, to compile, and to classify all such compilations, to ascertain where they are to be found, and to have a qualified expert at hand to examine them. The offices of the Institute are at 50 Church street, New York City.

The **Aero Pulverizer Company** announce that they have made an arrangement with the Cockburn Company, with works at Jersey City and offices at 126 Liberty Street, New York, to take over the manufacture and sale of the Aero pulverizer. The Cockburn Company has always manufactured these machines for the Aero Pulverizer Company, so that there will be no change in the product or workmanship. Mr. Wm. A. Evans will have supervision of manufacture and sales.

The **Copper Extraction Company,** Anaconda, Mont., has placed with the Ruggles-Coles Engineering Company, of New York, orders for two class "A 2," one class "B 10" and one class "F 8" dryers, for drying copper tailings.

Thermometers and Other Instruments for Breweries.—That chemical engineering plays an important part in brewing was well illustrated at the American Exposition of Brewing Machinery, Materials and Products, which will be held at the Chicago Coliseum, Oct. 12 to 22. Prominent among the exhibitors was the Schaeffer & Budenberg Manufacturing Company, of Brooklyn, N. Y., showing a complete line of its high-grade engineering instruments, among them its new recording thermometers, its special features being the mercury-filled steel capillary tube and the night and day chart, both new departures in thermometer construction. A full line of its brewers' thermometers, together with steam and ammonia gages for indicating and recording purposes, was shown, also its new steam engine and ammonia compressor indicators. Messrs. W. H Shenton and T. J. Mentin officiated at their booth.

Two varieties of natural graphite are generally recognized in the trade—crystalline, or that possessing a lamellar, flaky or fibrous structure, and amorphous, including all other forms. Domestic flake graphite is replacing to some extent the Ceylon graphite used in the manufacture of crucibles for the metal industries, and the increased demand is being met by increased domestic production rather than by increased importation.

Obituary.

Horace H. Emrich, manager of the copper refinery of the Kyshtim Mining Works Company, of Kyshtim, Russia, was killed, according to newspaper cable dispatches, on October 17th, while standing at the window of his residence, by a gun shot from the outside. The Russian government has ordered an investigation. Mr. Emrich is a well-known member of the American Electrochemical Society and has here many friends who will be greatly shocked by the news of his sudden death. He was formerly superintendent of the copper refinery of the American Smelting and Refining Company at Maurer, N. J. In a letter which we received from him this summer, he wrote that he had just finished the design of and was erecting a modern steam generating plant for his refinery. The concluding words of his letter were: "Please give my regards to my friends and tell them that I do not find Russia such a fierce place to live in as we Americans are led to believe. In fact my wife and I find Kyshtim living, people, and climate all that could be desired, and we have spent a very pleasant year here."

Personal

Mr. Philip Argall, manager of Stratton's Independence, Ltd., sailed from New York on Oct. 18 to attend the annual meeting of his company. Mr. Argall will spend some time traveling abroad before his return to this country.

Mr. C. A. Dart has resigned his position as manager of the Rambler Copper & Platinum Company, Holmes, Wyo., and is now in Denver.

Mr. R. R. Foster, late superintendent of the metallurgical plants of the La Tula Mining Company, at La Luz, Guanajuato, Mexico, resigned his position to enter consulting practice. He will have headquarters at Torreon, Coahuila, Mexico.

Dr. Charles H. Fulton is now in charge of the mining and metallurgical department of Case School of Applied Science at Cleveland, Ohio. Dr. Fulton recently resigned his position as president of the South Dakota School of Mines, at Rapid City, in order to relieve himself of executive duties and devote more time to professional work.

Mr. Charles W. Goodale, of Butte, Mont., attended the meeting of the American Institute of Mining Engineers at San Francisco last month.

Mr. Franklin Guiterman, Colorado manager for the American Smelting & Refining Company, returned to Denver Oct. 1, after spending the summer in Europe studying the possibilities of electric zinc smelting.

Mr. Victor G. Hills, of Denver, Colo., who has been in Nova Scotia for some months developing a scheelite property, returned to Colorado for a short time last month. He was called as an expert in a mining suit at Telluride.

Mr. E. M. Johnson is now superintendent of the Altoona Zinc Works, at Altoona, Kan., having lately resigned his position at Depue, Ill.

Mr. Henry P. Lowe, managing director of the Frontenac Mines, Ltd., Central City district, Colo., has gone to England to attend the annual meeting of his company.

Mr. W. J. Quigley, manager of the Chihuahua Mining Company, Chihuahua, Mexico, spent last month in Denver.

Mr. P. E. Van Saun, of the Mill & Smelter Engineering Company, New York, is in New Mexico on professional business for his company.

Mr. Charles T. Van Winkle has resigned his position as superintendent of the Magna plant of the Utah Copper Company, Garfield, Utah, and has opened an office as consulting engineer in Salt Lake City.

Mr. A. W. Warwick, who has been in New York making tests on the Clancy cyanide process, has returned to Colorado, and is at Victor superintending the opening of the Colburn mill in which the Clancy process is to be used.

ORE TREATMENT (*Continued*).

473,186. April 19, 1892. Parker C. Choate, Brooklyn, N. Y. Zinc. Treats complex ores containing zinc, iron, sulfur, lead, gold, silver, antimony, arsenic, selenium, cadmium, bismuth, etc. The ore is crushed and, if it contains an excess of sulfur, roasted at a moderate temperature. It is then mixed with coal-screenings, and roasted on a perforated grate beneath which air is admitted. The zinc and other bodies volatilized therewith, e.g., oxides of antimony, arsenic, selenium, cadmium and bismuth, are caught in bags. The condensed fume is taken from the bags and roasted at a temperature of from 300 to 800° F. in a muffle-furnace, to drive off the impurities more volatile than lead or zinc. The zinc oxide is dissolved in sulfuric acid, the lead sulfate settling out. The zinc sulfate solution is electrolyzed between anodes of lead or carbon and cathodes of zinc or copper. The freed acid rises to the surface of the cell and is drawn off through overflow pipes. As it contains considerable zinc, a portion is returned to the lixiviating tank and regenerated by the addition of fresh zinc oxide. Another portion is returned to the cell. Water is added from time to time to replace the loss. The deposited zinc is stripped off the cathodes and melted, or is melted therewith when zinc cathodes are used. The residual sulfates from the bottom of the lixiviating tank are smelted. The tailings from the roaster are also smelted to recover the iron, gold and silver.

484,809. Oct. 25, 1892. George J. Atkins, of London, England. Gold, silver, etc. The apparatus illustrated is substantially the same as that of the patentee's previous patent 473,105. The amalgamating apparatus is connected to the cathode of the electrolytic apparatus or to the positive pole of a dynamo, and a supplemental anode is placed in the exit mouth of the amalgamating apparatus to cause direct deposition of any gold and silver in the solution. The process is claimed as a continuous treatment consisting in passing the ore through an anode compartment while in contact with the anode and then amalgamating it; or, after the anode treatment, passing it slowly through the cathode compartment and thence to the amalgamator.

495,212, Apr. 11, 1893, John Franklin Wiswell, of West Medford, Mass., Assignor to the Electric Gold and Silver Chlorination Company, of Kittery, Maine, and Boston, Mass.

Amalgamates precious metals by adding to the ore in a crusher a solution consisting of mercuric chloride and sodium hypochlorite. The mercuric chloride is prepared by passing a current through cups containing mercury immersed in common salt solution, carbon cathodes being used. The overflow from this tank is electrolysed, carbon electrodes being used, to form sodium hypochlorite. The calomel formed in the cups is heated in a separate receptacle with aqua regia to form soluble mercuric chloride. Iron must be present during amalgamation, and if not present in the ore may be liberated from the iron crusher by the sodium hypochlorite, or may be introduced as iron filings.

BOOK REVIEWS.

Metallurgy of Tin. By HENRY LOUIS, D. Sc. 8vo; 138 pages; 41 illustrations. Price, $2.00. New York: McGraw-Hill Book Company.

A reprint of a monograph by the author in "Mineral Industry," 1896, with such more recent information as was available. The author deplores the non-progressive character of the industry, also the profoundly secretive attitude of tin smelters, and pungently remarks: "To what extent these two facts, the slow advance of the industry and the secretive habits of those engaged in it, are related as effect and cause, may be left to the judgment of the reader."

Hendricks' Commercial Register of the United States for Buyers and Sellers. Twentieth annual edition. 1420 pages. Price, $10. New York: Samuel E. Hendricks Company.

This well-known commercial register for buyers and sellers, which covers all branches of architectural, engineering, electrical, mechanical, and kindred trades and professions, appeared first in 1891. The twentieth edition, just issued, is more complete than any of the former.

The total number of classifications in the volume is now over 45,000, each representing the manufacturers or dealers of some machine, tool, specialty or material required in the above named industries. The whole represents upward of 350,000 names and addresses.

The new edition will, undoubtedly, prove as useful and reliable as the former ones.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Chlorination versus Cyanidation.

Less than a decade ago the respective merits of the chlorination and cyanide processes of treating gold-bearing ore formed the basis of many a heated controversy which aligned leading metallurgists in two opposing factions. Each process had its champions, but neither held undisputed sway in practice or received the unqualified approval of a majority of the profession. To-day cyanidation appears to have the field to itself, only one prominent chlorination plant remaining in this country, viz., that of the United States Reduction and Refining Company in Colorado.

With apparently such a sweeping victory for cyanidation it might be surmised that the disparity between the two processes is greater than it really is. An excellent opportunity has been afforded in Colorado for a close comparison of the two processes as applied to Cripple Creek ores. This comparison is the more complete because both chlorine made by electrolysis and chlorine generated from bleaching powder and sulphuric acid have been used for years in two competing custom plants. It is a significant fact that the one using electrolytic chlorine continues to treat ore by chlorination, while the last to use bleaching powder and acid has abandoned the method in favor of cyanidation.

In the matter of initial cost of installation of plant the chlorination process is more expensive than cyanidation, due largely to the lead-lined solution tanks, etc., required in the former process. If electrolytic chlorine is used, another item also is added to plant cost. Again, the chlorination process is restricted in its application to non-argentiferous gold ores and to those containing little or no lime. In the latter respect chlorination has been losing ground in Colorado, as lime has been an increasing constituent of Cripple Creek ores, requiring the addition of as much as 40 lb. of sulphuric acid per ton of ore treated.

The cost for chemicals in the two processes will be about the same per ton of ore treated, provided sufficiently cheap electrolytic chlorine is available for chlorination. If chlorine can be made at a cost of four cents per pound for salt and power, the latter costing about one cent per kw-hour, it is likely that chlorination can compete with cyanidation in cost of treating a favorable ore. Under the conditions given the cost of chlorine would range from 18 to 30 cents per ton on sulpho-telluride ores such as are now being mined in the Cripple Creek district.

In refining costs chlorination has an advantage over cyanidation, as it also has in the possibility of making monthly cleanups, thereby avoiding the necessity of carrying a large amount of gold in solution to be estimated in the monthly inventory. This is considered quite an important point in favor of chlorination for a custom plant.

Obviously the chlorination process has lost ground for good economical reasons. But it is a fact that in none of the chlorination plants of the past or present the latest advances in electrolytic chlorine processes (which have been significant in more than one way) have been employed, simply because they were not yet available when those plants were built. With electrolytic chlorine now constantly looking for new outlets, it is not impossible that the pendulum may swing back and chlorination may get another and better chance in the metallurgy of certain particularly suitable ores.

Spelter and Natural Gas

One of the most striking examples of the attractiveness of cheap fuel in metallurgical enterprises, is to be found in the Kansas-Oklahoma natural gas fields and the large zinc smelters located there. Statistics on the Western production of spelter show the transference of the zinc smelting industry from the vicinity of coal fields in Illinois and Missouri to the newer and more attractive gas fields of Kansas and Oklahoma. But no doubt with the gradual exhaustion of natural gas we shall witness a migration of the smelters back to Illinois.

In the first eight years of the decade from 1901 to 1910 the production of spelter in Illinois remained almost stationary at from 45,000 to 50,000 tons per annum. This increased slightly in 1909 to about 67,000 tons, and again in 1910 to 73,000 tons. The Missouri production during this decade held a fairly steady average at about 11,500 tons for the first eight years, but fell to 7000 tons in 1909 and 5500 tons in 1910. During the same period, however, the spelter output in Kansas increased from about 75,000 tons in 1901 to 105,000 tons in 1910. And beginning with 1907, which was the first year in which Oklahoma was credited with spelter production, that State has increased in output from 5000 tons to 35,000 tons in 1910.

This change in the reduction center of the zinc industry has been due to the cheap natural gas available in Kansas and Oklahoma, and any future change to Illinois will be due to cheap coal, for the spelter producing States are but minor producers of zinc ore, while the largest ore producing State is a diminishing producer of spelter. When the production of spelter in 1910 was apportioned to States according to source of ore, Kansas was found to have produced but 4.05 per cent of the spelter made in the United States; Illinois, 0.61 per cent; Oklahoma, 0.91 per cent, and Missouri, 55.71 per cent. But when apportioned to locality in which the ore was smelted, regardless of its source, Kansas led in spelter production among the Western States, followed by Illinois, Oklahoma, and Missouri in the order named.

The natural gas in Oklahoma and Kansas is nearly pure methane, containing approximately 90 per cent CH_4, from 1 to 2 per cent CO, and the balance oxygen, nitrogen, and carbon dioxide. The heat value of methane is 966 b.t.u. per cu. ft., and of carbon monoxide, 344. Based on the analysis of the natural gas it has a heating value of about 875 b.t.u. This is a high value compared with that of producer gas, which averages 150 to 160 b.t.u. per cu. ft. Natural gas is now bought for smelting in Kansas and Oklahoma for three cents per thousand cubic feet, which is equivalent to producer gas at 0.6 cent when fuel values are considered. Prices for other industrial uses of natural gas in this region are higher than for smelting, the enormous volumes used in the latter work giving the advantage of a lower price. For firing boilers in the Joplin field, to which district a great deal of gas is piped from Oklahoma, gas costs 12.5 cents per thousand cubic feet, while for gas engines the cost is 25 cents. Electric power generated from gas is sold at Joplin at a cost of one cent per hp-hour, and can be generated by individual large plants at a cost of six to seven mills per hp-hour.

In view of the favorable natural resources of the Kansas-Oklahoma-Illinois district it is not surprising that ore and concentrates from Montana, Utah, Colorado and other Western States, as well as from Mexico, are shipped there on favorable freight rates for the long haul. But the prospect of exhaustion of the gas is always in sight, and even now the tendency is to raise the price. Kansas has declined as a producer, but Oklahoma is rapidly coming to the front and promises large volumes of gas. Seven cents per thousand cubic feet is now being asked for some industrial uses, and even higher prices will prevail where the gas has to be piped long distances.

The Electric Furnace and the Scrap-Metal Business

We have pointed out on several occasions in these columns that the electric smelting and refining furnace has several peculiar fields of its own, due to the differential advantages which its own nature gives it. Chief among these fields is the electric refining of a semi-refined steel producing a high-grade tool steel, which has had a considerable degree of commercial success in the past few years. Then the production of the difficultly reducible ferroalloys, such as ferrosilicon, ferrotitanium and ferrochrome, has been an assured commercial success both here and abroad for some time past. At present we see the electric brass furnace and the electric smelting furnace for zinc-lead ores both measurably close to the commercial stage. In all these three are certain innate points of superiority, or, to be concise, certain points of differential advantage in the application of electric heat to the work to be done.

These same advantages repeat themselves in the case of the melting down, reducing and refining of metal refuse or waste products from cities and manufacturing plants. The first point of superiority that electrothermic treatment possesses over the older forms of treatment is high degree of control over temperature. This is apparent even to the layman, and it is both true and humorous that many engineers are more or less laymen when it comes to electrometallurgy. Granted once the proper reciprocal relation between the generation of heat and the absorption of heat we have as a logical conclusion perfect control over the temperature of the reacting zone and over the operations therein. As a matter of practical fact, in any successful electric furnace we have an approximation to this ideal condition.

Next in apparent importance is the control over the chemical properties of the fluxes and slags and the reducing properties of the atmosphere. This is particularly true of the electric zinc furnace. Other advantages are absence of dust and heat, the low labor charge and the freedom from exacting care by the furnace men. It is really surprising to see an electric furnace in operation with pointers on the ammeter and voltmeter staying at their positions "as if they were glued there." Such is the great regularity of electric smelting when it is properly

understood. As the thermal efficiency of the electric furnace is always high, provided it is over 150 kw capacity, all these factors combine together to make a low working charge with a high degree of metallurgical economy.

The greatest advantage to our way of thinking is a commercial one—the low capital cost provided power is bought from the outside and only the transformers and switchboards are owned. As the energy transferred per unit of working volume is large—3 kw to 10 kw per cubic foot—the furnace is not expensive.

So we see that every item of reasoning points directly to a wide potential field for the electric furnace in the smelting and refining of scrap metal and waste products that our foundries and manufacturing centers produce. The commercial reasons are both simple and obvious. In any large city many tons of such stuff as brass-founders skimming, skeleton brass, steel borings, etc., are produced each year. In any large city there is always a surplus of electrical power that can be sold reasonably on the 24-hour basis for nine months and on the 20-hour plan during the months of December, January and February. Join these two industrial things by a successful electric-furnace process and we have the raw material which is produced locally turned into the finished product locally. Four handlings and two railroad hauls are avoided. Besides there is created a market for some of the surplus power of the central station. With such a powerful metallurgical instrument at hand, the losses of metallic values would be necessarily low if this same agent were intelligently applied. In general there seems to be no room for doubt that the electric furnace will find a permanent useful place as a means for working up waste material into available material. In this century elimination of waste equals efficiency.

Of the various specific instances that seem apparent, the reduction of skimmings from brass or bronze foundries strikes us as the most promising. These analyze from 40 per cent to 70 per cent zinc plus tin plus copper. Consider a "government or navy" bronze of the composition copper 88 per cent, tin 10 per cent, zinc 2 per cent, which sells in the ingot form for 15 cents or 16 cents. The dross from this will contain a greater proportion of the more easily oxidized tin and zinc. It is sold for its copper contents alone at from 3 cents to 4 cents a pound. Experiments of which we have definite knowledge show that it is not a difficult task to reduce this in an electric furnace and with the mixture of copper to produce an ingot substantially the same as the original alloy. How much better it would be to have this done than to have the skimmings bought by a copper smelter where the copper alone is recovered and that, too, in the debased form of copper-matte. To repeat, the place to do the converting is at the point of production. Naturally there are obvious difficulties. Chief of these is the chance that there would be contamination of skimmings by iron or other foreign substances. It may also be argued that there will be a displacement of the crucible by the electric alloy-furnace which makes no dross and that hence the supply of skimming will rapidly diminish. But practically this should not carry too much weight because human inertia will see to it that the crucible furnace will be only gradually displaced by the electric alloy-furnace. The electric lamp has not supplanted the gas lamp, nor has the latter kerosene lighting. Indeed some wiseacres say that the consumption of candles per capita is as large as ever.

The next apparent fissure in the existing commercial structure into which the electric furnace can insert its wedge is the melting down of steel borings, chips and turnings. The same remark can be made of similar materials of cast iron. Their bulky nature makes them expensive to transport and smelt. The electric furnace which has no blast to oxidize the great surface exposed or to blow them out of the stack has a marked natural advantage over the open-hearth furnace in the case of steel borings, while it has a slight though marked advantage over the cupola furnace in the case of cast-iron borings. In each of these instances the proper and logical procedure is to take the borings, chips and turnings which are commercially unavailable, practically speaking, and to turn them electrically into steel castings or iron castings which are commercially much desired and of great worth. A fact that is apparent and of importance is that it is simple to attain in the electric furnace a casting of good physical properties, *i.e.*, freedom from slag, blow-holes and dissolved oxides. Interdependent with this is the fact that good physical properties conduce far more to a sound casting than do good chemical properties. Naturally, there are many essential details of engineering and business that must be learned and mastered in order to make this a success. But the manufacture of the finest and most difficult steel castings or iron castings out of the cheapest kind of scrap is not only theoretically possible but actually has been done. How attractive it is commercially can be seen by the fact that the raw materials sell at present for from 25 cents to 40 cents per hundred pounds and the finished material sells for as high as 6 cents a pound or over.

Other specific possible examples can be adduced, such as the smelting of tin dross, which indeed is being accomplished commercially, or of Babbitt metal dross. The melting of aluminium dross is possible, but here it is not possible to reduce the oxide, but only to save the entrained prills of metal. The reduction and distilling of galvanizer's skimmings and the galvanizer's "dross" is also open to the electric furnace. Unfortunately, the problem here is complicated by the presence of sal ammoniac in case of the skimmings and the necessity for a practical condenser in both cases. The refining of plumbiferous refuse products is also feasible. But here the older types of furnaces are securely intrenched. But the distinguishing characteristic in many of the above instances is that no great inventive ability and no great business enterprise is needed. A combination of average metallurgical experience and of average business knowledge and leavened by a grain of originality is enough.

A certain amount of commercial inertia, of course, acts like a brake on this and on all material changes in our industrial structure. Indeed it is very proper that it should be so, even though the adventurous minded think it unnecessary. But we are firmly of the opinion that in every manufacturing center good opportunities exist for the "little fellow" in electrothermal treatment of waste metal material, for the capital cost of a five-ton electric smelting and refining plant should not exceed $20,000. Broadly speaking, both specific and general observation indicate that the "trusts" leave plenty of just such opportunities for the "able little fellow."

American Institute of Chemical Engineers.

The fourth annual meeting of the American Institute of Chemical Engineers will be held in Washington, D. C., from December 20 to 22. The headquarters will be at the New Willard Hotel, where all the professional sessions will be held.

The first session will be held on the morning of December 20 (Wednesday), when the following papers will be read and discussed:

Clarence Hall, "Advances in Testing Explosives."

Richard X. Meade, "Distribution of Power in Portland Cement Manufacture."

J. T. Baker, "Manufacture of C. P. Acids."

L. S. Hughes, "Combustion of Pulverized Coal."

Ludwig Thiele, "Manufacture of Gelatin."

S. F. Peckham, "The Natural Bituminous Rocks of the United States."

In the evening the retiring president, Dr. F. W. Frerichs, will present his address on some problems in chemical engineering practice (manufacture of chloroform from alcohol; construction of laboratory apparatus; manufacture and testing of shipping cylinders for liquid ammonia gas).

This will be followed by a paper by John C. Minor, Jr., on the manufacture and testing of carbonic acid cylinders.

On the morning of December 22 (Friday), there will be a symposium on the U. S. patents, papers to be presented by Messrs. E. B. Moore, Edw. T. Fenwick, Walter D. Edmonds, and R. N. Kenyon.

In an evening session Mr. F. G. Wheeler will present an illustrated lecture on the adaptation of the centrifugal pump to chemical service, and Dr. J. C. Olsen will read a paper on a course in chemical engineering education.

The social functions include a subscription dinner at the New Willard on Thursday evening and a reception at the White House on Friday afternoon.

The program of visits and excursions includes the Bureau of Standards on Wednesday afternoon, the U. S. Proving Grounds at Indian Head, Md., on Thursday, the Patent Office on Friday afternoon, and the steel plant at Sparrows Point, Baltimore, or the cement plant of the Tidewater Portland Cement Company on Saturday.

Surface Combustion.

A most interesting lecture was presented on October 27, by Prof. William A. Bone, of the University of Leeds, Eng., at the Chemists' Club in New York, before the members of the different chemical societies. Professor Bone gave a review of the results of the work which he has done on this subject for a long series of years, and his discourse, as well as the very successful experiments by which the lecture was illustrated was greatly enjoyed.

The subject is fully covered in a special article by Mr. Kershaw on page 628 in this issue.

The Western Metallurgical Field.

Cyaniding Concentrates.

A fine example of careful experimental work, followed by successful application of the results obtained, is to be found in the cyaniding of concentrate at the Treadwell mines, Alaska. At the time the experimental work was undertaken the concentrate was being shipped to the smelter at Tacoma, and the cost of treatment of 3-oz. gold concentrate was $11.95 per ton. From the experimental work it was estimated that the concentrate could be treated at home by cyaniding at a cost of $3.25 per ton. The details of experimental work and the present operation of a 100-ton plant were presented by Mr. W. P. Lass, superintendent of the plant, at the recent San Francisco meeting of the American Institute of Mining Engineers. We note here the most interesting features of the experimental work, which will show the development of the process now used.

The concentrate from the various mills amounts to about 1.8 per cent of the original ore, and contains: Fe, 40 per cent; S, 1 per cent; SiO_2, 11 per cent; Au, 2.5 to 4 oz. gold, and 0.75 oz. silver per ton. Preliminary tests were made in glass jars, after which 50-lb. composite samples were ground to 200 mesh in a clean-up barrel with iron balls, the pulp passed over amalgamated plates and then agitated in small Pachuca tanks 4 ft. high and 14 in. in diameter. The results showed that 75 per cent of the gold could be recovered by fine grinding and amalgamation, and 96 per cent by amalgamation followed by cyaniding. The next step was the construction of an addition to one of the mills, and the erection of a 4-ft. x 12-ft. Abbé tube mill. Various forms of classifier were tried, the Dorr proving most satisfactory. Callow cones were used for dewatering, and the agitation was carried on in a Pachuca tank 10 ft. in diameter and 22 ft. high.

The results further showed that by grinding in a 1.5-lb. cyanide solution an extraction could be obtained by cyaniding alone equal to that obtained by cyaniding and amalgamation, or 96 per cent. Thus a satisfactory extraction was obtained either by amalgamating and cyaniding or by cyaniding direct. A preliminary agitation with alkali solution was found to shorten the time of cyanide treatment and save 25 per cent in cyanide consumption. Passing the air used for agitation through a receiver filled with caustic soda or milk of lime also decreased the cyanide consumption, presumably by the removal of oil and CO_2 from the air. When grinding in solution of over 1 lb. per ton, followed by amalgamation, it was difficult to keep the plates bright, due to a dull white surface deposit which, if allowed to remain, turned to a dull gray. A muntz-metal plate was substituted for a copper plate, but as all the plates were coated, no variation in the result was noted, and there did not appear to be any essential advantage in its use.

The results obtained from a period of two years' investigation justified the building of a 100-ton plant. The plans provided for the use of amalgamation if desired, and ultimately nearly 5000 tons were treated by each method before finally deciding to abandon the time-honored amalgamated plate.

The following table shows the work of one of the 5-ft. x 22-ft. tube mills when treating an original feed of 88.75 tons per day.

	+ 100 mesh	+ 200 mesh	— 200 mesh
	%	%	%
Feed	48.7	41.5	9.8
Discharge	10.1	26.4	63.5

This product is classified in Dorr classifiers and only the overflow passes to the cyanide tanks. This material screens more than 98% through 200 mesh.

An interesting device is used in the Pachuca tanks to bring settled concentrate into circulation. After the first treatment the pulp is allowed to settle, and it forms a 30-ton packed mass in the bottom of the Pachuca. This is brought into agitation in 15 minutes by means of a device known locally as a spider, which is an adjustable hollow annular casting with radiating fingers, the whole encircling the central agitation column. When the charge is to be put in agitation the spider is lowered by a small hand windlass until it rests on the settled charge. Air is then turned through the fingers, and at the same time the solution for the next treatment is run into the tank. The device rapidly bores its way to the bottom of the Pachuca, clearing a path to the bottom of the central agitation column. As soon as this is opened and air has been admitted to the central pipe the spider is raised from the tank and full agitation of the charge proceeds.

Kelly presses are used for the final filtration of the pulp, and Merrill zinc dust precipitation presses are used for the recovery of the gold precipitate. In connection with zinc dust precipitation considerable annoyance has been occasioned by the clogging of the cloths in the gold presses. Filter cloths of several kinds have been tried, and now the lightest and cheapest muslin is used with results no worse than with the more expensive

grades. Another trouble was experienced due to the accumulation of precipitated gold in the pipes carrying the gold solution and zinc emulsion to the presses. The interior of the pipes gradually becomes smaller in area; in one instance a 6 in. pipe having an area of 28 sq. in. was reduced by incrustation of gold slime to less than 4 sq. in. After three months' use 80 ft. of the pipe was cleaned with a recovery of $25,898.

A change has been made in the Merrill precipitating presses, so that the effluent solution passes through open pipes into a launder on top of the presses instead of through cocks as usual. This was to permit of intermittent operation of the presses without draining the solution each time the press was cut out, and thereby allowing zinc to oxidize and the mass to settle in the frame so that the full efficiency of the zinc could be obtained. This change has resulted in raising the gold value of the precipitate from $15 to $25 per pound.

The cyanide plant has now been in operation for a year, and during the month ended August 15, 2010 tons of concentrate were treated at a cost of $2.8764 per ton and an estimated extraction of 97.025%, as compared with the experimental estimates of $3.25 per ton and 96% extraction.

New Smelter for United Verde.

The United Verde Copper Mining Company, Jerome, Arizona, is to build a new and modern copper smelting works. The United Verde has long been a prominent copper producer, largely owned and controlled by W. A. Clark. Owing to the policy pursued by the owners, little has been known about the operations of the company, either financially or technically, and this lack of knowledge has caused many rumors to spread regarding the company. Metallurgically speaking, the United Verde was for many years in the fortunate position of being able to run and make money without due regard to that careful technical direction which is considered essential by our present large producers. Many interesting stories are told of the perplexities of former managers and superintendents, many of whom were better fitted for many other forms of work than smelting; and whether true or not, they illustrate well the ludicrous situations in which a non-technical man might find himself in conducting the smelting business.

A number of misfortunes have befallen the United Verde, such as mine fires and caving ground, the latter having been specially disastrous because the smelting plant had been built on the mine property and the settling of the ground damaged the buildings and necessitated much reconstruction. It has been rumored repeatedly that on account of this condition the company would erect a new plant, and undoubtedly the present decision has been influenced by the misfortunes of the past. It will be remembered that the United Verde expected to make a trial of the Knudsen converting furnace, as reported in these columns some months ago, but this was rendered impossible by reason of a serious cave which ruined the construction work before the process could be tried out.

The new smelter will be situated about six miles from Jerome, and at a lower elevation than the present plant. The men in charge of construction are C. H. Repath and J. B. McIntosh, who were prominently identified with the designing and construction of the Tooele plant of the International Smelting & Refining Co., in Utah.

Tooele Lead Plant.

Construction work at the lead plant of the International Company has been progressing, and all of the excavation and foundation work is reported to be completed. Some of the minor buildings such as the bag house, extension of power house, flues, etc., have been completed, and a large amount of steel is on hand for the construction of the bins. Erection of the furnaces is to proceed at once, and it is hoped that two of the three furnaces will be ready for operations early in 1912. New ore contracts are being made with Idaho and Utah producers, and apparently there will be a large quantity of ore on hand and contracted for when operations begin.

Nevada Hills Mill.

In October the new mill of the Nevada Hills Company, situated at Fairview, Nevada, commenced operations, and is now running at practically full capacity. The plant should be one of the best in Nevada for its construction and design were in charge of engineers who had been connected with other successful plants. According to preliminary reports the mill has shipped its first consignment of gold and is making a recovery of between 92 and 93%.

Company Reports.

Utah Copper Company report for the third quarter of 1911 shows that 1,273,373 tons of ore were treated at both plants, the average grade of ore being 1.4829% copper. The gross production for the quarter was 25,851,456 lb. copper, an average monthly production of 8,617,152 lb. The average cost of copper per pound, after making allowances for smelter deductions, and without crediting miscellaneous income, was 7.56 cents, the lowest in the history of the company. The entire Magna plant was in operation through the whole quarter, but only five remodeled sections of the Arthur plant were in commission. The Magna plant treated about 12,000 tons per day and the Arthur plant 3000 tons. This indicates a final capacity for the Arthur plant of 8000 tons per day when the thirteen sections are completely remodeled.

The Ray Consolidated Copper Company has issued a report showing operations since the interim report of April 1, 1911. Four sections of the concentrator are in operation, running at a capacity of about 800 tons per day each. The sections were designed to handle 1000 tons each daily, and have demonstrated their ability to do so. The gross production is about 2,500,000 lb. per month from ore averaging 1.85% copper. The mill extraction is averaging 69%.

Non-Ferrous Metal Market.

There has been little or no change in the market for non-ferrous metals since our last report. The demand for all continues good and the prices generally are firm, reflecting the active condition of foreign markets.

Copper.—Domestic consumption has not been more than normal, but the demand for export has continued to be heavy. As a result there was a large business at advancing quotations. At our last report Lake copper is quoted at 12¾ to 12⅝ cents, and electrolytic at 12.30 to 12.35 cents.

Lead.—The market is unchanged at 4.10 to 4.12½, St. Louis, and 4.20 to 4.25, New York.

Tin.—A large business has been done in this metal, mostly for future delivery. Stocks are so low that a premium on spot tin may come to pass. November tin was quoted at 42¼ cents per pound.

Spelter.—The scarcity of November spelter was more pronounced than in previous months, but there has been no change in the prices. Business has not been more than normal for immediate needs. St. Louis spelter was quoted at 6 to 6.10 cents and New York at 6.15 to 6.25 cents.

The Iron and Steel Market.

November in the iron and steel market opened with gloom universal and closed with sentiment uniformly optimistic, buying heavier and prices showing a tendency toward firmness.

Sentiment had been uniformly pessimistic for three months when on Oct. 26 the United States Government brought suit against the United States Steel Corporation for its complete dissolution, not simply a dissolution of the Steel Corporation as a holding company, but a dissolution also of the component elements, the consolidations of 1898, 1899 and 1900, which in 1901 were brought under the ownership of the corporation. The immediate effect of the bringing of this suit was a fresh accretion of pessimism, but this made no material

impress upon the market, which was depending upon actual conditions and not upon sentiment for its strength. So thoroughly had the previous pessimism liquidated the situation that the market rather tended to improve.

Suddenly the railroads became rather free buyers. Several large purchases of rails for 1912 delivery were made, and although rails were the only commodity which had suffered no decline, the $28 price established early in 1901 having been maintained since, no question seems to have been raised, and the orders booked, aggregating 200,000 tons or more, appear to have been placed at this price, although perhaps the sales were made with a guarantee against decline. It has long been known that the railroads are much more interested in raising the standard of quality than in depressing the price.

In the closing days of October roads comprising the New York Central system began placing orders for cars, and other car orders soon appeared. The total bookings for November cannot be stated at this time, and the movement is not yet over. In brief, it may be said that in the first half of this year car orders amounted to about 50,000 and in the next four months to about 20,000, while November and December are likely to see a total of between 50,000 and 100,000. When early orders in this movement amounted to 20,000 the large plate mills estimated that the business would be sufficient to give them as heavy operations through December as they had had in September and October; later orders guarantee them heavier operations than formerly.

An incentive for the purchase of cars at this time is their cheapness, prices being lower than at any time since the steel car came into vogue. The railroads, however, are believed actually to need the cars. They have never been known to make large purchases in cars or any other line merely because prices were low, even though it has frequently been urged that in certain cases they would eventually save money by doing so.

Unfilled orders of the United States Steel Corporation increased during June, July and August, decreased 84,668 tons in September and increased 83,011 tons in October. Estimates are that in November a considerably larger increase occurred.

Production of pig iron in November was at a slightly lower rate than in October, when the rate was approximately 25,000,000 tons a year, but there had been a continued increase since July.

Operations in the steel industry as a whole continued at about 75 per cent of full capacity. It should be observed, however, that at the present price level no more than 90 per cent could be expected to be operative, so that the addition of business equal to 15 per cent of capacity would in all probability effect some slight advance in prices.

The general level of finished steel prices, averaging the various commodities approximately according to their tonnage importance, declined about $1 per ton during November, as was the case in both October and September, while the months of July and August together witnessed a decline of about $1 a ton.

Pig iron production in 1911 may be forecasted at about 23,700,000 tons, to fulfill which prediction would require about 370,000 tons more to be made in the second half than the 11,665,706 tons officially reported for the first half.

Pig Iron.

The pig iron market has shown remarkable quietness. Almost as a unit buyers have refrained from making any purchases for the new year and are endeavoring to clean up their yards completely by the end of this year. Purchases have been very light. On the whole, the statistical position of the furnaces is good, as in the main they are reducing stocks. The present situation is fraught with some danger, in that buyers may wait too long and then be forced to come into the market in a body, with the result of prices advancing and an unwarranted increase in production occurring. The most important transaction in November was the purchase of 25,000 tons of Bessemer iron by the Republic Iron & Steel Company from the Ohio Iron & Steel Company, operating a merchant stack at Lowellville, near the company's Bessemer steel plant at Youngstown, Ohio. The price paid was $14.25 and delivery was to be completed in a few weeks, the iron being shipped from stock. Brokers had sold a few odd lots of Bessemer at $14, a cut price, and the Republic purchase served to stiffen the market. The market stands quotable as follows: Birmingham, $10 for No. 2 foundry; delivered Philadelphia, $15 for No. 2X, $14.50 for basic, $20 for standard low phosphorus; f. o. b. Chicago district furnaces, $14 for No. 2; $14 f. o. b. valley furnaces (90 cents higher delivered Pittsburgh); Bessemer, $14.25; basic, $12.50; No. 2 foundry, $13.25; forge, $12.75; malleable, $12.50 to $12.75.

Steel.

The market in billets and sheet bars has been a decidedly open one, with special prices made on the few transactions which have occurred. The general level may be quoted at $20, Pittsburgh, for Bessemer and open-hearth billets and sheet bars. Rods are quotable at $26, Pittsburgh.

Finished Material.

Open quotations on bars and plates declined $1 a ton during the month, and on wire products and structural shapes $2 a ton. At the present level the market is firmer all along the line than it has been at any time for months. There may be some further declines, but in general the present level is likely to hold, and some slight advances may occur before the end of the year. This is the first time since April that an advance in any steel commodity is a distinct possibility.

We quote regular open market prices as follows, these prices being occasionally shaded:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.10 to 1.15 cents, Pittsburgh.

Shapes, 1.10 to 1.15 cents, Pittsburgh, for beams and channels, 3 to 15-in., inclusive, zees and angles 3 x 3-in. and larger.

Steel bars, base, 1.05 to 1.10 cents, base, Pittsburgh, for prompt delivery, 1.10 to 1.15 cents on contracts for first quarter; 1.20 to 1.23 cents, Chicago, 1.10 to 1.15 cents, Buffalo.

Iron bars, 1.25 cents, Pittsburgh; 1.20 cents, Philadelphia; 1.15 to 1.20 cents, Chicago.

Wire nails, $1.55, base; plain wire, 1.35 cents, base.

Black sheets, 28 gage, 1.85 cents; galvanized, 2.85 cents; blue annealed, 1.40 cents; painted corrugated roofing, $1.35 per square; galvanized, $2.50, f. o. b. Mahoning valley mills.

Tin plates, $3.40, Pittsburgh, for 100-lb. cokes.

CORRESPONDENCE.

Manufacture of Pig Iron in the Electric Furnace.

To the Editor of Metallurgical and Chemical Engineering:

Sir: In the paper of Mr. E. Odelberg in your October issue on electric pig iron and the manufacture of steel therefrom much stress is laid on the fact that when a low-silicon, low-carbon iron is produced which is filled with blow holes the inner surfaces of these blow holes are white, showing entire freedom from oxidation (page 509).

It is pointed out that an entirely different condition prevails as to the surfaces of blow holes in similar iron made in the blast furnace, this showing all the colors of the rainbow; the oxide colors familiar in hardening and tempering steel. This difference is held to prove the entire absence of an oxidizing condition and of oxides in the hearth of the electric furnace, and their presence in that of the blast furnace.

This would be interesting and important if it were true, but, as a matter of fact, the writer has made many tons of white iron full of blow holes (which is known under the trade name of "Spongy Six") in a charcoal blast furnace, and of the many thousand blow-hole surfaces examined, none ever showed any

color except silvery white just as described by Mr. Odelberg.

The real truth of this matter is that these blow holes are produced by the action of imperfectly reduced ore in the bath reacting on the carbon (presumably that dissolved in the iron) and forming thereby carbon monoxide. This, of course, is unable to exert any oxidizing influence under the conditions prevailing in the bath, and the interior of the blow holes which it forms are necessarily free from oxide and perfectly white in consequence. The carbon monoxide does not escape from the iron because the temperature prevailing in the hearth under such conditions is extremely low and the iron is too pasty to permit the bubbles of gas to rise through it.

The electric furnace will come into its own in time, probably in Sweden and on our Pacific Coast sooner than elsewhere on account of the presence in those regions of iron ore and water power in abundance, and the scarcity of mineral fuel. But it is as well to let its growth be a natural one, unhindered by extravagant claims which tend to make the claimants, and sometimes the process, ridiculous.

As the ores of iron are all oxides and gradually reduced as they descend through the furnace, it is always possible for cold or irregular operation to introduce into the hearth imperfectly reduced material containing oxygen, quite irrespective of whether the source of heat for the reduction process be the combustion of carbon or an electric arc. This is so rudimentary that it should not require statement, but apparently it does.

JOHN J. SMITH.

Abandoning the Terms Carbonic Oxide and Acid.

To the Editor of METALLURGICAL AND CHEMICAL ENGINEERING:

Sir: Some time in the middle of the last century chemical nomenclature was reformed by progressive chemists, so as to make terms correspond more nearly with the facts; the formula for water, for instance, was thus changed from HO to H_2O.

It was, I believe, at that time that the consistent applications of the terminations -ous and -ic were introduced for the lower and higher oxides respectively, in order that the names should correspond more nearly with the compounds. According to this nomenclature the lower or monoxide of carbon, CO, should for consistency sake be called carbonous oxide, and the higher or dioxide, CO_2, be called carbonic oxide, even though there may still be some uncertain theories about the valency of carbon.

Notwithstanding these very desirable reforms, and the length of time since they were introduced (more than a generation ago), one still finds the term carbonic oxide used by some for the *lower* oxide CO, the higher one being called by them "carbonic acid," although it is in no sense an acid, any more than the oxide of sulphur, SO_3, is sulphuric acid. These were the older terms used before the reform of the progressive chemists. A prominent metallurgist even went so far as to say that he had never heard or seen the term carbonic acid used for anything but CO. I believe it has been the custom of careful writers for many years to abandon the older nomenclature.

At present the state of affairs is that when one hears or reads the term carbonic oxide one is at a loss to know what the author meant, unless the context determines it. In view of the fact that in metallurgical reactions it generally makes a very great difference whether CO or CO_2 is meant, this confusion is most unfortunate, and as it seems to take more than a generation to bring about a complete reform in terms, and that it therefore seems hopeless to do so at the present time, it would, in the opinion of the writer, be better to abandon the term carbonic oxide entirely (and of course also the positively incorrect term carbonic acid for CO_2) and use only the terms carbon monoxide and carbon dioxide, about which there can be no doubt; this I believe is what is taught in modern up-to-date colleges. It would be better still to use the symbols CO and CO_2.

There is no objection to using the term carbonous oxide for CO, as there should be no confusion. After several generations have passed by the term carbonic oxide might perhaps again be introduced so that the nomenclature concerning carbon will be consistent with that used for other elements, like cuprous and cupric, ferrous and ferric, stannous and stannic, etc.

Philadelphia, Pa. CARL HERING.

Induction Furnace Design.

To the Editor of Metallurgical and Chemical Engineering:

Sir: In the report of the Toronto meeting of the American Electrochemical Society, in your October issue, page 536, Mr. FitzGerald is reported to have said, in reply to an inquiry of Dr. Waterhouse, that the Roechling-Rodenhauser furnace for such sizes would be found greatly superior to other forms of induction furnaces.

As I and certainly many other readers of your journal would be greatly interested to know *in which respects* a Roechling-Rodenhauser furnace of this size would be greatly superior to mine and other induction furnaces, I ask you to put this inquiry to Mr. FitzGerald into your columns.

Kristiania, Norway. ALBERT HIORTH.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir: Unfortunately I have not got a copy of the stenographer's report of the discussion following Mr. Hiorth's paper at the Toronto meeting of the A. E. S. My remembrance is that Dr. Waterhouse asked for someone's opinion, specifically mentioning my name. I think my reply was substantially as reported, but it must, of course, be treated as an opinion based on my own experience, *so far as it goes.* This is a different thing than an opinion based on an investigation made for the purpose of comparing all types of induction furnaces. I think it is only fair to Mr. Hiorth and his furnace to explain this.

My reply to Dr. Waterhouse was based on the experience I have had in the construction and running of various induction furnaces, on what I have seen of the running of an 8-ton Roechling-Rodenhauser furnace and on what I have read of other induction furnaces, such as that of Mr. Hiorth. There can be no doubt at all as to the superiority of the R-R furnace over various induction furnaces I have had personal experience of. I have seen the R-R furnace running in a most satisfactory way on cold scrap and hot metal from Bessemer converter and turning out high-quality steel.

As to the Hiorth furnace—so far as I know the largest one that is regularly working has a capacity of 5 tons, and according to Richards' report last year[1] was melting high-grade materials used in the manufacture of metal of crucible-steel quality. According to the same authority[2]: "At Mr. Hiorth's plant the induction furnace is used for *melting down high-quality metal* and making a high-quality steel, *but he also uses an electrode furnace for working up scrap.*"

The italics are mine. So far as my information goes the R-R furnace seems up to the present to be the best tool, working by induction, for the manufacture of steel.

FRANCIS A. J. FITZGERALD.

FitzGerald and Bennie Laboratories, Niagara Falls, New York.

An Instructive Experiment on the Flow of Heat.

To the Editor of Metallurgical & Chemical Engineering:

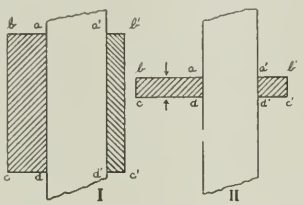
SIR.—In the communication from Mr. Carl Hering in the November issue, entitled "An Instructive Experiment with the Flow of Heat," some conclusions are drawn which rest on a misconception of the conditions involved.

Without going into the mathematics of the conduction and

[1] Transactions of A. E. S., vol. 18, p. 200.
[2] *Metallurgical and Chemical Engineering*, Oct., 1911, p. 545.

radiation of heat, it should be pointed out that Mr. Hering is not warranted in arguing from the fact that more heat is lost through the long than through the short end of a long metallic *rod* held in a flame, that, therefore, more heat will be lost through a thick wall than through a thin one.

Now the cooling in the former case takes place not merely at the ends of the rod, but also—and here to a far greater extent—at the cylindrical surface; while in the case of a furnace or a "tank containing a red hot liquid," the *wall* may be considered as an *extremely short* thick rod of which the cooling surface consists to all intents and purposes of the end only, the remaining surface being comparatively small. In other words, the radiation conditions in the wall are exactly the reverse of those in the rod.



CONDITIONS OF WALLS AND ROD.

In Fig. I, which represents the wall conditions, the total radiation surface is practically the same with the thick wall as with the thin one, being composed chiefly of the end surfaces of which *b c* and *b′ c′* are the diameters. Consequently the amount of heat lost will depend on the rapidity of the *conduction* in the walls, which will evidently be lower for the thick one.

In Fig. II, which represents the rod, on the other hand, the cylindrical surfaces of rotation about *a b* and *a′ b′* make up practically all of the total—and in this case it depends on the relative magnitudes of the radiation and of the conduction coefficients of the material whether more heat will be lost through the long or the short rod. Thus, with a good conductor like copper, Mr. Hering finds the long rod loses more heat; with a poorly conducting substance, like pipe clay, the reverse seems to be true.

The important practical conclusion, however, which needs to be emphasized here, is that noted above, namely, with any material, a thick wall will insulate better than a thin one. Thus, Mr. Hering's experiment does not contradict furnace practice.

B. S. Lacy.

Perth Amboy, N. J.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir: Mr. Lacy would do less injustice to others if he would read over more carefully what he criticises with such rather strong terms as "misconception," "not warranted," etc., before publishing such criticisms.

If he will read over my communication again, he will find that the chief point in it (which he seems to have missed) was to call attention to the surprisingly high virtual thermal resistance which exists at a red-hot surface exposed to the air. In this there are no "misconceptions of the conditions involved"; at least he has not been able to point out any.

In his second paragraph he misrepresents me if he is trying to make it appear in the last clause as though I had concluded that the loss through thick furnace walls in general was greater than through thin ones. The term copper is not mentioned by him. What I did say applied only to copper walls, and I distinctly stated that with clay, and therefore probably with other refractories also, the results would very likely be reversed.

I did and still do maintain, and Mr. Lacy will probably not deny it, that with such a monstrosity as a furnace with relatively very thick walls of copper, the leakage per sq. ft. would be greater through the walls than through the top surface of the charge, if liquid. This would certainly be true when the cross sections and exposed surfaces had the same relations as in the experiment, and this is all that I claimed. Such a monstrosity was used by me only as an illustration in an argument, not as a practical case. When the walls are relatively thin, I should want to try an actual experiment before drawing conclusions. The mathematical relations are complicated and the final result depends on several relations combined (see this journal April, 1911, p. 189). Until Mr. Lacy can show proof to the contrary, I therefore deny that I am "not warranted" in drawing the conclusion which I did.

Mr. Lacy's diagrams are not very clear, but as I understand them he has omitted the flare of the walls, which, of course, is one of the chief features implied by the term relatively thick walls. A furnace with relatively thick copper walls is, of course, a practical absurdity, and was used by me merely as an extreme case, in order to bring out the point more clearly.

In his last paragraph I differ with him when he says "any" material, as with relatively thick walls of copper his conclusions are not correct. In this paragraph he again misrepresents me, if he intends to imply by it that I had claimed that my experiment contradicted furnace practice. My original article clearly states that with clay the results would probably have been the opposite to those with copper, and therefore would confirm furnace practice. In fact, it was to try to satisfy myself that thick walls of insulating material were justified, that I made the experiment.

I desire to add here, however, that I believe that increasing the thickness of walls may easily be overdone, and my experiment tends to strengthen this view. Our data of the necessary physical constants is too meager to determine this mathematically. A furnace which I recently designed remained positively cold on the outside, and it is therefore a question whether the extra thickness was warranted. I am inclined to believe that the thermal resistance of fire-brick work is higher than we now suppose, probably owing to the joints, particularly when the bricks are set parallel to the walls so as to make as many joints as possible, as was the case in this furnace.

Philadelphia, Pa. Carl Hering.

Presidency of the American Electrochemical Society.

To the Editor of Metallurgical and Chemical Engineering:

Sir: As the Eighth International Congress of Applied Chemistry will be held in this country in the year 1912, on which occasion many foreigners are expected to visit this country, and as electrochemistry and metallurgy are represented as sections of this congress, the American Electrochemical Society should, in our opinion, take this into consideration in the selection of its president for the coming year, as he will be expected to represent this society at the official and social functions.

Dr. Charles A. Doremus is in our opinion especially well qualified for the presidency for that year, and would do credit to the society. We hereby recommend to the members of this society that they nominate him in the ballots which they will soon receive. He has an international reputation as a chemist, is a graduate of Heidelberg University, under Bunsen, is versed in the duties of international functions, is acquainted with many of the foreign visitors, having been Official Delegate from the State Department to the Second International Congress, and made chairman of the American Committee of Organization by Moissan, for the Fourth Congress, is conversant with the three principal languages, is able to devote the necessary time to the duties which would be imposed upon him, has been a Director and Vice-President of this society, a member since its organization, was one of the eleven original organizers taking a very active part in starting the society, and in the work of the New York Section, of which he has been Chairman.

Charles S. Bradley, Henry S. Carhart, Carl Hering, P. Heroult, Alois von Isakovics, W. R. Whitney.

Sizing, Diametric and Volumetric, with and without Screens.

By B. F. RICE.

In a large number of the manufacturing industries and in the treatment of ores it very frequently becomes necessary to grade dry and granular material according to size or bulk of particle. This constitutes one of the most serious problems with which engineers and mill men have had to deal.

Up to the present time machines working on two separate and distinct principles have been used for this work. I refer, first, to the different forms of classifiers which classify the material according to its weight, putting a large particle of low specific gravity with a smaller particle of high specific gravity. This is accomplished by the introduction of an hydraulic or pneumatic floating medium. A grading of this kind can be made also on dry material without the use of a floating medium. A machine for work of this character was developed by us, but was discarded for want of a promising field.

Second, different forms of screens, such as the impact, shaking, belt, inclined, trommel and gyratory screens, which have met with only a limited degree of success. This is probably due to a number of different causes, but more particularly to the high cost of maintenance, together with a rather low efficiency.

It has been our aim in the development of the McKesson screenless sizer[1] to provide a cheaper and more efficient method of sizing dry granular material than is afforded by any screening device. This was no small undertaking, and as we were the originators of the idea, as is clearly shown by the United States patent records, we have not only developed a new machine but an entirely new principle, which appears to the uninitiated to be contradictory to the known laws of gravitation. But like a great many other radical departures from old established laws, it is very simple when once understood.

Our policy has been to bring this machine to such a high state of development that its commercial success would be assured before it was presented to the public. We have passed our greatest expectations and I am safe in making the assertion that the sizer is well within the commercial limits of 90 per cent of the industries requiring closely sized material. There are, of course, special cases in this field as in others, that will require especially designed machines to successfully meet their requirements, but the fundamental principle of this machine is such that there is no question but that its development will eventually reach a point far beyond anything ever considered by the advocates of close sizing.

Comparing the work of this sizer to that of a screen, we find, to begin with, that the principle of the sizer is as far removed from that of a screen as is the principle of a classifier from that of a screen, but in the opposite direction. In other words, a screen is intermediate between the two principles. A classifier grades according to weight regardless of size, volume or bulk of particle. A screen grades according to the diameter of a particle and takes cognizance of two dimensions only. The McKesson sizer grades according to the bulk or volume of particle, regardless of its shape, and is affected by specific gravity only to a very limited degree, and that directly opposite to the effect of specific gravity in a classifier. This will be shown by the chemical analysis of the screen oversize and undersize in the products tested.

It is obvious that if a product, graded according to bulk or volume of particles, be tested on screens, there will naturally be a wide range between the two extremes in this product. That is, the difference, between a scale and a cube as measured by a screen which takes cognizance of two dimensions only will cover a relatively wide range, while in reality the volume of the particles may be identical.

[1]See October issue of this journal, p. 553.

The reverse is true of a screened product, for, while the product may be between screens of only a few points difference, the ratio of volume of largest to smallest particle may be several times the ratio of the cubes of the apertures of the screens limiting the product.

Quoting Dietz & Keedy, METALLURGICAL AND CHEMICAL ENGINEERING, November issue, page 578: "In the practical application of close and accurate screening we have adopted as a standard a series of thirteen screens between 20 and 200 mesh conforming to a harmonic series, thus producing fourteen products including oversize and fines. The average volumetric ratio is 2:1, while the efficiency, when measured by the screen actually limiting the grades, averages better than 90 per cent, the only drop under 90 per cent being in the —150 + 200 mesh grade, which, with the screen area usually exposed, varies between 80 per cent and 85 per cent. The series, as developed by us and used as a standard, is the following, in which screen cloths have been selected of apertures conforming to the law of cubes."

Mesh.	Apertures, Inches.	Ratio of Volumes of Largest to Smallest Particles.
20	.0410	1.722:1
24	.0342	1.722:1
28	.0282	1.783:1
34	.0229	1.867:1
42	.0183	1.959:1
50	.0145	2.012:1
62	.0116	1.953:1
74	.0089	2.214:1
86	.0068	2.242:1
109	.0054	1.996:1
125	.0041	2.284:1
150	.0032	2.103:1
200	.0026	1.865:1
Average		2.000:1

To show the fallacy of this system let us take the product between the screens 20 and 24 mesh, and assume a particle in the shape of a flat scale that will just correspond to the square of the aperture of the 24-mesh screen, but having a third dimension or thickness of, say, 0.0026 in., which is the aperture of the 200-mesh screen. It is obvious that this particle is bound to report between the screens 20 and 24 mesh, and will represent the smallest particle in that product with a volume of 0.000003041064 cu. in. Now take a cube that will correspond to the cube of the aperture opening of the 20-mesh screen, which is 0.000068921 cu. in. Here we have a volumetric ratio of largest to smallest particle of 22.66:1 instead of 1.722:1 as claimed. Take the next two screens, 24 and 28 mesh, and figuring on the same basis we get a ratio of 19.37:1 instead of 1.783:1. It is quite true that in some cases an ore is found that will have a fracture favorable to the application of the law of cubes, but unfortunately these cases are very much in the minority.

From the foregoing it is evident that in a product graded by screens it is a physical impossibility to get anything like the ratios claimed in all but a few rare cases where all the material will break in the form of cubes, and it is equally impossible to test by the use of screens with any degree of accuracy the efficiency of a machine which grades according to volume or bulk of particle.

Dietz and Keedy have taken the results of a test on the McKesson sizer, and have calculated the volume ratio of largest to smallest particles according to the aforementioned law of cubes. Taking, for example, their calculation for product No. 7 which apparently shows the largest ratio, their figures are as follows:

Product No.	Screen Mesh.	Efficiency per Cent.	Volume Ratio of Largest to Smallest Particle.
7	—50 + 82	90.63	6.20:1

A very careful test was made on this product to determine the actual, not theoretical, ratio of largest to smallest particle in this product. It was screened to give two products, viz., —50 + 66 which is the largest grade, and —74 + 82 which is the first grade in product No. 7. Equal volumes of these two grades were then taken by displacing 0.02 cc. of water, and the number of grains in each grade was accurately counted. There were 2200 particles in the coarse grade and 4105 particles in the fine grade. Now we have something definite to work upon and we find that there is an actual volume ratio of largest to smallest particle of 1.893:1 instead of 6.20:1 as calculated from the law of cubes. This accounts for the lapping of products so seriously objected to and shown graphically by Dietz and Keedy on page 578. A careful examination of the different products under a powerful microscope reveals the same condition throughout all the products.

Taking the case of product No. 15:

Screen.	Per Cent.	Efficiency.
—82	.....	
+97	6.25	
+116	18.75	
+139	43.75	68.75
+172	25.00	
—172	6.25	

We have here a product ranging from +97 to —172 which, when examined under the microscope reveals the scaly nature of the grades +97 and +116. In this case a scale corresponding to the square of the aperture of screen 97, which is 0.0058, and having a third dimension or thickness of one-seventh that amount, will give a particle +97 mesh which belongs in a 200-mesh product.

Now to take up the effect of specific gravity: From the analysis given herewith it is evident that whatever effect specific gravity has, it manifests itself in such a way as to remove all semblance of a doubt as to reversal of the accepted fundamental principles governing agitated material.

The attempt to show that the McKesson sizer is a dry classifier has led Dietz and Keedy into the error of predicting certain things regarding the nature of the products of this machine. They say, speaking of classified products, "In each grade it will be found that the lightest mineral reports to the greatest extent in the coarsest grade, while the heaviest mineral will be found to the greatest extent among the finer particles of the particular product under consideration. This same action is to be expected in a machine of the McKesson type."

In other words, they believe that if one of the McKesson products be subjected to a screen analysis the coarsest portion will contain the most gangue and light mineral, while the finest portion will carry the most mineral of high specific gravity, and the intermediate sizes will contain proportionate quantities of the minerals according to their specific gravities. They suggest a chemical analysis of the products from a mixed sulphide ore as being the best way to prove their contention.

With this object in view I have taken a product from such an ore and have had its several screen grades analyzed. The results are exactly opposite to what Dietz and Keedy predict, and show that in no sense is the product a classified material. In fact the analysis shows conclusively that the product is a sized material.

Screen Analysis on Size No. 8 of a Zinc-Iron Crude Ore.

Screen.	Per Cent.
—40	.....
+50	12.50
+66	75.00
+74	9.36
—74	3.12

According to Dietz and Keedy's anticipation that the product is classified material we should find a preponderance of gangue and lighter minerals in the coarse grade, and a similar excess of iron and zinc in the fine grade. If their contention is correct we ought to find the highest percentage of insoluble in the +50 grade, with diminishing percentages in the finer grades. Similarly, iron and zinc as the heavier minerals should appear in the different grades in increasing proportions. But such is not the case—indeed the facts are the reverse of Dietz and Keedy's assumptions, and disprove their idea that the McKesson machine is a dry classifier. Its different products are sized, and this has been proved many times by treating the most complex mixtures, the components of which were widely separated in specific gravities.

Flameless or Surface Combustion.

A New Method of Using Gaseous Fuel for Heating and Steam-Raising Purposes.

By John B. C. Kershaw.

Sir Humphrey Davy, during his remarkable researches upon flame in the year 1816, discovered that under certain conditions a mixture of a combustible gas and air (in proper proportions) when forced into contact with a heated porous and refractory material or metal could *be burned without the production of any flame*, yet with the maintenance of a very high temperature. For various reasons this method of employing gas has made little progress, as regards its industrial application for heating or steam-raising purposes, and it is only to-day, nearly one hundred years after the first discovery of the method, that flameless or surface combustion has been developed into a practical and valuable industrial process.

Professor William A. Bone (F.R.S.), professor of applied chemistry in the Leeds (England) University, and Mr. C. D. McCourt have for some time past been engaged in the study of the theoretical and practical side of the subject, and have recently patented a process and apparatus, by means of which this method of combustion can be applied either for heating crucibles, furnaces or steam-boilers, with efficiencies that approach 95 per cent. of the actual heat value of the fuel gas used. The practical importance of this new method of using gaseous fuel for heating purposes *depends altogether upon this question of efficiency*. If, as stated by Bone and McCourt, thermal efficiencies of 90 per cent to 95 per cent can be attained in practice with all varieties of fuel-gas, whether for steam-raising or for furnace operations, the future of the new process would seem to be assured.

The one drawback attending the gasification of solid fuel in the past has been that the gas when employed for heating purposes (owing to its low radiant heat power) only yielded from 50 to 70 per cent of its heat to the object that required it, and that the direct thermal loss (apart altogether from the heat lost during gasification) amounted, therefore, to from 30 per cent to 50 per cent of the total heat value of the fuel.

The gasification of solid fuel and the employment of the gas for heating purposes have therefore only been adopted in the past under special conditions, when a very high temperature was required (as, for instance, in the glass and steel industries, where regenerative gas furnaces are employed), and it has been most unusual to find any steam-boiler or ordinary furnace heated by fuel gas, on account of the low thermal efficiencies obtained with this method of heating.

Bone and McCourt by rendering it possible to produce the greater portion of the heat as radiant heat at a very high temperature, and to attain heat transfer efficiencies of 95 per cent with gaseous fuel, have, however, brought this method of heating within the domain of practical application in the manufacturing industries. In the future one may expect to see a gradual extension of the plan of gasifying the solid fuel at the pit's mouth, recovering the ammonia and more valuable organic by-products of the destructive distillation of the coal in adjacent chemical works—and then selling the residual gas to manufacturers, either for power generation or for heating purposes. This method of utilizing fuel is undoubtedly the most scientific and the most promising, since it makes the best use of all the constituents of the fuel, involves the least waste and indirectly helps to solve the smoke problem.

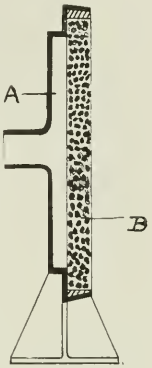

FIG. 1—DIAPHRAGM FOR SURFACE COMBUSTION.

The readers of this journal may therefore be assumed to have a special interest in it. In the following notes the writer will give some details of the apparatus used for the trial results obtained with the new method.

Fig. 1 shows in sectional elevation the simplest form of apparatus for applying surface combustion to heating purposes. *A* is the feed-mixing chamber through which the gas and air pass; *B* is the diaphragm at the surface of which combustion occurs. The amount of air used is in slight excess of that required for *complete* combustion of the gas.

The air and gas are forced into the mixing chamber, and

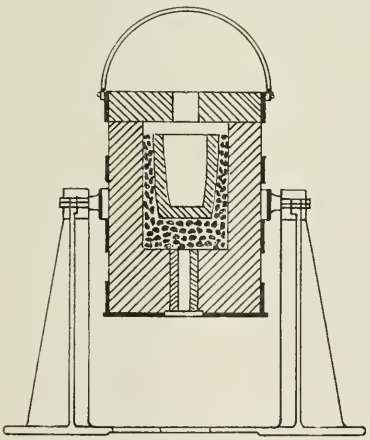

FIG. 2—APPLICATION OF SURFACE COMBUSTION TO A CRUCIBLE FURNACE.

therefore through the diaphragm, at a speed greater than that mixture; otherwise what is known as "backfiring" will occur. The prevention of "backfiring" and the choice of a suitable refractory material are in fact the two difficulties which have hindered the successful operation of this method of burning gas.

The gas-mixture burns without flame within a layer ⅛ in. (3 mm) in thickness, at the surface of the diaphragm, and maintains it in a high state of incandescence. The other parts of the apparatus are cold enough to touch with the naked hand, and the slightest variation in the pressure of the gas at which the explosion wave is propagated through the gas-supply causes an instant change in the degree of incandescence of the diaphragm, showing that there is no reserve of heat in the body of the same, and that the temperature attained by this method is under instant control. An incandescent surface of this type can be used for concentrating heavy liquids similar to solutions of sodium silicate and sulphuric acid by surface evaporation.

Fig. 2 shows the new method applied to the heating of a

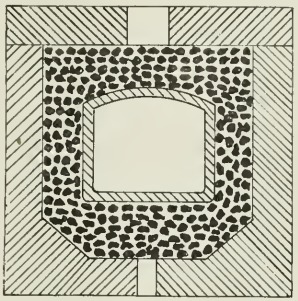

FIG. 3—APPLICATION OF SURFACE COMBUSTION TO A MUFFLE FURNACE.

crucible tipping furnace and Fig. 3 to a muffle furnace. In these cases a bed of well-graded pieces of the refactory material surrounds the crucible or muffle and the explosive gas-mixture is blown into this bed through the opening shown in the diagrams at the bottom of each furnace. As the gas-mixture impinges upon this incandescent bed, combustion is completed almost instantaneously, and the products of combustion as they rise through the upper portion of the bed rapidly impart their heat to the material composing it.

A charge of cast iron can be melted in one of these crucibles in ten minutes, starting with cold metal, and the only limit at present as regards temperature is that imposed by the melting or decomposing point of the refractory materials employed. Carborundum (silicon carbide), which has been widely used for the purposes of a furnace lining and is considered highly refractory, is decomposed quickly into CO_2 and SiO_2 in the

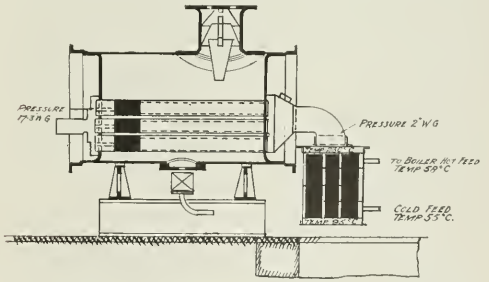

FIG. 4—APPLICATION OF SURFACE COMBUSTION TO STEAM RAISING.

interior of these furnaces, indicating that a temperature of 2000° C. has been approached.

With mixtures of coal gas and air, or water gas and air, in theoretical proportion, injected into the furnaces at a maximum speed, temperatures have been attained which no material hitherto used for furnace or muffle construction can long withstand. Gases of lower calorific value, such as coke-oven and blast-furnace waste gases, of course yield lower temperatures. No unburnt gas escapes by this method of combustion when once the correct proportions of gas and air have been properly adjusted, and, therefore, the maximum

temperature possible to the gas is always obtained unless, as already explained, an excess of air is purposely admitted to reduce the temperature.

Fig. 4 indicates how this principle of combustion can be applied to steam-raising purposes. The experimental boiler shown in diagrammatic longitudinal section in this illustration is provided with ten fire-tubes, each 36 in. in length and 3 in. in diameter. Each tube is packed for ⅞ of its length with the refractory material, broken and graded into pieces of suitable size.

At the front end of each tube is a fireclay plug provided with a central hole ¾ in. (18 mm) in diameter. This plug serves the double purpose of keeping the front end of the boiler cool and of providing a suitable aperture through which the explosive gaseous mixture can be injected at a speed very much higher than the speed of "backfiring."

Attached to the front plate of the boiler is a mixing-chamber of special design. The economizer at the rear end of the boiler is provided with nine tubes, each 3 in. in diameter and 12 in. in length, and packed as before with the refractory material, suitably graded.

Under working conditions this experimental boiler showed *complete combustion* of the gaseous mixture before it had traversed half the length of the fire-tubes. The central portion of the refractory core of each tube was maintained at a very high temperature; this was rapidly transferred to the water in the boiler by radiation.

As regards the rate of combustion, about 1000 cu. ft. of coal gas have been burned per hour, in this small boiler. The temperature of the exit gases is from 60° to 70° C. higher than that of the water in the boiler, but the economizer intercepts the larger portion of this heat, and reduces the temperature of the exit-gases to less than 100° C.

Sixty-five per cent of the total evaporation of the boiler occurs over the first foot length of the fire-tubes. This causes violent ebullition and rapid circulation, the latter being an important factor in obtaining rapid heat transmission.

In an ordinary Lancashire boiler the rate of heat transmission is equivalent to the evaporation of 6 to 7 lb. of water per square foot of heating surface per hour; in the locomotive boiler this is increased to 10 lb.; whereas in the boiler just described it rises to 20 lb.

The following are figures obtained during a test run of the boiler:

The amount of coal-gas fed into the boiler, expressed as dry gas at 0° C. and 760 mm, was 0.96 cu. ft. per hour. The net calorific value of the gas was 562 b.t.u. per cubic foot—the total heat supplied to the boiler in terms of the net calorific value of the gas was 550,800 b.t.u. per hour.

The actual amount of water evaporated was 450.3 lb. per hour, which in terms of water evaporated from and at 100° C. would be 550 lb. per hour. The actual heat transmitted to the water was $450.3 \times 1172 = 527{,}800$ b.t.u. per hour. The ratio between the heat transmitted to the water and heat supplied was, therefore, $\frac{527{,}800}{559{,}800} = 0.943$.

The pressure under which the gas-mixture is blown into the boiler is equal to 17.3 in. (water gage), while the exit gases escape to the economizer at a pressure of 2 in. The resistance to the flow of gas, offered by the fire-clay plugs and the packing of refractory material in the fire-tubes, explains this steep pressure gradient. According to the inventors of this system, the actual power expended in drawing or forcing the gases through the boiler and economizer is only 4 per cent of the total power generated. This reduces the net efficiency of the method to 90 per cent, which is still considerably higher than that obtained with coal or gas-fired boilers.

Another advantage of this system is the rapidity with which steam can be raised. Starting with the ten-tube boiler all cold it is possible to obtain steam at 150 lb. per square inch pressure in about twenty minutes, and to continue the high rate of evaporation indicated—viz., 20 lb. of water from and at 100° C. per square foot of heating surface per hour—so long as the gas supply is properly maintained.

If, in order to meet an "emergency" demand for steam, there is occasion to force the boiler so as to obtain an evaporation of say 30 lb. of water (from and at 100° C.) per square foot of heating surface per hour, all that is necessary is to force more of the gaseous mixture through the boiler tubes, and to sacrifice 5 per cent in efficiency.

A final advantage of the system, as applied to steam-raising purposes, is that in a large boiler the tubes could be arranged in groups, and that the gas mixture could be cut off, or put on to, any group of tubes, according as the demand for steam was diminished or increased.

This elasticity of the system is claimed by the inventors as of great value and advantage in those manufacturing industries where a widely fluctuating load has to be carried by the boilers. A large boiler fired on this system is now being erected at Leeds by the Radiant Heat Syndicate, which has taken over the industrial development of the Bone and McCourt patents, and the test results obtained with this boiler will be awaited with great interest by all power engineers. As already stated, this novel method of combustion seems to open up a new era of progress in the application of gaseous fuel to manufacturing and industrial purposes.

Direct Smelting of Argentiferous Copper Ore at Rio Blanco, Chile.

By Ignacio Diaz Ossa.

The ore deposit known as Cristobal Colon occurs almost on the summit of the chain of mountains forming the left side of the Rio Blanco valley, and is situated 5 km from a station on the Transandino Railroad. The deposit consists of a narrow vein of high-grade copper ore, carrying high silver values, crossing three thick beds of mineralized volcanic turf.

The vein was worked by a day-level until the first bed was cut; a shaft was then sunk at the junction of the vein with the bed, when two other beds were discovered. These have been attacked along the face. During the year the output amounted to 1800 tons.

The ore is raised by winches to the level of the adit, which is about 25 m above the lowest bed. Near the mouth of the adit the ore is trammed along the edge of a precipice for about 200 m to the upper station of a ropeway connecting the mine and smelter, the latter being erected on the banks of the river. The ropeway is in two stages, and usually remains idle from 1 to 3 p. m. daily, owing to the high winds which prevail at that time.

The beds, the total thickness of which amounts to about 15 m, contain on an average 5 per cent copper. Rapid hand sorting raises this percentage to 8, and the value of the silver to about 75 pesos per ton. (One peso = $0.23 gold.)

Smelting Operations.

The blast furnace, which is of the cylindrical type, is defective and not built on modern lines. Its daily capacity is 20 tons. The dimensions are as follows: Height from charging floor to tuyeres, 2.17 m; diameter of cylinder at charging floor and tuyeres, 1.10 m; number of tuyeres, 12; diameter of tuyeres, 0.17 m; length of water jacket, 1.53 m; upper part, covered with brick, 0.87 m; height from tuyeres to crucible, 0.23 m. The blast is provided by a Root blower operated by two Pelton wheels producing 25 hp. A short channel conducts water from the Blanco to the wheel house.

On taking charge of the smelter I did away with the old heavy forehearth on rails, and made an inner crucible 1.40 m deep, with a diameter at the floor of 0.58 m; and another 1.10 m below the level of the tuyeres. I also dispensed with the

lip for the discharge of slag, making an arrangement with firebrick which gave much better results.

The following figures show the percentage composition of the ore: Silica, 45 to 50 per cent; lime, 8 to 12; iron, 7 to 11; sulphur, 4 to 6; alumina, 7 to 10; lead, 1.5 to 3; copper, 8.9 to 12; arsenic, 0.1; silver, 700 to 800 grams per ton.

As the only flux obtainable was a dolomite limestone containing 8 to 10 per cent heavy spar, old reverberatory slags had to be used as well. Analyses showed them to have the following percentage composition: Silica, 45 per cent; iron, 31; lime, 12; alumina, 8; copper, 2.5; silver, 150 grams per ton.

The ore, flux and slag were mixed in such proportions as to form a bisilicate of lime. The resulting slag analyzed as follows: Silica, 50 to 52 per cent; lime, 26 to 30; iron, 10 to 12; alumina, 6 to 9; copper, 0.15; silver and lead, traces only. The slag ran well at a temperature exceeding 1250 deg. C. Both iron and sulphur oxidized easily, the final products being matte containing 75 per cent copper, and copper in bars. About 25 per cent of the copper was obtained in bars of 90 per cent metal. The copper matte contained from 7 to 9 kg of silver per ton.

In ten days we smelted 54,530 kg of ore carrying 12 per cent copper and having silver to the value of 60 pesos per ton; 12,910 kg of ore of 7 per cent copper and 40 pesos silver per ton; 38,200 kg of ore and slag of 2.5 per cent copper and up to 10 pesos silver per ton; 176,000 kg of flux, and 30,200 kg of coke. The total costs amounted to 8576.8 pesos, and the value of the product was 14,718 pesos, giving a profit of 6141.2 pesos. With proper fluxes, which are now being accumulated, the profit should be about double the above.

Cooling in the crucible was reduced by increasing the blast. In order to prevent as much as possible firing at the level of the charging floor, and consequently black tuyeres, charges of 450 kg were used, the coke and charge being moistened with water. The coarse ore and fuel were charged around the circumference of the furnace, and the fine material in the center. This prevented small pieces passing down the vertical sides of the furnace without being properly calcined.

No doubt many ores can be smelted to a matte containing a high percentage of copper, and even to metallic copper, provided pyrites is not added to the furnace charges, but only calcareous or ferruginous oxidized fluxes, such as basic slags, hematite, etc. Loss in the slag is generally said to be the result of producing mattes of high copper content, but in the Rio Blanco smelter, with a high crucible, the slag never rises above 0.16 per cent copper, and the average is only 0.12 per cent.

Santiago de Chile, S. A., Casilla 962.

Tests on Monel Metal Castings.

The Bayonne Casting Company, which has succeeded in making castings of monel metal up to 25,000 lb. in weight, has made some interesting tests of such castings under U. S. Navy inspection.

This new "natural alloy" bids fair to displace steel and bronze in a large number of cases as it has been found to be as strong as steel and is less corrodible than bronze, while it takes a finish like pure nickel. Below are the results of the tests and the U. S. Navy specifications for monel metal castings.

Bureau of Steam Engineering, United States Navy specifications for monel metal castings are as follows:

Yield point (minimum).....	32,500 lb. per sq. in.
Tensile strength (minimum)...	65,000 lb. per sq. in.
Elongation in 2 in. (minimum)	25%

An average of tests of monel metal from 25 heats made under U. S. Navy inspection gave:

Yield point	35,197 lb. per sq. in.
Tensile strength	72,843 lb. per sq. in.
Elongation in 2 in.....	28.2%
Reduction of area.....	35.6%

The Electric Reduction of Iron Ores.

With Special Reference to Results Obtained in the Electro-Metals Furnace at Trollhättan, Sweden, and in the Noble Furnace at Heroult, California.

BY OTTO FRICK.

The publication of Mr. J. A. Leffler's report* on the Trollhättan furnace, presented at the annual meeting of "Järnkontoret" in Stockholm on May 31, 1911, offers an opportunity to discuss the possibilities of the electric reduction of iron ores.

The writer has not had an opportunity to personally inspect the Trollhättan furnace, but Mr. Leffler's report gives a very detailed account, both of the construction and of the working of this furnace. The information with regard to the Noble furnace has mainly been collected during a visit at Heroult, Shasta County, Cal., last year.

Type and General Design of Furnaces.

The Trollhättan furnace and the Noble furnace belong to the same type, and are on most essential points alike. This type has been developed from experiments carried out on different lines and without any mutual understanding or communication.

Both furnaces consist of a wide melting chamber superposed by a shaft of smaller diameter so as to allow the introduction of electrodes through the roof above the crucible—a type of furnace which has been proposed by Keller already in 1901.

The main advantage of this type of furnace is the possibility of using a high shaft and introducing the electrodes in the lower part of the furnace without exposing them to too great a pressure from the charge and the possibility of producing a hot zone on the outside of the charge column at some distance from the brick work.

The shape of the shaft is in both cases of a similar form as used in an ordinary blast furnace, that is to say conical towards the melting zone as well as towards the furnace top. This shape is preferable to a cylindrical shaft, as it allows to increase the volume of the shaft without interfering with the dimensions of the melting chamber, which in an ordinary blast furnace has to be narrower than the shaft to allow the blast to reach the center, and in the case of the electric furnace has to be wider than the shaft to allow the introduction of the electrodes through the roof of the said chamber.

In the first furnace of the Electro-Metal type, built at Domnarfvet, Sweden, the shaft of the furnace was supported on iron pillars. In the Trollhättan furnace the shaft is hung on strong beams, in a similar manner as used in the Noble furnace, erected one year before the Trollhättan furnace, which arrangement is preferable to the previous one as it secures free space all around the melting crucible.

It has been claimed that this shape in the case of an electric furnace should offer special advantages not present in an ordinary blast furnace, in so far as it should prevent the charge in the melting chamber from being pressed against the roof, an effect pretended to occur with a shaft of cylindrical shape. This is, however, not the case, as the shape of the shaft has no influence on the behavior of the charge in the melting chamber.

Whether the lower part of the shaft is conical or cylindrical, there will be the same pressure at the neck of the melting chamber, and if the temperature of the charge at this point is below the one at which the material gets pasty, the charge will in both cases take a conical shape in the melting chamber, the surface of which will form an angle of about 35° to the horizontal. Only if the temperature at the neck were high enough to make the charge enter into the melting chamber in a semi-fluid state there would be a danger of the charge spreading against the roof.

As it is under no circumstances desirable, and, in fact, next to impossible to work the furnace in such a manner, no such danger needs to be feared. In later runs of the Noble furnace

*See this journal, July issue, p. 368, September, p. 459, October, p. 505.

the shaft has obtained a cylindrical shape without altering the behavior of the charge in this respect.

Size and Power Consumption	Trollhattan Furnace	Noble Furnace
Maximum power consumption	2,500 hp 1,830 kw	2,040 hp 1,500 kw
Total height of furnace	14,700 mm	8,300 mm
Outside diameter of crucible	5,650 mm	3,960 mm
Outside diameter of shaft	3,200 mm	2,790 mm
Volume of shaft	25.5 cu. m	7.9 cu. m
Radiation surface	189 sq. m	105.5 sq. m

From these figures it will be seen that the dimensions of the Trollhättan furnace are considerably bigger than that of the Noble furnace.

The diameter of the crucible is mainly governed by the size of the electrodes which have to be introduced through the roof. By the use of graphite electrodes, and also by using the greatest possible number of electrodes, a saving in the diameter of the crucible is obtained.

The size of the shaft in the Trollhättan furnace has been calculated for an average ouput of 23 tons of pig in 24 hours, and on the assumption that the proportion:

$$\frac{\text{volume of charge in 24 hours}}{\text{volume of shaft}} = 1.55.$$

This figure is evidently based upon the average practice of the Swedish charcoal blast furnaces, in which it varies between 1.21 and 1.91.

The author of the Trollhättan report expresses the opinion that the correctness of this calculation has been substantiated by the results obtained, but it appears as if these results in reality show that the shaft is unnecessarily big.

In a paper read by the present writer at Järnkontoret in Stockholm in May, 1905, it was shown that the electric reduction furnace theoretically only needs to be 1/12 of the size of that of an ordinary blast furnace.

The main object of a shaft on any furnace is to recuperate the heat of the gases from the melting zone, and if possible to give the carbonic oxide an opportunity to reduce part of the ore.

In an ordinary blast furnace the weight of the gases exceeds the weight of the ore, limestone, and coke or charcoal by 30 per cent to 50 per cent.

In an electric reduction furnace the gases evolved amount only to about 40 per cent of the weight of the charge.

By the use of a circulating gas introduced in the lower part of the furnace, it is, however, possible to increase the total weight of the gases passing through the shaft so much as to make it exceed the weight of the charge in a similar proportion as in an ordinary blast furnace, but even then a considerable difference between the blast furnace and the electric furnace remains in so far as the temperature of the gas entering the lower part of the shaft cannot be as high in the electric furnace as in the blast furnace unless the circulating gas is heated outside the furnace by the use of hot blast stoves.

In the Trollhättan furnace such an arrangement has not been provided. The heat, carried by the circulating gas to the shaft, has thus to be absorbed from the melting zone, and is necessarily restricted by the surface and the temperature of the charge through which the gas is passed.

The result of the Trollhättan furnace demonstrates to full evidence that this surface and this temperature just mentioned are not sufficient to allow the gases to reach more than 500° C.

From the records collected the highest temperature ever observed at the bottom of the shaft has been 682° C, and the lowest has been 241° C, while the average temperature at this point has been 510° C.

The corresponding temperature in a blast furnace is considerably higher and probably a great deal above 1000° C. The total heat stored in gases at 1000° C. is nearly 2.5 times bigger than that at 500° C. It is, therefore, evident that with the same amount of gas per ton of pig the volume of the shaft of an electric reduction furnace can be made 2.5 times smaller than the corresponding shaft of an ordinary blast furnace with an equally satisfactory transfer of the heat from the gases of the charge. Whether it is consistent with economical working to use so much circulating gas will be discussed later on.

The volume of the shaft of the Trollhättan furnace is 25.55 cu. m.

The corresponding volume in the case of the Noble furnace has been only 7.9 cu. m., and this has proved to be more than ample. In later runs the volume of the shaft has been further reduced by being made cylindrical, apparently without interfering with the economy of the process.

The temperature of the gases leaving the shaft of the Trollhättan furnace has varied between 205° C. and 29° C. and has on an average been 76° C.

These figures compare well with the temperature generally held by the gases from a blast furnace, which as a rule is above 200° C. It has, however, to be kept in mind that the total heat contained in the gases in a blast furnace, say at 1100° C., exceeds the heat which can be absorbed by the charge, whereas the heat of the produced gases in an electric furnace is very much less than that required by the charge.

By varying the amount of circulating gas in the electric furnace, the total heat brought into the shaft by the gases can be made to equal or to exceed or to become less than the heat which can be absorbed by the charge.

Electric Arrangements.

The Trollhättan furnace is supplied by two single-phase transformers, each of 1100 kilovolt amperes, on the primary side connected to a three-phase system of 10,000 volts, 25 periods, according to the Scott method of transformation from a three-phase to a two-phase system. From the transformers a two-phase current is delivered to the four electrodes of the furnace.

The Noble furnace has three single-phase transformers each of 750 kilovolt amperes connected to a three-phase system of 2200 volts and 60 periods.

The low-tension current from the transformers is supplied to the six graphite electrodes.

In both furnaces the regulation of the current is effected by a variation of the number of turns of the primary coils of the transformer. The priority of this device belongs to the Noble furnace for which it was designed by the General Electric Company in the early part of 1900.

The arrangement is well known for other purposes and it is only natural that it has been adopted for electric reduction furnaces as it affords a simple and effective means of maintaining a steady power consumption, and is the only possible way if the furnace has not an individual dynamo but is connected to a great power distribution system.

At the Noble furnace it has also been found useful to use the regulating coils alone, and thus to increase the secondary voltage for the purpose of starting the furnace. It was found, for instance, that with cold charcoal and the normal voltage of 70 volts no current would pass through the charge, and only by raising the voltage to about 100 volts in the above explained manner it became possible to make the current start.

This difficulty will evidently not arise if the charge is preheated to a sufficiently high temperature by blowing air into the crucible.

Electrodes and Method of Heating.

The Trollhättan furnace and Noble furnace differ essentially with regard to the method of heating and to electrodes.

The former furnace has four ordinary carbon electrodes of 660 × 660 mm, which enter into the charge only slightly, as it is endeavored to keep them "free burning"; that is to say, to produce a small space between the electrodes and the charge across which electric arcs are formed.

The latter furnace has six graphite electrodes of 8½ in. diameter—216 mm—which enter into the charge as far as

possible so as to prevent them from becoming "free burning" and so as to insure best possible contact between the electrodes and shaft.

In the report on the Trollhättan furnace it is said that "free burning" is an essential feature, as otherwise the voltage becomes unnaturally low and the dimensions of the electrodes and leads must become excessive and that finally too great variations of the power consumption would result.

It is noteworthy that several of the electrodes of the Trollhättan furnace must have entered into the charge quite considerably, as demonstrated by the sketches given in the report. The electrode III, for instance, appears to have entered into the charge with about 90 cm. This electrode shows also the smallest net electrode consumption per ton of steel.

In using "free burning" electrodes the main resistance in the path of the current between the electrodes, and between the electrodes and the bottom, if this is made to form one pole of the circuit, is concentrated in the arcs near the electrodes, so that nearly the whole of the electric energy is commuted into heat at this point. To convey this heat from the electrodes to the different parts of the charge it is necessary that the temperature near the electrodes be essentially higher than that required for the reduction of the ore and for the melting of the pig and the slag.

A further inconvenience of "free burning" electrodes is that the hottest zone is generated near the surface of the charge and thereby causes difficulty in protecting the roof from the heat. This difficulty has, however, in the Trollhättan furnace been proved to be overcome by introducing a suitable amount of cooling gas around the electrodes.

The introduction of the electrodes into the charge to such an extent as to prevent their "free burning" reduces the resistance at the contact between the charge and the electrode, and thereby the amount of heat produced by the passage of the current at this point and increases the heat generated by the current in passing through the charge. Less heat has thus to be transferred from the zone around the electrodes and a lower temperature would thus be required. As the further end of the electrode is at a considerable distance from the surface of the charge, there is no danger of over-heating the roof and no gas circulating for the purpose of cooling the roof will be necessary.

The difficulty which this arrangement causes is undoubtedly more serious in the case of ordinary carbon electrodes than in the case of graphite electrodes.

There is no doubt that it is not the extra cost of cables and electrodes which would prevent the use of the method applied in the Noble furnace.

The essential difficulty is really to be sought in obtaining electrodes of sufficient length and strength.

The great size of ordinary carbon electrodes makes it difficult to manufacture them in great length or to provide them with a reliable joining device.

Also the jointing of graphite electrodes offers certain difficulties. At Heroult the one end of the electrode is shaped into a conical screw fitting into the upper part of another piece of electrode.

The cutting of this screw joint is very easy on account of the softness of the material, and the joint makes a perfect electrical connection, but the strength of the electrode is considerably reduced and has proved not to withstand the pressure exercised by the charge.

In the Noble furnace the pressure of the charge on the electrodes is very nearly equal to their breaking strength, so that the additional force arising from a sudden descent of the charge easily causes the breaking of the electrodes at the joint. By proper design the electrodes can, however, be made strong enough.

In the case of the Noble furnace the patrice part of the joint was essentially weaker than the matrice part, and only by giving them equal strength, the total strength of the electrodes can be increased by as much as nearly one hundred per cent.

The strain on the electrode, caused by the charge, also depends on the inclination given to the electrodes. This inclination is 35° to the vertical, and by reducing the same to 20° the strain on the electrode can be approximately reduced by about 30 per cent.

With graphite electrodes of bigger diameter than 8½ in. still less trouble from this source needs to be experienced.

The method of introducing the electrodes into the charge and thus working the furnace as pure Resistance Furnace requires a bigger current and a lower voltage than in a furnace with "free burning" electrodes.

With increasing amperes it is of great importance that provisions be made to avoid inductive losses along the path of the current. In this respect, the care taken at the Trollhättan furnace does not seem to equal that at the Noble furnace, in so far as the inductive voltage drop per 1000 amperes in the former furnace appears to be 2.5 volts with a periodicity of 25 as against 2.8 volts in the Noble furnace with 60 periods, so that the inductance in the former case is more than double that in the Noble furnace.

Consumption of Electrodes.

The consumption of electrodes in an electric Reduction Furnace is of no small influence on the economy of the process.

The average consumption during the run of the Trollhättan furnace has amounted to 10.28 kg, costing about 75 cents per ton of pig produced. The actual consumption from wear has, however, only been 5.27 kg, so that a waste of nearly 50 per cent has been caused by no arrangement for jointing the electrodes having been provided.

It is, however, to be noted that the total electrode consumption during the four periods to which the report refers has dropped from 11.24 to 7.45 kg. The cause of this reduction in the electrode consumption is probably to a large extent due to the high average content of CO_2 in gases during the first period, but also other causes may have been of influence.

With reference to the consumption of graphite electrodes due to the wear and tear, no reliable figures are available as the breakage has been very big from causes mentioned above.

From the inspection of such broken electrodes which had been in use for some days the actual wear does not seem to have been appreciable.

As there is no arc between the electrodes and the charge, no particles from the electrodes will be carried away by arcing and the erosion of the electrodes can only be caused by the oxygen in the charge or in the circulating gas.

Taking into consideration the much smaller surfaces of contact as against an ordinary carbon electrode, and also the greater resistivity against oxidation, it is not unlikely to be expected that the actual wear of graphite electrodes will be less than that of ordinary carbon electrodes.

At the present price difference, and disregarding the advantages of graphite electrodes in other respects, the wear of these electrodes should only be 40 per cent of that of carbon electrodes to make this item of cost equal for both kinds of electrodes.

Charcoal Consumption.

The average coal consumption of the Trollhättan furnace during the whole run to which the report refers has amounted to 418 kg of charcoal per ton of pig besides the carbon derived from the electrodes and from the coke and electrode pieces charged. As this figure appears to be rather high it has been thought of interest to investigate this question more closely.

For this purpose it has been necessary to figure out the average analysis for all the materials which have been charged into, respectively delivered from the furnace.

In Appendix I these analyses are recorded. In this appendix are also noted the total amounts of material per ton of pig.

Appendix II contains a complete investigation of the different

purposes for which the carbon has been used during the different periods of operation, with the view of finding out the causes of the differences in coal consumption during different periods.

At first the total weight of gases per ton of pig are calculated from the average gas analyses and the total weight of C charged into the furnace. The total weight of gases produced per one ton of pig varies between 810 kg and 905 kg, and averages 855 kg.

The next calculation aims to find out the value of:

$$\frac{\text{Volume CO}}{\text{Volume CO}_2} = \frac{\text{Weight of C burnt to CO}}{\text{Weight of C burnt to CO}_2} = K$$

To arrive at this value the CO and CO_2 contained in the charcoal and limestone have been subtracted from the total amounts contained in the gases.

The value of K which may serve as an indication for the economy of the process varies between 2.57 and 5.58 and averages 3.71. This figure does not differ very much from the figure obtained in an ordinary blast furnace.

Next come the calculations made to find out the amount of oxygen to be reduced from water and ore, and of oxygen introduced into the furnace by air.

The weight of oxygen from water is found with the aid of the hydrogen in the gases reduced by the amount of hydrogen in the charcoal.

The weight of oxygen from the air is calculated on the assumption that the nitrogen in the gases is derived from air introduced into the furnace or into the piping connected with the circulating fan.

The amount of oxygen from ore is calculated on the basis of the analysis of the pig, and the average analysis of the oxygen connected to Fe in the ore, so arrived at, varies from 434 and 460 kg, and averages 445.7 kg.

These figures are very closely in accordance with those previously found from the analysis of the gases.

The amount of C necessary for the reduction of the oxygen is calculated from the formula:

$$C = 0.75 \frac{K + 1}{K + 2} O$$

and should vary between 0.586 and 0.651 kg C for one kg O, the average value for the whole run being 0.619. The calculated weight of C varies between 285.58 and 332.22 kg per ton of pig and differs only by a few per cent from the actual weight of C supplied.

The result is most instructive, as it furnishes full information about the manner in which the carbon has been consumed, and thereby indicates by what means it would be possible to reduce the coal consumption.

From a study of the figures it will be seen that quite an appreciable part of the carbon, 10 per cent to 15 per cent, is consumed in the reduction of the water introduced by the circulating gas.

This part of the carbon is saved in a furnace without any gas circulation and can also be saved in the case of a furnace with circulating gas if provisions are made to take the gas from the furnace at a level below that at which the water is evaporated and by preventing the gas from absorbing any moisture in cleaning the same from the dust.

The only way to diminish the amount of carbon used for the reduction of the ore is by striving at a lower value of "K." In this respect it is noteworthy that the best value of "K" obtained during the second period coincides with the smallest amount of limestone and that during the third period "K" reaches the high value of 5.58, indicating a rather uneconomical working at the same time as the weight of limestone per ton of pig is highest or 336 kg per ton.

This should indicate that the coal consumption in an electric furnace will be reduced by using burnt lime instead of limestone, and as the burning of the limestone can economically be done by using part of the escaping gases for the purpose it thus will save current as well. It should always be made a rule to burn the limestone outside of an electric furnace.

During the period 2 practically all of the Fe_2O_3 has been reduced to FeO by CO. It is scarcely to be expected that any FeO can be reduced by CO under the conditions at present prevailing in a furnace of the Trollhättan type, and it is therefore not probable that the amount of charcoal for the reduction of the ore can be brought down further than during the said period 2 unless some radical alterations of the process are introduced.

Power Consumption.

The average actual power consumption for one ton of pig has been 2391 kw-hours. This corresponds to 3.66 tons per kw-year or 2.692 tons per hp-year if the power were fully utilized during the 8760 hours of the year.

It has become the general practice to express the output of a furnace in tons per kw-year or in tons per hp-year, but it ought to be pointed out that these figures may in fact be rather deceptive, as they do not take into consideration stoppages and loss in output by the furnace not always working at full capacity.

Only in very rare cases electric reduction furnaces will obtain the electric current on the basis of a meter tariff, thus only paying for the actual amount of electricity consumed. As a rule the electrical energy will have to be paid for at a fixed price per year for a certain amount of maximum available power.

In Table 1 the production per kw-year, according to these two different modes of expression, is given for the different periods of the run. From this it will be seen that the tons produced per hp-year to be paid for have varied between 1.315 and 2.7, with an average of 1.88 tons, whereas the production per hp-year, according to the report, has varied between 2.43 and 3.0, with an average of 2.69 tons per hp-year.

It is evident that it is most misleading to people not thoroughly conversant with the question to state the production per hp-year actually consumed, instead of hp-year to be paid for, and it may correctly be suggested that if the production is stated in the former figure it should be accompanied by a statement of the load factor.

As it has been deemed of interest to investigate how the electricity has been spent, an approximate calculation of the power consumption during the different periods has been made in the Appendix III.

The heat required for the reduction has been calculated from the analyses of the pig produced and with due regard to the heat developed by the combination of the oxygen in the ore with the carbon.

The heat necessary for the reduction of the water carried into the furnace by the circulating gas has been found in a similar way.

The heat absorbed by the calcination of the limestone can easily be found from the analyses of the limestone and the weight thereof charged.

In the calculation of the heat necessary for the evaporation of water no consideration has been taken of the water which escapes from the furnace, the amount of which could only be accurately ascertained by knowing exactly the amount of circulating gas. As it seems probable that this has been three to four times bigger than the amount of escaping gas the evaporation of the water in the escaping gases will require one-third to one-fourth of the heat calculated for the evaporation of the water in the circulating gas and would then amount to 10,000 to 15,000 calories per ton of pig.

This undervaluation of the heat necessary for the evaporation has in some way been counterbalanced in calculating the heat carried away by the gases.

As no figures with regard to the temperature of the pig and slag are given, the heat carried away by them can only be approximated and it has been assumed that each kilogram of

TABLE I.—POWER CONSUMPTION.

Tons of pig per kw-year, to be paid	2.98	3.66	1.78	2.98	2.55
Tons of pig per hp-year, to be paid	2.19	2.70	1.315	2.19	1.87

pig has contained 283 calories and each kilogram of slag 500 calories, figures which should not be far from accurate.

In adding up the total power consumption the same has been expressed in kw-hours.

The total kw-hours theoretically required varies according to this calculation between 1536.3 and 2153.6 kw-hours per ton and averages 1721.4 kw-hours per ton. The actual energy consumption has varied between 2149 and 2710 and has averaged 2391 kw-hours per ton.

To this consumption of electric energy should be added the heat generated by air entering into the furnace with the circulating gas. The amount of this heat has varied between 13.95 and 35.5 kw-hours per ton, making the total actual heat consumption to vary between 2184.5 and 2735.8 and to average 2416.3 kw-hours per ton.

The difference between this actual heat consumption and the theoretically calculated energy consumption should correspond to heat losses from radiation from furnace walls, electrodes, leads and transformers, including the heat carried away by the cooling water used at the neck of the furnace and round the electrodes.

Calculations of this kind must always be more or less approximate and cannot be expected to give an absolutely correct image of what is actually taking place, but the information with regard to the distribution of the heat on different purposes will nevertheless be sufficiently accurate.

On studying the different items on which the heat has been expended it is found that a reduction of the energy consumption can be obtained by the same means which will secure a reduction of the coal consumed; that is, by preventing water from being introduced into the crucible with the circulating gas and by using burnt lime instead of limestone in the charge.

A further economy can be secured by drying the charcoal outside the furnace to get rid of the water.

By these precautions the theoretical energy consumption can be reduced by 136 to 232.8, or on an average 208 kw-hours per ton. The actual economy would vary between 195 and 358 and average 294 kw-hours per ton, the economy so secured would amount to from 9.1 to 15.2 and average 12.3 per cent. of the total power consumption.

A further saving will ensue from the use of burnt lime instead of limestone in so far as a lower value of K can be reached.

The average calculated efficiency of the furnace has been 71 per cent. This figure is hardly satisfactory for a furnace of this size, but is to a great extent due to the average low load factor.

In Appendix III it has been attempted to arrive at a distribution of the losses as close as possible corresponding with the actual conditions. The losses in the iron of the transformers and in the copper can be fairly accurately calculated from the information given in the report about the efficiency of the transformer and the size of the leads.

The heat absorbed by the cooling water has been measured at several opportunities and found to vary between 5.3 per cent and 8.2 per cent and average 6.56 per cent of the load.

The report also contains observations of the surface temperature of the furnace, which observations enable one to calculate the radiation losses to be about 200 kw, to which figure has to be added the radiation from the upper part of the electrodes with about 20 kw.

Comparing the losses calculated in this manner with the figures arrived at by the subtraction of the theoretical power consumption from the actual, it will be found that with the exception of the periods 2 and 3 the agreement is very fair.

Taken over the whole run, the two figures are exactly alike, which will indicate that the calculated distribution of losses is not far from being correct.

An appreciable reduction of the losses can only he gained by diminishing the dimensions of the furnace and by suitable precautions to prevent too much heat being carried away by the cooling of the electrodes.

The possible efficiency of the furnace if working at full load can be calculated from the above figures to be

$$\frac{1840-240-0.104\times1840}{1840}=\frac{1408.5}{1840}=0.7655=76.55\%$$

When a more satisfactory load factor can be secured after having overcome the troubles caused by the transformers there should be no difficulty in maintaining this efficiency, which is sufficiently high to make the working of the process satisfactory, although further progress also in this direction may be expected.

As to the power consumption of the Noble furnace, no accurate figures are at hand, but from the manager of the plant it has been stated that the power consumption has averaged 1940 kw-hours per ton. This figure has never been reached in the Trollhättan furnace.*

The cause of this lower power consumption is certainly partly due to the high-grade ore used, but the fact that gas circulation has only been used incidentally and also that the dimensions of the furnace are considerably smaller than those of the Trolltättan furnace have also contributed to the greater economy obtained.

Gas Circulation.

The idea of using circulating gas in an electric reduction furnace was originated by Harmet in 1901.

The effect of the circulating gas is a double one, namely, on one side the cooling of the charge in the neighborhood of the point of introduction of the gas and on the other side the conveying of the heat absorbed in the lower part of the furnace to the charge in the shaft.

The cooling effect becomes of paramount importance in furnaces which are worked along the line of the Trollhättan furnace and in which most of the heat is generated near the free surface of the charge in the melting chamber.

The cooling effect depends upon the amount of heat absorbed by the decomposition of H_2O and CO_2 when brought into contact with incandescent carbon, respectively, in raising the temperature of the gas.

*See, however, the very latest results obtained at Trollhättan, as recorded in our October issue, p. 482. During the week of September 3 to 9, 1911, the figure of 1736 kw-hours per ton was reached.—Editor.

To obtain an idea of the amount of heat that in this way can be absorbed, Table 2 has been computed from the average results of the Trollhättan furnace.

TABLE II. EFFECT OF CIRCULATING GAS

Ratio of Circulating Gas to Produced Gas.	1.		2.		3.	
Temperature to which gas is raised	500°	800°	500°	800°	500°	800°
Heat in gases in kw hours	205	290	410	580	615	870
Heat absorbed in decomposition of CO_2, kw hours.	354	354	708	708	1,062	1,062
Heat absorbed in decomposition of H_2O, kw-hours.	110	110	146	146	165	165
Total heat absorbed by circulating gas kw hours per ton of pig	669	754	1,264	1,434	1,792	2,097

These figures should show that a very effective cooling can be obtained for the protection of the roof, but from the great amount of heat that would be absorbed by a complete decomposition of the CO_2 it appears probable that only a comparatively small part is actually decomposed, considering that the total power consumption has only been 2391 kw-hours per ton.

For the effective protection of the cover against the heat radiation from the arcs it appears as if it should be sufficient to use a circulating gas of not more than twice the amount of produced gas.

In the case of a furnace of the Noble type, in which the electrodes enter so far into the charge as to prevent arcing, it has been found unnecessary to use any circulating gas at all as long as the electrodes remain unbroken.

It has been previously stated that the weight of the gases produced are only 35 per cent to 40 per cent of the weight of the charge, and as the specific heat is very nearly the same for the gas as for the charge the heat absorbed by the produced gas is not sufficient to heat the charge to any high temperature. In fact gases of 1000° can only heat the charge to about 350°.

This has already been recognized in 1901 by Harmet, who has in several patents proposed to increase the volume of gas by establishing a current of circulating gas taken from the top of the shaft and introduced into the melting zone by means of a blower.

The quantity of heat that can be absorbed by the circulating gas is, however, restricted by the temperature of the charge and the surface of contact of the charge through which the gas has to pass.

Without arrangements by which the circulating gas is forced to pass through the space between the electrodes and the charge, and thus through the electric arc, it is not possible for the gases to acquire any high temperature. The observations made at the Trollhättan furnace tend to show that the circulating gas in fact only serves to cool the charge and has not been able to acquire a temperature exceeding 690° C. at the neck of the melting chamber, the average value having been only 510° C.

The manner in which the circulating gas is introduced into the furnace at Trollhättan can thus not effect an essential extension of the zone within which a reduction by CO takes place.

To make the gas effective in this respect arrangements must be provided by which the gases find an opportunity to acquire a higher temperature mainly by passing the gas through the hottest part of the charge

Load Factor.

The average power consumption of the Trollhättan furnace constructed for 1840 kw has been about 1285 kw over the whole time of operation from Nov. 15, 1910, to April 9, 1911. The average load factor has thus been only about 70 per cent.

As the load factor is of the greatest importance for the economical working of the process, it is of interest to study the variation of the same during the different periods. This is done in Table 3.

TABLE III. LOAD FACTOR

	Period. From	To	Total Hours	Total Kw hours	Average Kw.	Load Factor.
1	Nov. 16	Feb. 11	2,115.5	22,651,029	1,252	68.1%
2	Feb. 11	Feb. 19	189.5	312,601	1,650	89.7%
3	Feb. 19	Mar. 19	660.2	650,480	986	53.6%
4	Mar. 19	April 9	528.5	877,706	1,660	90.3%
	Nov. 16th	April 9th	3,502	1,500,596	1,285	69.9%

The low load factor during the first period is probably partly to be ascribed to inexperience with the manipulation of the furnace, partly to the defectiveness and the long break down of Transformer II.

The poor load factor during period 3 seems to have been due exclusively to the break down of the Transformer II. The load factors of the periods 2 and 4 approach 90 per cent, a figure which must be considered very satisfactory.

As there should be no difficulty to avoid break downs of the transformers, the experience at Trollhättan shows that an average load factor of 90 per cent can be maintained during the period of the working of the furnace, thus without taking into consideration the time for repairing and heating up.

It has already been shown that the temperature in the shaft does on an average not exceed 500° C. With suitable bricks it ought, therefore, to stand for years without any repair.

The melting chamber, which naturally is exposed to heavier wear and tear, will have to be relined from time to time. The duration of the first crucible, being about six months, must be considered as most satisfactory. The loss of time for exchange of the lining can be greatly reduced by arranging the melting chamber in such a way that it can be removed altogether and a spare crucible, ready lined, can be put in place.

With such an arrangement the total interruption from the exchange of the lining should not need to exceed a week, and can probably be reduced to two or three days. The load factor for a whole year should, therefore, not need to fall below 88.5 per cent, which means that the furnace could be worked at full capacity during 7750 hours out of a total of 8760 hours per year.

Conclusions.

The results of the Trollhättan furnace prove that the electric reduction of iron ore can be carried out in a technically satisfactory way, although the process is open to improvements by which the cost of production can be reduced.

By eliminating the water from the circulating gas the coal consumption can be reduced by about 14 per cent. The use of burnt lime instead of limestone will secure a further economy as there will be less CO_2 in the gas, which thereby will become more strongly reducing.

The average economy in power consumption which may be gained is:

By eliminating the water in the circulating gas 139 kw hours per ton of pig, or 5.76 per cent.

By using burnt lime instead of limestone 92 kw-hours per ton of pig, or 3.18 per cent.

By heating the charge outside the furnace so as to evaporate the water 62 kw-hours per ton of pig, or 2.58 per cent.

The total average saving thus possible amounts to 293 kw hours per ton of pig, or 12.15 per cent.

Further savings in power are possible by reducing the dimensions of the furnace as much as possible and by always running the furnace at full load.

A small saving may also be secured by preventing the air from entering into the furnace. The average amount of air per ton of pig has been approximately 45 kg, burning 6 kg of charcoal and producing 25 kw hours. If the price of the current is 0.16 cent per kw hour, corresponding with $10 per hp

year, the value of the heat generated is 4.4 cents, whereas with a price of the charcoal of $10 per ton the value of the charcoal burnt is 6 cents.

If provisions were made to obtain all the savings possible, the following result would have been obtained. The average coal consumption would have been 360 kg instead of 418 kg per ton of pig, and probably still lower, as a greater part of the ore would most likely have been reduced by CO on account of the stronger reducing action of the gases. The average power consumption would have been:

$$\frac{1,721\ 4-208\ 1\ 513\ 4}{0.765} = \frac{}{0.765} = 1,985 \text{ kw-hours,}$$

instead of 2391 kw-hours per ton.

With an average load factor of 88.5 per cent the output would have been:

3.0 tons per kw year, paid for
2.87 " " hp year " "

Even still better results may be anticipated because of the saving in power consumption through the stronger reducing capacity of the gases. As it is not possible to predict how much the reduction of the ore by CO may be increased, the saving in power-consumption from this source has not been taken into consideration.

Beckenham, Kent,
England.

Appendix II. on the coal consumption during different periods and Appendix III. on power consumption will be found on pages 638 and 639 respectively.

Electrolytic silver may be removed easily from cathode sheets by painting the sheets with a mixture of silver nitrate, copper nitrate and hydrochloric acid. After drying these sheets can be used for two or three months before deposits will begin to stick. At the San Francisco mint electrolytic refining is done with a direct current at 15 volts, and a current density of 8.3 amperes per square foot of cathode surface.

Concrete mortar blocks may be constructed according to the following method, as outlined in the *Cement Age*. The proportions of material are: 1 part by volume of portland cement, 3 parts by volume of freshly screened sharp sand, 5 parts by volume of freshly broken rock of any character suitable for concrete work, and passing a 3-in. ring. This proportion is continued to a point within 2 ft. of the upper surface of the mortar block, when the proportions may be changed as follows: 1 part by volume of portland cement, 2 parts by volume of freshly screened sand, 4 parts by volume of freshly broken rock passing a 1.5-in. ring. The upper layer of 6 in. from the top of the block should be constructed with the following proportions: 1 part by volume of portland cement and 1 part by volume of freshly screened sand. In some cases these blocks have been built for each 10-stamp battery, or in others a solid block has been built under the entire 100 stamps in the mill, without any expansion joints; and after several years' service the block appears to be in excellent condition.

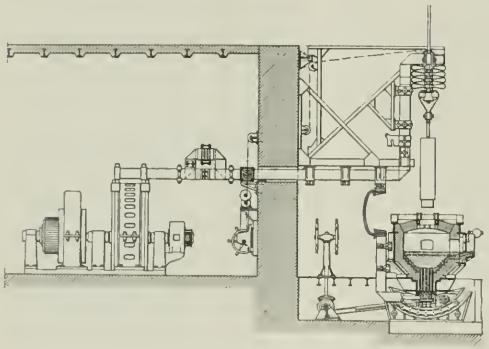
Remelting of Ferromanganese in the Electric Furnace and the Use of Molten Ferromanganese for Deoxidation.

An article by Bronn and Schemmann on the remelting of ferromanganese and the use of molten ferromanganese as a deoxidizer was abstracted in the November issue of this journal, page 575.

Another very interesting article dealing with the same subject was published in *Stahl und Eisen* of Sept. 7, 1911, page 1467, the author being Dipl. Engineer Felix Schroeder, of Livet (Isere), France.

The waste of ferromanganese when charged cold, especially during the time when slag is being removed, caused the abandonment of this process. Other disadvantages were delays due to the time required for the absorption of the solid ferromanganese, a cooling down of the bath and an irregular distribution of the manganese in the steel.

The best method for melting ferromanganese was found to be the use of the electric furnace, and the results obtained with one furnace of the Keller system* at the Burbacherhutte in Saarbrücken are described. It was adopted there after previous tests at the works of Keller-Leleux Company in Livet had shown the possibility of melting 80 per cent ferromanganese in the electric furnace without any losses of manganese.



ELECTRIC FURNACE FOR MELTING FERROMANGANESE.

The furnace seen in Fig. 1 was designed for the manufacture of steel and was run alternately on steel and ferromanganese during the last nine months. The use of molten ferromanganese was begun at once on a large scale. More than 1000 tons of ferromanganese have been remelted in the electric furnace, to be used as molten addition to all basic converter metal in the ladle for several months.

The continuous operation of the converter plant during the six weekdays required an uninterrupted running of the electric furnace in order to have hot ferromanganese ready whenever needed. On Sunday the metal usually remained in the furnace and was maintained fluid by the electric current, the consumption of electric current for this purpose being "very low." When no electric power was available the furnace was emptied and restarted on Sunday night. During the week the furnace was never emptied. Small repairs were done on Sunday, the hot metal meanwhile being poured into a ladle.

Changes of electrodes were very seldom necessary and required only a short time. The electrode was raised, the arm turned aside, and the new one, already hanging on another arm, lowered into the furnace.

Special attention was paid to the lining of the furnace, in order to avoid any interruption of the furnace operation due to repairs of the lining. The longest period during which the furnace was used for melting ferromanganese was three months. During this time the roof of acid brick, which had already been used before during a period of steel refining, was neither repaired nor renewed.

The dolomite lining was not renewed, and only a few small repairs were made from time to time. After these three months of ferromanganese melting the furnace was started to run on steel again, and the lining was still in fair condition.

The roof and lining of the furnace when used for melting ferromanganese, therefore, last at least three months, and the author claims that a lining of magnesite would stand from six to nine months in continuous operation.

The inclined lower lining between door and hearth and also the lining of the hearth itself were not changed for nine months, requiring only a few repairs.

The above facts, therefore, disprove the fear sometimes expressed that the hearth of the Keller furnace, owing to its complicated structure, would have only a short life. It has also been suggested that the iron rods of the hearth would likely melt or be converted into ferromanganese, but neither did happen, as it could be avoided very easily*

The furnace is started by lowering the upper electrode to the charge of solid ferromanganese. It is not necessary nor desirable to have previously melted iron in the furnace.

The operation of the furnace is very simple, one melter and a boy being sufficient. The best place for the furnace is the charging floor of the converter.

The molten ferromanganese is poured into a small ladle and brought to the different converters. The addition of it into the steel ladle is carried out in the same way as the addition of spiegeleisen in the production of rail steel. The furnace may be dipped by hydraulic pressure like the converters.

From the results obtained at the Burbacherhutte, the following conclusions may be drawn:

1. The remelting of ferromanganese in the Keller furnace occurs without any losses of manganese by volatilization.

For example, 10 average samples of solid ferromanganese had the following analyses before charged into the electric furnace:

80.44	81.60	82.32
80.12	79.81	79.18
79.80	79.52	79.71
80.32	Average = 80.20 per cent Mn.	

Thirty-seven successive samples of molten ferromanganese taken from the electric furnace had the following analyses:

81.35	79.82	79.18	80.32
81.06	81.06	79.18	81.06
81.38	80.12	81.06	81.38
80.44	80.44	80.75	81.06
80.12	80.12	81.06	80.44
79.81	80.44	79.50	79.81
79.20	79.50	80.12	79.50
80.12	80.32	79.91	80.32
80.11	79.32	79.51	79.91
79.32	Average = 80.22 per cent Mn.		

The remelting, therefore, causes practically no loss of manganese. There is no smoke nuisance at the furnace.

2. The net saving due to the use of molten ferromanganese amounts to 35 per cent. of the amount of solid ferromanganese which would be necessary for the production of steel of the same quality and under the same conditions of operation. Another saving results from the fact that all the fine pieces of ferromanganese, which are usually lost in ordinary practice, can be used up.

In this comparison it is assumed that the same amount of manganese shall be in the finished steel as in usual practice. As a matter of fact, however, it is possible, if the addition of

*For a detailed description of the Keller furnace see our Vol. VII, page 255 (1909).

*This would seem to contradict the experience of Bronn and Schemmann with the steel electrodes in the bottom of the Girod furnace (see page 575 of our November issue).—Editor.

ferromanganese is made in molten form, to reduce slightly the manganese content in the finished steel without affecting the rolling quality.

3. Costs of melting based upon a price of half a cent per kw-hour were approximately $5 per ton of ferromanganese, including electric power consumption, electrode consumption, wages, linings, and repairs. These are not the costs of special experiments, but a monthly average, and therefore include costs of heating and starting the furnace, delays, interruptions due to electrode changes, Sunday work, etc., or, briefly, all the expenses of using the process in a commercial basic converter plant.

Assuming that the melting-cost per ton of ferromanganese is $5, the price of one ton of ferromanganese $40 only (abroad), and that 5 kg. of ferromanganese are to be used per ton of steel, we obtain the results given in Table 1.

TABLE I.

Yearly production of steel in tons.	Ferromanganese remelted in tons.	Total melting cost in dollars.	Saving of ferromanganese in tons, if 1 kg. of ferromanganese is saved per ton of steel.	Price of ferromanganese saved in dollars.	Saving of ferromanganese in tons, if 2 kg. of ferromanganese is saved per ton of steel.	Price of ferromanganese saved in dollars.
100,000	500	2,500	100	4,000	200	8,000
200,000	1,000	5,000	200	8,000	400	16,000
300,000	1,500	7,500	300	12,000	600	24,000
400,000	2,000	10,000	400	16,000	800	32,000
500,000	2,500	12,500	500	20,000	1,000	40,000
600,000	3,000	15,000	600	24,000	1,200	48,000
800,000	4,000	20,000	800	32,000	1,600	64,000

It may be said that, on account of the smaller ferromanganese consumption, the weight of steel so produced is also less. The slag is also less. The useful phosphorus in the slag increases and there is no reduction of phosphorus back into the metal. All these facts have a very small influence on the final results.

The price of ferromanganese at present is very low and may still decline. The above consumption of 5 kg. ferromanganese per ton of steel is also an assumed figure; it will in reality vary according to the quality of steel produced at different plants, therefore the above calculation should only be considered as an example.

It shows, however, that in no case in melting costs exceed the saving in ferromanganese even if only 1 kg. of ferromanganese per ton of steel should be saved. But the situation is improved considerably if 2 kg. or more of ferromanganese can be saved.

Besides this, the use of ferromanganese offers many other advantages which should not be overlooked. The desired quality of the steel is far more easily obtained than is possible with the use of solid ferromanganese. All of the molten alloy is completely absorbed by the hot metal. With some experience in estimating the manganese contained in a sample of converter metal taken after the blow, it becomes easy to determine accurately the amount of ferromanganese to be added. This is of great value for high-carbon steels.

Using solid ferromanganese on cold heats in the converter, one always runs the risk of its not being absorbed in the bath.

The distribution of molten ferromanganese in the ladle is uniform, the deoxidation quick and more effective, and rephosphorization impossible.

Not only is the quality of the steel improved, but the capacity of the converter plant can also be increased since the time required for the resting of the metal to permit the ferromanganese to dissolve is saved. The gain per heat is always a few minutes, which amounts to something when running full capacity.

There is no reason why this process should not be successfully employed in open-hearth practice. R. J. W.

The Production of Oxygen in the Workshop.

I.—The Production of Oxygen from Alkali-Chlorates.

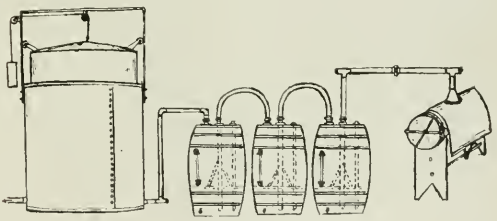
BY AUG. S. NEUMARK.

There are two ways open for the average consumer to obtain oxygen, namely, to purchase the gas compressed in tanks from the manufacturer or to make it himself by chemical means.

Among the various methods used for the production of oxygen, the one generally used (and the most abused, I might add) is the chlorate process. If potassium chlorate is heated to a temperature of 350°-370° Cent., it melts and then liberates all of its oxygen.

The decomposition is an exothermic one, *i. e.*, heat is evolved during reaction, and when it once has set in, the evolution of the gas becomes very violent. This action can be checked by adding a medium which serves to prevent too rapid generation and also lowers the temperature necessary to start the same. For want of a better name such agents are called catalytic agents; the part they play during decomposition is somewhat obscure.

Manganese dioxide (black oxide of manganese) is usually employed for that purpose and is intimately mixed with the chlorate in the proportion of 1:6 or 1:8. The addition of manganese dioxide causes the formation of small quantities of chlorine, and since pure chlorate does not liberate such, it is most likely that the manganese dioxide causes a momentary conversion into potassium manganate, thus setting free chlorine, which on further heating decomposes the manganate again, liberating oxygen and leaving as a residue a mixture of potas-



OXYGEN PLANT (COMPRESSOR TYPE).

sium chloride and manganese dioxide. The reactions may be expressed by the following two equations:

(1) $2KClO_3 + 2MnO_2 = 2KMnO_4 + Cl_2 + O_2$.

(2) $2KMnO_4 + Cl_2 = 2KCl + 2MnO_2 + 2O_2$.

The admixture of the manganese dioxide reduces the temperature necessary for decomposition to 200-210° Cent.

A much better substitute would be ferric oxide, a red powder, used as a material for paints. However, it must be pure and previously have been thoroughly heated. It will reduce the temperature required to 110-120°C.

Other so-called catalytic agents, which have been recommended, are copper oxide, lead peroxide, graphite, dry quartz-sand, and powdered glass.

The addition of common table salt will further check a too violent generation. Mixtures giving the best results consist of 2 parts of chlorate, 2 parts of table salt and 3 parts of ferric oxide; or 12 parts of chlorate, 6 parts of salt and 1 part of manganese dioxide.

According to an English formula, the addition of powdered iron and a small quantity of iron oxalate will still further reduce the temperature.

Large crystals of potassium chlorate must never be used and care should be taken that the chemicals are pure and in the dry state. The presence of any chlorite or hypochlorite in the chlorate is liable to cause an explosion; barium sulphate, which has been used to adulterate the chlorate can also cause explosive decomposition.

One pound of potassium chlorate yields 4¼ cu. feet of oxygen, the cost being about 2½ cents per cubic foot.

Sodium chlorate, having a lower molecular weight, produces from 16 to 18% more gas per unit of weight, thus reducing the cost to about 2 cents per cubic foot. There is no reason to think that sodium chlorate is more dangerous to use than the potassium salt. If the conditions are alike, the decomposition of the former will be as slow and smooth as with the latter.

Violent generation is caused by the melting of the chlorate before giving of its oxygen, and then liberating all of it at once. This, however, can never happen if the materials are pure, if the chlorate is in a perfectly dry state and in form of small pieces or crystals and if intimately mixed with the catalytic substance.

The retorts used for generating oxygen must be of a proper construction. Manganese dioxide or ferric oxide is always carried along by the force of the oxygen current. It is, therefore, essential that the outlet pipe is sufficiently wide. If the outlet is too small, the gas may come off at such rapid rate as to exceed the delivery power of the exit pipe, which, to make matters worse, may be choked up from a previous charge.

Even for the smallest generating outfit, the piping should have a diameter of not less than 1 inch, preferably 1½ inches. It is advisable to have a dome or a cone-shaped exit piece, and that the exit pipe should be short, without any sharp turns, so as to offer the least resistance to the gas. "L" fittings should not be used; "T's" should be substituted, with the open end closed up by a plug. This facilitates cleaning of the pipes.

The oxygen is purified by allowing it to bubble through barrels, partly filled with water and a solution of caustic soda. The delivery pipe reaches nearly to the bottom of the barrel and is provided with some arrangement to break up the bubbles. The barrels should also have a safety pipe which not only prevents any bursting, in case of a too rapid generation, but takes care of the back-pressure when generating ceases.

The last wash-barrel is connected with the gasholder from which the oxygen is forced into storage tanks by means of suitable compressors. The latter are probably the most expensive part of an oxygen plant, although a fairly good compressor, able to produce a pressure of 250 lbs. per sq. inch, can be bought for $125.00. Those having two stages of compression are, of course, more expensive. The compressors must be water-cooled and provided with proper means of lubrication. Oil must never be used as a lubricant; a soapy solution or a diluted solution of glycerine may be used instead.

Oxygen can also be generated under sufficient pressure to force it into storage tanks which would do away with gasholder and compressor and therefore take up very little space. However, such a plant is neither economical nor are the results obtained satisfactory. The waste of gas during recharging reduces the yield of oxygen to 4 cu. ft. per pound. The purification, too, is incomplete and accidents caused by leaving the valve between retort and storage tank (or scrubber) closed are liable to happen. Several of such accidents have come to the writer's notice. Safety valves are of little use; the use of check-valves, made of non-corrosive material, might, however, minimize the possibility of such accidents.

In both the compressor type and pressure type of oxygen plant the gas is liberated by external heating of the retorts. Another type is the internally heated type, where the chlorate mixture is lighted with a match or with the aid of some ignition powder whereupon the retort is sealed. The chlorate which is always in the powdered state is mixed with some combustible substance (charcoal, hydrocarbons, cellulose, powdered metal) and an inert matter (infusorial earth, clay, sand).

Following are a few mixtures which have been used for this purpose:

100 parts chlorate of potash, 40 to 60 manganese oxide, 5 to 20 infusorial earth.

70 to 90 parts chlorate of potash, 0.9 to 8.5 coal dust (lampblack), 0.1 to 21 infusorial earth.

100 parts chlorate of potash, 20 to 40 infusorial earth, 3 to 5 powdered charcoal.

500 parts chlorate of potash, 62 manganese dioxide or ferric oxide, 4 lampblack.

"Oxygenite" belongs to this class of combinations.

The Applications of Electricity in the Metallurgical Industry of Italy.*

By R. Catani

The development of the use of electricity in recent years has greatly benefited the metallurgical industry in many ways, as a means for driving the auxiliary machinery of metallurgical apparatus, blast-furnaces, and mixers, the hoisting and transport of raw and finished materials, and the driving of rolling-mills. The last and most important development, however, is that of furnaces dependent, for their heat, upon the thermal effects of the electric current.

The Italian metallurgical industry has also largely benefited by the introduction of electric energy, but it is proposed to confine this report mainly to an account of the furnaces and electric processes applied in Italy to metallurgical production.

The subject might perhaps have been dealt with from the point of view of the various types of electric furnaces which have been tried or are being worked at present in Italy, but seeing that this would comprise almost every kind of electric furnace, both of the arc and induction types, and that the paper would consist of a series of descriptions of furnaces such as have already lately appeared in many technical publications, it appears more desirable in the present paper to discuss the metallurgical products obtained in Italy by means of the electric furnace.

The author therefore proposes to deal first with the production of electric steel; secondly, with the smelting of pig iron by electricity; and, lastly, with alloys of iron with other metals,

I. Production of Steel in the Electric Furnace.

In Italy steel is manufactured in the electric furnace either direct from ores or from iron products, and, indeed, the first experiments in the direct production of steel from ore in the electric furnace were made at Rome by Stassano in 1898.

A. Steels Produced Direct from the Ore.—The problem of the direct reduction of steel from the ore presents difficulties of such a kind as to deter many metallurgists, however well skilled, from attempting to solve it. The numerous experiments carried out last century in the endeavor to attain this object, using coal as fuel, met with no success on a commercial scale.

On the other hand, the results of a few years' trial with the electric furnace have surpassed expectation, and it may be affirmed with certainty that, in due time, by the aid of the electric furnace, the problem of producing steel by a direct process on a commercial scale will have been overcome.

The experiments of the last century cleared up several essential points which have assisted greatly in the further development of the process. In Stassano's experiments at Rome the charge was prepared in the same manner as in previous attempts to effect the direct reduction of ore with coal as fuel. The material was first crushed, pressed into briquettes with tar and finally treated in the electric furnace.

Recent trials have shown, however, that in the electric furnace it is equally easy to treat the ore whether in a fine state or in lumps, and hence it is possible to dispense with the preparation of the raw material, which forms a not inconsiderable item in the first cost of the steel.

The early experiments of Stassano, as stated by him in 1902, led to no practical results for the reason that he adhered too closely to blast-furnace practice, both in regard to the shape of

*A paper presented at the October meeting of the Iron and Steel Institute in London.

the furnace and the process itself. In fact, the first furnace used at Rome in 1898 to 1899 was a shaft furnace in which, instead of having tuyeres for blowing, electrodes were provided for conducting electric current. As to the method of smelting, Stassano arrested the ore by means of a grating at a distance of about 20 cm above the electric arcs. The experimental furnace afterwards put up at Darfo did not differ very materially from that at Rome, nor were the results much better than those previously obtained.

Stassano finally adopted a furnace of the hearth type; the principal characteristics were that it was roofed over, and long electric arcs played between the mass of the charge and the arch of the furnace. The arcs swept the surface of the slag without passing through it; the heat, therefore, was not imparted direct by the contact with the slag or the molten mass, but passed indirectly into the bath by radiation. The electrodes had a high density, and were held in water-cooled supports. The furnace was completely closed in, and provision was made for collecting and carrying off the gases evolved during the process.

Some Stassano furnaces are fixed, others can be rotated. In some the only rotary movement is that of tilting toward the side of the tapping hole so as to facilitate tapping. Others can be rotated on their vertical axis so as to stir the bath. Single-phase current with one or more pairs of electrodes or three-phase current can be used. Stassano's experiments for the direct production of steel by means of his electric furnace may be divided into two groups, namely, those performed during the years 1898 to 1902, the results of which were published in the *Rivista di Artiglieria e Genio*, March, 1902, and those which were published in 1908 in the *Giornale del Genio Civile*.[1]

In the *first trials* only hæmatite ore of first-class quality, from the Island of Elba, was used. The chemical analyses of the material smelted, of the product obtained, and the proportions of materials used per 100 kgs. of product are given in Table I.

TABLE I.—FIRST EXPERIMENTS OF STASSANO.

Ores per cent.	Charcoal per cent.	Pitch per cent.	Limestone per cent.	Average Product.

QUANTITY USED PER 100 KG. OF STEEL PRODUCED.

Kilog.	Kilog.	Kilog	Kilog.	Kilog.
165.8	26.5	20	19.1	100

Altogether there were produced only 125.6 kg of steel. The loss of iron in transition from the ore to the steel was about 8 per cent. The consumption of energy averaged 4187 kw-hours per ton of product, and the mean efficiency of the furnace was 48 per cent. Stassano omitted to give particulars of the electrode consumption, but, according to an estimate of his, it was stated to amount to 12 kg per ton produced.

These experiments prove, first, the possibility of obtaining fluid steel direct from the ore in the electric furnace; secondly, the advantage that with such a furnace the amount of materials consumed approximates more closely to the theoretical amount of materials required than was the case in the older processes for the direct production of steel from ore.

The industrial importance of the process, however, was insignificant, for the reason that only material of first-class quality could be used, that the total production was negligible, that it was considered necessary to crush the ores and agglomerate them with tar and, finally, that the energy consumption was excessively high. Stassano concluded his account of 1902 with the following estimate of the cost of the direct production of steel by his processs:

[1]See also the extensive article on his work by Major Stassano in this journal, Aug., 1908 (ELECTROCHEM. & MET. ING., vol. VI, p. 315).

	Lire.
1600 kg of ore at 15 lire per 1000 kg	24.0
Crushing the ore at 3 lire per 1000 kg	4.80
200 kg of limestone at 5 lire per 1000 kg	1.0
250 kg of coke at 45 lire per 1000 kg	11.25
Crushing the coke at 2 lire per 1000 kg	0.50
190 kg of pitch at 70 lire per 1000 kg	13.30
Manufacture of briquettes at 3 lire per 1000 kg of the mixture.	6.75
Consumption of electrodes (12 kg at 30 lire)	3.60
Maintenance of the furnaces	12.0
Labor	6.0
Maintenance of ingot molds and apparatus	3.0
4000 hp at 0.0057 lire per hp hour	22.80
General expenses	3.0
	112.0 =$27.62

(NOTE.—1 lira may be taken as equivalent to 19.3 cents.)

Certain of the data in this estimate appear to be inaccurate; for instance, the use of metallurgical coke is referred to, whereas charcoal was used in the experiments. Also, the cost per kilogram of electrode at 0.30 lire (6 cents) is too low, and the electrode consumption of 12 kg per ton of steel is untrustworthy.

Moreover, Stassano subtracted 18 lire from the 112 lire as representing the value of the carbon monoxide and of the volatile hydrocarbons of the pitch, the total amount of gas yielded being 900 cu. m., valued at 2 centesimi (0.4 cent) per cubic meter. But it is to be noted that, if that consideration is reasonable in the case of the electric furnace, it also holds good for the other ordinary processes in which gas is evolved from coke furnaces, blast-furnaces, and steel furnaces. Theoretically speaking, these gases would have a higher value than the gas from an electric furnace.

Hence, in making comparisons of the cost of ordinary steels, the amount of 112 lire, as given above, should be taken instead of 94, the figure obtained by deducting the value of the gas estimated at 18 lire. Further, to the figure of 112 lire ought to be added the charges for cooling water, for depreciation and for the additions in the refining process, though, on the other hand, it might be reduced by the amount of cost of preparing the ore mixture if, as in other electrical processes for the conversion of ore into steel, it should prove possible to treat pulverulent ores by the Stassano process.

In the *second series of his experiments*, Stassano used a different ore, of the following composition:

	Per Cent
Fe_2O_3	68.70 Fe=48.09
Mn_3O_4	3.23
SiO_2	17.15
Al_2O_3	2
CaO	1
MgO	5.67
P	0.15
S	0.12

In this case, also, the ores were crushed and briquetted, but with a 25 per cent solution of silicate of soda instead of with pitch.

In spite of the impurity of the ore, steels of good quality were obtained, the analyses of the product of charges Nos. 2 and 4 being given in Table II:

TABLE II.—STEELS PRODUCED DIRECT FROM THE ORES IN A STASSANO ELECTRIC FURNACE.

Charge No.	COMPOSITION.					MECHANICAL TESTS.		Coefficient of Quality A×R.
	C.	Mn.	Si.	P.	S.	Tensile Strength, Kg./mm². R.	Elongation per Cent. A.	
2	0.26	0.21	0.03	0.010	0.040	55	23	1,265
4	0.80	0.30	0.22	0.015	0.045	86 3	13	1,122

In the case of this second series of experiments, in which only four charges were worked, particulars were not given either of the total production or of the consumption of electrode and of water, or of the composition of the limestone and the charcoal. The furnace was of 200 hp, with three-phase current, and the average consumption of electric energy was 4250 kw-hours.

The charges were as follows:

	Kilograms
Ore	100
Limestone	35
Charcoal	21
Aqueous solution of silicate of soda	8
Carbide of calcium	5

On the basis of these figures and of the percentage of iron in the ore, and assuming that in this second series of experiments the loss of iron was the same as before, namely, 8 per cent, the consumption of material per ton of steel produced would have been:

	Kilograms.
Ore	2,250
Charcoal	540
Limestone	787
Silicate of soda	180
Carbide of calcium	112

In addition, the author has calculated from the particulars furnished by Stassano at the Sixth Congress of Applied Chemistry, that his three-phase electric furnace of 200 hp used in these last experiments consumed, for every ton of metal produced, about 50 cu. m of water for cooling the holders of the electrodes.

B. Steels from Iron Products.—With the electric furnace, however, the general practice is to use pig iron for the production of iron and steel in the same manner as in the ordinary type of furnace, in which case the material can be charged into the furnace in either the liquid or the solid state. The consumption of electric energy diminishes rapidly the greater the amount of heat stored in the materials when charged, and the greater the degree of the purity of these. Table III shows the approximate power consumption in certain cases taken from actual practice.

TABLE III.—KW-HOURS NECESSARY FOR THE PRODUCTION OF A TON OF STEEL. (RODENHAUSER-SCHOENAWA FURNACE).

	Kw-Hours.
From cold pig iron	1,500
From liquid pig iron	1,100 to 1,200
From cold pig iron and cold scrap	900 " 1,300
From liquid pig iron and cold scrap	600 " 1,000
From cold scrap	300 " 900
Refining.	
Steel of crucible quality from liquid iron	200 to 300
Ordinary electric steel from liquid iron	120
Mixer	50

In general, where electric energy is costly, it is convenient to refine only liquid charges in the electric furnace, but steel-works are not always in the neighborhood of electric power stations of sufficient capacity to supply energy at reasonable prices. In that case it is necessary to melt solid charges in the furnace.

1. **Cold Charging.**—The raw materials consist generally of pig iron, scrap, ore, and additions.

Stassano Furnace.—The first installation in Italy was that of Stassano at the Royal Artillery Works at Turin, established by the Italian Ministry of War. That furnace has been in operation since 1903, and is of 200 hp. Subsequently there was formed in Italy the Stassano Electric Furnace Company, which established an electric steel works at Turin. The electrical characteristics and the number of these furnaces were as follows:

Number of Furnaces.	Horse-power.	Kind of Current.	Volts.	Amperes.
2	100	Single-phase	75	1,000
2	200	Three-phase	100	900
2	1,000	"	150	2,700

Three-phase currents at 21,500 volts were supplied by the Societa Anonima Electtricita Alta Italia, and the voltage reduced by special transformers to 75, 100, and 150 volts for the furnaces of 100, 200 and 1000 hp respectively. The single-phase furnaces of 100 hp were shunted on a single-phase circuit.

The current suplied by the above-mentioned company to the furnaces amounted to about 350 kw from December to March, and to 800 kw from March to December, while the total power of the furnaces was 2600 hp = 1910 kw, as may be calculated from the foregoing data.

The Turin works of the Stassano Electric Furnace Company manufactured chiefly parts of railway carriages and wagons, and of automobiles. The Stassano Thermo-Electric Furnace Company went into liquidation in 1909, and some of the electric furnaces of the Turin plant have been transferred to the works of the "Elba" Company at Portoferraio and some to the Milan Steel Works.

The Stassano furnace installed at Portoferraio now works with cold charges, but it is probable that as the company has available liquid pig iron and Bessemer steel it will soon adopt liquid charging for the production of high-quality steel. The installation at Milan is not yet in operation.

The results obtained with the 200-hp furnace at the Royal Artillery Works at Turin and at the Stassano Thermo-Electric Furnace Company, published by Stassano in 1908, are set forth in Tables IV to VII.

The Héroult Furnace.—Héroult furnaces are installed in Italy at the works of the Mannesmann Tube Company, formed by the amalgamation of the Mannesmann Tube Works at Düsseldorf and of the Metallurgical Company of Rome. The works are situated at Dalmine in the district of Sabbro, Province of Bergamo. Three-phase currents are delivered at the central station at 12,000 volts, where they are transformed to 550 volts. There are two furnaces in which open-hearth steel scrap is melted, and both furnaces are in operation at the present time.

The Girod Furnace.—One Girod furnace is in course of construction at the steel works at Cornigliano Ligure of the Giovanni Ansaldo Company. The furnace is three-phase, of 350 kw at 50 cycles, with a capacity of 4 to 5 tons. The material is charged cold, the maximum potential between phases being 70 volts. The furnace will shortly be put into operation, and is intended for the manufacture of special steels only. It can also be operated with liquid charges, in which case the production will be increased by about 40 to 50 per cent.

Liquid Charging.—Electric steel furnaces may be charged either with liquid pig or with steel produced in the converter or open-hearth, and either the acid or basic process may be employed. Where steel from the converter or open-hearth furnace is charged a simple refining operation alone is required, and the improved quality, and particularly the increased resistance to shock, of the electric steel appear to be due to the much lower percentage of occluded gas in that material as compared with the gas contained in ordinary steel, the commercial composition being the same in both cases.

The Kjellin Furnace.—The first furnace which was worked with liquid charges in Italy was the Kjellin furnace installed at the works of the Giovanni Andrea Gregorini Steel & Iron Foundry Company at Castro on Lake Iseo. At first cold scrap was used, but it is now working on liquid steel taken from a 4-ton open-hearth furnace, which supplies to the electric furnace 1400 kg of metal of the following composition at each heat:

Carbon per cent.	Silicon per cent.	Sulphur per cent	Phosphorus per cent.	Manganese per cent
0.08 to 0.10	0.03 to 0.05	0.010 to 0.020	0.008 to 0.015	0.18 to 0.35

The final product contained:

Carbon per cent.	Silicon per cent.	Manganese per cent.
0.60	0.25	0.12

The recarburization was effected by adding pig iron, and since the furnace is tapped every 2½ hours, yielding at each heat 1400 kg of steel, the daily production, reckoning in the added pig iron, amounts to about 15 tons.

The steels produced, whether of a very soft quality or hard, are very malleable notwithstanding when the manganese is

Sulphur	0.018 " 0.007
Phosphorus	0.008 " 0.006
Manganese	0.006 " 0.08

The Kjellin furnace of the Gregorini Company is a simple induction furnace taking 300 kw. It is supplied with single-phase current at 25 cycles. When working on cold charges the production is about 10 tons daily, the energy consumption in that case being 690 kw-hours per ton of steel produced. The patent furnace lining of the Poldihütte is used, which lasts for about 120 heats, during the first 80 of which exceptionally rapid working is possible. High speed steel can be manufactured in this furnace containing, say, 25 per cent of tunsgten and 6 per cent of chromium.

II. Production of Pig Iron in the Electric Furnace.

Experiments made in Italy in the smelting of pig iron in the electric furnace differ somewhat from those made in other countries with the same object. In the trials made at Sault Ste. Marie, on behalf of the Canadian Government, a full account of which was given in Dr. E. Haanel's report in 1907, iron ores were smelted in a Héroult furnace. Dr. Haanel referred in his previous report to the First Canadian Commission in 1904 to the manufacture of electric steel, in which he described his experiments with the Héroult process at La Praz and with the Keller process at Livet. That report deals only with experiments, and not with the manufacture of steel on an industrial scale, such as that which has been attempted by the Swedish Company Aktiebolaget Elektrometall, which, having ample financial resources at its disposal, has produced many tons of pig iron in the furnaces of Lindeblad, Stalhane and Grönwall. Ordinary grades of iron ore were used, both in the experiments described by Dr. Haanel and also in the smelting of pig iron on an industrial scale by the Swedish Company.

In Italy experiments have been carried out by Carcano[2] for the production of pig iron from the residues of the pyrites which abound in this country. The pyrites residues can always be used in the blast-furnace, but thorough purifying and enrichment, as well as agglomeration by special processes, are necessary to prepare them for treatment in the blast-furnace. The chemical composition of the natural pyrites residues varies considerably, but what chiefly differentiates it from ordinary iron ore is its high sulphur percentage, often exceeding 4 per cent.

The pyrites residues treated by Carcano in the electric furnace had the following composition:

	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Silicon	8.0	12.25	9.10	7.9
Iron	56.0	47.0	52.0	60.3
Aluminum	9.30	18.80	12.30	6.9
Sulphur	2.01	2.63	4.25	2.01
			Per Cent.	

The residues were charged in their natural powdery condition, and it was endeavored to work with the most basic slag possible, preferably with a multiple base and with a certain percentage of manganese, so as to ensure that the slag had a sufficiently strong desulphurizing effect. The necessity of highly basic slag has been much discussed when it is desired to obtain a very energetic desulphurizing action, but, generally, manganese is found to have a sufficiently desulphurizing influence. This was also evident in the experiments under consideration, as may be seen from the following chemical determinations made on the raw material and on the pig iron produced under these conditions:

	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Manganese	0.558	0.744	1.28	2.14	2.54
Sulphur	0.146	0.124	0.093	0.048	0.026

The production of pig iron amounted to something under 100 tons, and the quality of the product may be judged from the following analyses:

Sulphur.	Phosphorus.	Manganese.	Silicon.
Per cent.	Per cent.	Per cent.	Per cent.
0.046	0.063	2.23	3.83
0.058	0.075	2.17	4.46
0.015	0.073	2.26	6.70
0.026	0.016	2.54	5.70 carbon = 1
	Ferro-Alloys.		
0.015	0.060	11.25	3.30
.....	0.060	13.66	8.90

In sample No. 4 of the foregoing series of analyses the carbon amounted to only 1 per cent, while the manganese and silicon were much higher. The material might be classed as a special kind of steel rather than as a pig iron.

In these trials various types of electric furnace of different powers were used. The first furnace was 180 hp, while that tried in 198, which Carcano found to give the most favorable results, was of a capacity varying from 200 to 300 hp. It was a closed furnace with neutral hearth supplied with single-phase or three-phase current with automatic charging, and with recovery of the carbon monoxide evolved during the reactions. That gas was used for the purpose of preventing deoxidation of the pyrites residues.

The energy consumption per ton of pig produced averaged 2100 kw-hours in a furnace of 180 kw and using pyrites residues containing 50 to 55 per cent of iron in the form of ferrous oxide.

The lower ends of the vertical electrodes rested on the slag, so that the furnace worked as a surface resistance furnace and the slag was of very high temperature, much above that of the bath. By this means it was possible to obtain highly fluid slags sufficiently basic in character, which accounts for the ability to desulphurize sufficiently when using materials containing so high a proportion of sulphur.

As regards the economic aspect of the process, too many data are unfortunately lacking, such as electrode consumption, charges for cooling water, refractory material for lining, and labor, to make it possible to present a practical estimate. There is to be taken into account, besides, the cost of raw material and of transport, the pyrites, at least in Italy, being generally situated at a considerable distance from the regions where water-power is plentiful. On the other hand, the districts abounding in water-power are far from the markets for metallurgical products and from the seaports.

III. Ferro-Alloys.

The chief metallurgical products manufactured in the electric

[2]This journal, April, 1909 (Electrochem. & Met. Ind., vol. VII, p. 155).

furnace in large quantities are ferro-alloys. Some, such as ferro-manganese and ferro-silicon low in silicon, were already known before the introduction of electric smelting, but with the electric furnace it is possible to produce alloys with a carbon content very much lower than that obtainable when smelting these alloys in the blast-furnace. The production of alloys such as high grade ferro-silicon, ferro-chromium, ferro-tungsten is only practicable in the electric furnace, and these are manufactured either from the ores of the respective metals or direct from the metals themselves or from the metals and ores together. The only ferro-alloy electrically manufactured in Italy on an important scale is that of ferro-silicon, of which 628 tons were produced in 1909. It may be useful, nevertheless, to describe briefly some of the experiments which have been made.

A. *Ferro-Alloys from Ores.*—As already stated, Mr. Carcano has obtained a kind of spiegel and silico-spiegel using pyrites residues. The author of the present paper has made some experiments for the purpose of studying the economic possibility, under certain given conditions, of producing ferro-silicon by smelting, in the electric furnace, silicates of iron or iron ores too highly siliceous for treatment in the blast-furnace, also cast or pig iron that has been rejected on account of its high sulphur or phosphorus contents.

The electric furnace used for the experiments was one of those specially modified by the author, the special characteristics of which are the absence of any kind of flexible conductor, a minimum quantity of current passing through the conductors and, above all, through the electrodes, a minimum space taken up by the conductors and confinement of water-cooling to those parts of the furnace above the plane of the electric arcs.

As a result of careful attention to these details the furnaces, which have also been used, with suitable modifications, for the manufacture of carbide of calcium, have a high thermal and electric efficiency and consequently a high total of efficiency, whatever kind of current is employed.

With alternating current, which is now generally used in modern metallurgical works, the power factor of such furnaces approaches as near as practicable to unity. The current supplied to the furnace is one of 12,000 amp at 42 volts, 25 cycles. The production in round figures was about 20 tons of ferro-silicon of varying silicon percentages.

At first a silicate of iron was used of the following chemical composition:

	Per cent.		
Silica	25		
Ferrous oxide	56.22	Iron	43.85
Alumina	2.55		
CaO_3	12.50	Lime	7
$MgCO_3$	2.10	Manganous oxide	1
Moisture and impurities	1.63		

The ratio of ferrous oxide to silica, in the specimen treated, was $56.22/25 = 2.25$.

One difficulty consisted in estimating beforehand what weight of silica would pass into the slag. Supposing that the slag formed a bisilicate, $SiO_2 + MgO$, $SiO_2 + Al_2O_3$ ($3SiO_2$), the silicon of which amounted to 28 per cent, then on the basis of that composition and the percentages of CaO, MgO and Al_2O_3 contained in the ore the quantity of silica taken up by the slag would be as follows:

$$SiO_2 = 2.55(Al_2O_3)\frac{180}{102} + 7\ (CaO)\frac{60}{56} + 1\ (MgO)\frac{60}{40} = 4\ 5 + 7.53 + 1.50 = 13.53\ (SiO_2).$$

So that of the 25 units of SiO_2 contained in the ore only 11.47, corresponding to 5.39 of silicon, will have remained for the ferro-silicon alloy. On the other hand, the ferrous oxide would have yielded 43 units, making a total of 48.39 units of ferro-silicon. The percentage composition of the ferro-silicon obtained would thus consist of:

	Per cent.
Silicon	11
Iron	89

According to the known formula for the reduction, by means of carbon, of ferrous oxide and silicon, and according to the analysis of the ore, the fixed carbon necessary for 100 kg of ore would amount to

$$56.22\ (FeO)\frac{12}{72} + 11.47\ (SiO_2)\frac{24}{60} = 13.94,$$

and if the metallurgical coke at disposal contained 85 per cent of fixed carbon, the weight of coke required would be

$$\frac{13.94}{0.85} = 16.4.$$

The weight of the slag per 100 parts of the ore would be:

$$2.55\ (Al_2O_3) + 7\ (CaO) + 1\ (MgO) + 13.53\ (SiO_2) + \text{ash}\ (16.4 - 13.94) = 26.54$$

In the absence of an analysis of the ash of the coke, and in consideration of its small amount, it may be assumed that the chemical composition of the slag would be that corresponding to the formula of the supposed bisilicate. Its composition would therefore be

$$Al_2O_3\ (3\ SiO_2) = 2.55 + 4.50 = 7.05$$
$$CaO,\ SiO_2 = 7 + 7.53 = 14.53$$
$$MgO,\ SiO_2 = 1 + 1.50 = 2.50,$$

and the proportion of the several constituents would be:

	Per cent.
Al_2O_3	10.6
CaO	29.1
MgO	4.2
SiO_2	56.1

According to the triangular diagram of Boudouard of silico-aluminates of calcium, the melting temperature of such a slag is about 1350° C., which is considerably lower than that of silicon, at 1900° (according to Boudouard); of alumina, at 2200° (according to Richards); and much lower than that of calcium, 3000° (according to Moissan). The slags become in fact quite fluid, and are very easily poured off and separated from the ferro-silicon.

The melting temperature will be even lower than the theoretical, since the material also takes up a certain proportion of ferrous oxide of the furnace lining and of burnt electrodes.

The charge, consisting of 100 parts of ore and 16.4 parts of coke, should yield 48.34 kg of 11 per cent ferro-silicon, and about 27 kg of slag with a silicon content of $56.1 \times \frac{28}{60} = 26.32$ per cent; whereas the average of the analyses showed that the silicon in the slag was 23.5 per cent, and in the ferro-silicon 16.5 per cent. The weight of the slag was greater than the calculated weight.

In order to increase the silicon content quartz of the following composition is added:

	Per cent.
SiO_2	91
FeO	2.6
Al_2O_3	4.10
CaO	0.9

By this means alloys of increasing percentages of silicon can be produced, up to a maximum of 25 per cent.

Still richer alloys were obtained with the same quartz, but substituting for the silicate of iron an ore of the following composition:

	Per cent.		
Ferrous oxide	75.5	Iron	57.3
Silica	9		
Alumina	4		
Lime	0.84		
Manganous oxide	1		
Moisture and losses	9.4		

There were produced 9400 kg. of ferro-silicon. Of a 40 per cent alloy 5400 kg. were manufactured, the following materials being used per 1000 kg.

	Kilograms.
Ore	1,300
Quartz	2,330
Coke	1,000

The yield per kw-hour was 0.143 kg., and per kw-year 1.444 tons.

The electric energy was measured on the high tension connection at the switchboard, so that the pressure at the terminals

on the furnace may be taken as 5 to 8 per cent lower. The year is taken at 8000 working hours.

During these trials slags were obtained rich in silicon, even up to 38 per cent. Assuming again that such a slag was a bisilicate, the silicon by weight would have been

$$4\frac{180}{102} + 0.84\frac{60}{56} + 1\frac{60}{40} = 9.46$$

the slag by weight would have been 15.30, and its chemical composition would be Al_2O_3 = 26.1 per cent, CaO = 5.4 per cent, MgO = 5.5, SiO_2 61.8 per cent. The melting temperature of such a slag is at least 1500° according to Boudouard.

The remarkable quantity of quartz consumed accounts for the refractoriness of the slag. The furnace worked at a high temperature, and there was a noticeable volatilization of the silicon. Another series of results was similarly interpreted by the author. An ore was treated, consisting of the following composition:

	Per cent.
Ferrous oxide	33
Silica	56
Alumina	5
Lime	1

By means of calculations similar to the foregoing it was reckoned that the slag, without making additions, would have the composition, silica = 62 per cent, alumina = 32 per cent, lime = 6 per cent, the melting point of such a slag being above 1600°. The consumption of raw materials was somewhat higher than the theoretical amount. The ore actually contained 25.74 per cent of iron, 26.32 per cent of silicon, of which 4.65 passed into the slag. Hence for every 100 kg of ore there should be produced 25.74 + 21.67 = 47.41 kg of ferro-silicon. That is, for 100 kg of ferro-silicon, the ore consumption should amount to 211 kg, whereas instead it amounted to 356 kg.

From the results tabulated above, the efficiency of the electric furnace may be deduced. The following thermoelectrochemical data constitute the necessary factors:

Energy of dissociation.—(SiO_2) = 180,000 calories = 3,000 calories per kg. of SiO_2:

= 6,384 calories = 7.4 kw. hrs. per kg. of silicon.
(FeO) = 657,000 calories = 1.36 kw. hrs. per kg. of iron.

Heat Units required for Heating.—The melting temperature of anhydrous silica is about 1900°, but for the quartz used containing 91 per cent of silica the melting temperature may be assumed, on account of the impurities, to be not higher than 1800°.

Per kilogram of quartz from 0° to 1,800°, there are required 761 calories (Richards)
Per kilogram of ferrous-oxide from 0° to 1,800°, there are required 887 calories (Richards)

This latter item is based on an analogous calculation made by J. W. Richards.[1]

The mean specific heat of the carbon between 0° and 1800°

$$\frac{120}{1800} = 0.433.$$

is 0.5 —

On the basis of these figures, the energy required for the production of 1 kg of 40 per cent ferro-silicon from ores may be calculated as follows:

Energy of dissociation per 0.40 of a unit of silicon . . . = 0.40 × 7.4 = 2.96 kilowatt hours,
and per 0.60 of a unit of iron . . . = 0.60 × 1.36 = 0.816 "

Total . . . 3.78 "

Heating
Ores . . . 1.3 × 887 = 1,153 calories
Quartz . . 2.33 × 761 = 1,773 "
Coke . . . 1 × 0.433 × 1,800 = 779 "

3,705 "

Less—Coke, with 85 per cent. carbon, burnt to CO, yielding . . . 2,430 × 0.85 = 2,065

1,640 " = 1.9 kilowatt-hours

864

Total kilowatt-hours = 1.9 × 3.78 = 5.68

[1] "Metallurgical Calculations," part I.

The theoretical production per kw-hour is therefore

$$\frac{1}{5.68} = 0.176.$$

The actual production per kw-hour was 0.143.

The efficiency of the furnace, therefore, equals

$$100 \times \frac{0.143}{0.176} = 80 \text{ per cent.}$$

The efficiency of the kw-year, like that of the electric, is, of course, higher, when manufacturing ferro-silicon from quartz and scrap-iron, and the use of ore or scrap is governed by the cost of the raw material and of the electric energy. In Italy, where the cost of the kw-year is generally comparatively low, it is more economical to use ore, and in order to make the question more clear the following calculations relating to the energy necessary to produce 1 kg of 40 per cent ferro-silicon, using scrap, are given for comparison with the preceding figures:

The loss of silicon is assumed to amount to 5 per cent.

Quartz required (SiO_2 90 per cent) = $\frac{0.4 + 0.05}{0.47 \times 0.9}$ = 1 kilogram.

Scrap required (Loss = 10 per cent) = 0.66 kilogram

Energy of dissociation as above = 3.78 kw-hours. Heat units required:

Scrap. 450 calories per kg. = 450 × 0.66 = 297 calories
Quartz. 1 × 761 . . . . . = 761 "
Coke . . . 0.7 × 0.433 × 1,800 . . . . . 545 "

1,603 "

Less—Carbon burnt to CO, yielding 0.85 × 0.7 × 2430 . . . . . = 1,446 "

157 calories = 0.18 kilowatt-hours.

The energy required per kg. of 40 per cent ferro-silicon is therefore 3.78 + 0.18 = 3.96 kw-hours.

The theoretical production per kw-hour = $\frac{1}{3.96} = 0.252$,

and the efficiency of the furnace is 80 per cent.

The actual production = 0.252 × 0.8 = 0.20 kg per kw-hour = 4.8 kg per kw-day.

Hence the consumption of energy in the ore process exceeds that in the scrap process by 1000 (5.69 — 3.96) = 1730 kw-hours per ton of 40 per cent ferro-silicon. The extra cost of this is more than saved in the cheaper raw material, especially with careful attention to the slags and to the temperatures of the thermo-chemical reactions.

With the object of reducing the slag the author has tried to produce ferro-silicon by the partial substitution of pig iron containing 94 per cent of iron for the ore. The raw materials consumed per 1000 units of the product were: ores, 520; quartz, 2200; coke, 540; anthracite, 300. With this mixture some 4000 kg of 42 per cent ferro-silicon were produced. No additions were made, and the output was low on account of the considerable loss of silicon through volatilization.

B. *Ferro-Alloys from Metallurgical Products.*—The greater part of ferro-silicon manufactured in Italy is produced from quartz and scrap iron. The first works in Italy which manufactured ferro-silicon on an industrial scale were those of the Societa Elettrochimica at Bussi. The production in 1907 was 175 tons; in 1908, 808 tons; and in 1909, 606 tons.

In 1909 the Piedmontese Company for the Manufacture of Carbide of Calcium and Allied Products produced 22 tons of ferro-silicon. According to the particulars officially published, the electric furnace for smelting ferro-silicon is absolutely identical with that used for the production of carbide of calcium, and works with the same current at the same pressure.

The author has also experimented in the production of ferro-silicon, using pig iron in place of scrap, the price of which latter material is very high in Italy. The furnace was of the same type as that mentioned in the preceding paragraph. Waste pig iron was used broken to the size of nuts. The mixture con-

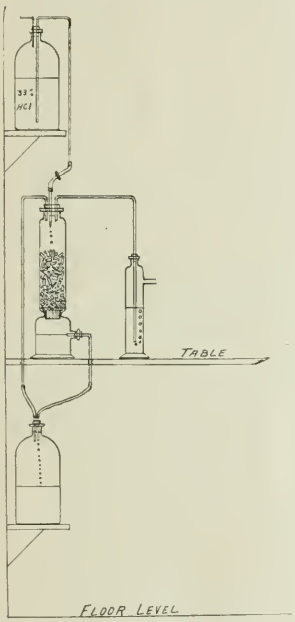
sisted of 1000 parts of pig, 3000 of quartz, and 1300 of coke. The product averaged about 65 per cent of silicon, and the total yield was somewhat under 3 tons. The raw materials used per 1000 kg of product amounted to 620 kg of pig iron, 1775 of quartz, and 810 of coke. The yield corresponded to 2.112 kg of ferro-silicon per kw-day.

Rome, Italy.

Apparatus for Making H_2S.

BY J. R. HUBER.

The accompanying sketch illustrates a convenient and satisfactory method for making H_2S in the laboratory. A Kipp generator, owing to the pressure necessary to hold up the acid when not in use, has a tendency to leak around the stoppers and consequently generates most of the time, being a continual source of annoyance besides wasting acid and iron sulphide.



APPARATUS FOR MAKING H_2S.

Hydrochloric acid, about 1 to 2, is placed in the upper bottle, the syphon filled and the flow of acid adjusted by means of a screw pinch cock. When no more gas is required the pinch cock is screwed up tight. The generation of gas ceases almost immediately.

By using an 18-in. tower the acid trickles over sufficient FeS to be entirely neutralized when it flows out at the bottom. A large cork with several small holes punched through it serves to hold up the FeS and permits the waste acid to flow into the reservoir below.

Two holes are drilled through the table top, one for the tube which carries away the waste acids and the other for a tube connecting the waste acid bottle with the top of the tower. This tube relieves the pressure in the waste acid bottle, permitting it to be tightly corked, thus preventing any odor of the gas from getting out into the room. The other bottle contains pure water for washing the gas, and after it may be placed whatever purifying or drying apparatus is considered necessary for the work in hand.

FeS in fused sticks is the most convenient form to use. The apparatus is best set up in the hood against one of the walls.

Lumen Bearing Co., Buffalo, N. Y.

Electrolytic oxygen is proposed by T. H. Aldrich, Jr., as a means of keeping cyanide solutions in an oxidizing condition. Heretofore we have depended on oxygen dissolved from the air during agitation, or on the addition of salts known to be strong oxidizing agents, for the supply of oxygen in cyanide solutions. Mr. Aldrich has found that if lead electrodes be suspended in the pulp under treatment and a current of 0.25 amp. passed through them an oxidizing condition will be maintained which effectually aids in dissolution of the gold contained in a reducing ore.

Platinum Laboratory Utensils.

At the Minneapolis convention of the American Chemical Society in a session of the Division of Industrial Chemists and Chemical Engineers, a Committee on Quality of Platinum Laboratory Utensils was appointed, which presented a preliminary report at the Indianapolis convention this summer. This committee consisted of Dr. WM. F. HILLEBRAND, of the Bureau of Standards; Dr. PERCY H. WALKER, of the Bureau of Chemistry, and Dr. EUGENE T. ALLEN, of the Geophysical Laboratory of the Carnegie Institution.

The object of the work of the committee was to study the alleged inferiority of platinum ware made in recent years as compared with that procurable many years ago.

The objections made to inferior ware are:

(1) Undue loss of weight on ignition (generally due to a content of iridium and perhaps of base metals of low boiling point).

(2) Undue loss of weight on acid treatment, especially after strong ignition (due essentially to a content of iron and calcium, which are being brought slowly to the surface and there oxidized, so as to give in extreme cases a reddish coating of ferric oxide on one hand and an alkaline reaction on the other).

(3) An unsightly appearance of the surface of the ware after strong ignition, especially in the early stages of heating (sometimes due to volatile impurities, but later caused by crystallization of the platinum, the important question arising whether this crystallization is due to the presence of an impurity).

(4) Adherence of crucibles and dishes to triangles, sometimes to such an extent as to leave an indentation of the vessel at the points of contact with the triangle, even when complete cooling has been reached before the two are separated from each other (possibly due to an inferior quality of the triangle as contrasted with the vessel).

(5) Alkalinity after ignition. (Compare above under 2.)

(6) Blistering, a defect of long standing and of somewhat infrequent occurrence.

(7) Development of cracks after continued heating, a defect "of far too common occurrence."

The committee asked for the co-operation of American manufacturers of platinum ware and received this co-operation by interviews with special representatives of these manufacturers, sent to Washington, and by the supply of platinum ware for the investigation of the committee. These samples were compared among themselves and with foreign-made ware as to behavior on heating, both as regards appearance and stiffness, loss in weight, and tests for iron and alkali. As standards for comparison were taken one crucible from Heraeus, one of his own make, of "Thermoelement" platinum, which is claimed to be free from all impurities, and three of his "Tiegel" platinum, containing, according to the latest information, not over 0.05 per cent iridium and probably less.

The committee in its preliminary reports describes the experiments made as follows:

"Surface Aspect of Ware after Heating.—Leaving out of account the discoloration due to the oxidation of iron, the surface indications shown by ware that has come under the observation of the committee at different times are not easy to describe.

"With good ware the crucible becomes uniformly affected by the blast when this envelops the whole vessel, either taking on a whitish, frosted appearance or becoming uniformly mottled inside and out with crystal plates which do not all reflect the light alike. There is great difference in the size of these plates, to almost microscopic in the case of the frost-like aspect noted from those that are easily apparent to the naked eye. Sometimes, when the plates are large, a decided blue color is imparted to the surface. The crucible of 'Thermoelement'

platinum of Heraeus which was tested showed only the frosted surface, while his 'Tiegel' platinum became in every case coarsely marked. No explanation for this difference has yet been offered, a difference that seems surprising in view of the supposed very slight differences in composition of the two.

"On poor ware the surface becomes more or less whitish, sometimes faintly brownish in places, but the discolorations are not uniformly distributed, and they often impart an unsightly appearance. As a rule, the lower part of the crucible, where it was hottest, remains bright, and from it stretch out more or less fan-shaped areas, the direction of which is affected by that of the flame, i. e., whether this was inclined or applied vertically. The areas often have the appearance of sublimates, such as are often produced from charcoal before the blowpipe. Now and then they have been seen starting sharply from a point. On direct and continued application of the flame their appearance and location may undergo change, and they may even disappear entirely.

"Surface Alkalinity."—Concerning this single phenomenon, which was first observed by Dr. H. C. P. Weber, of the Bureau of Standards, before the committee was organized, little definite information has thus far been gained. When manifest it can be detected by applying moist red litmus paper to the surface of the vessel after it has been blasted for several hours. It has been noted in varying degrees of intensity and is not always apparent. The element producing the alkalinity is calcium. Its sources might be lime from the crucibles used for melting the platinum or a lime salt used in polishing. Opinions as to this were conflicting, and the committee has not yet enough evidence at hand to warrant an expression of opinion of its own. The question is to be tested in part by comparison of ware that has been polished with Vienna lime and that which has not been so treated. What effect, if any, the presence of lime has on the quality of the ware is not known, although the observations of Mylius and Hüttner[1] and of Hillebrand,[2] have direct bearing on this point.

"Iron Content."—Rouge is sometimes used for polishing ware, and steel enters into its manufacture at more than one stage. These may account for a portion of the iron content of all ordinary ware, and for the minute traces that may occur in the specially refined ware, but the evidence all goes to show that the introduction from this source (unless possibly when hot rolling of sheet and hot shaping of utensils are practised) accounts for but a small fraction of the amount actually present.

"The committee has found that the 'Thermoelement' and 'Tiegel' platinum of Heraeus are satisfactory with respect to iron. It is either not detectable after long blasting or gives such a faint reaction as to represent a negligible quantity. One American firm has submitted what is claimed to be its own refined ware, which seems to be with respect to iron the equal of the 'Tiegel' platinum of Heraeus.

So far as the experience of the members of the committee goes, all the ware supplied by the American manufacturers as of their own make during recent years, has been strongly contaminated by iron. Sometimes its amount has been so great as to reveal itself after less than a half hour's exposure to a Bunsen burner flame, by a darkening, even reddening, of the inside of the crucible. More often the color change becomes pronounced only after long blasting. In an extreme case as much as 6 mg. of iron oxide were removed from the surface of a 22-gram dish of German make some years ago by one of the committee members. An amount less than 1 mg. in weight suffices to impart a very dark color to a crucible of 20 cu. cm. capacity. Even when the iron does not reveal itself thus, treatment with pure hydrochloric acid or with alkali pyrosulphate will often do so. Renewed heating will invariably bring more iron to the surface of the platinum if originally present. If the heating is done electrically instead of over a blast flame the color change due to iron oxide appears outside as well as inside the crucible. In one case a few years ago a dark color due to iron oxide was observed on ware from the maker.

"Loss in Weight on Ignition."—Aside from a content of volatile base metals, iridium is supposed to be the volatile constituent of platinum which contributes chiefly to the observed loss of weight on strong ignition. This belief is supported by the experience of the committee.

"The following set of tests on the ordinary commercial ware submitted by one firm is perhaps typical in general for a grade of ware that is supposed (from the statements made to the committee) to carry about 0.05 per cent iridium, but further confirmative tests must be made before final conclusions are reached.

"A crucible, weighing without cover about 16 grams, lost in four hours over a vertical blast 3.4 mg. The temperature inside the crucible and near the bottom was 1180°-1190°C. The rate of loss per hour was 0.85 mg. At 1100° the loss in less than four hours was 1.2 mg., or at the rate of somewhat over 0.3 mg. per hour.

"Another crucible of the same lot, but slightly heavier, suffered a loss over the blast in 3 hours at 1200°-1210° of 2.3 mg. (0.77 mg. per hour) and of 1.9 mg. in addition at 1100° in 4.5 hours (0.42 mg. per hour). The surface of the crucible was very unevenly and strongly frosted, in marked contrast to the crucible of refined metal.

"Other tests by one of the committee, on purchased domestic ware, showed losses of the same order, in some cases fully 1 mg. per hour at or near 1200°.

"Contrasted with these, the 'Tiegel' platinum of Heraeus above referred to shows to decided advantage. A crucible weighing about 16 grams lost in 12 hours (heatings of 4 hours each) 2.3 mg. (0.2 mg. per hour) at temperatures not exactly known but approximating 1200°. At 1100° the loss was 0.9 mg. in 8 hours (0.11 mg. per hour). Another lost at the same rate as the first in 8 hours at 1190°-1210°.

"Marked improvement was shown also by crucibles made of metal specially refined in this country, free from iron, and submitted by one firm, the rate of loss per hour being 0.3 mg. at 1200° in 12 hours, and 0.1 mg. at 1100° in 8 hours. The losses in the several periods of heating at 1200° were irregular, due perhaps to marked variations in atmospheric conditions, causing errors in weighing.

"The crucible of 'Thermoelement' platinum lost in 14 hours at 1200° 2.3 mg. (0.17 mg. per hour), and in 4 hours, at 1100°, 0.2 mg. (0.05 mg. per hour).

"The triangles furnished with the crucibles, and of the same composition, suffered corresponding losses.

"The last test shows that at the temperatures employed and over a blast-lamp even platinum that is claimed to be free from iridium has a perceptible vapor pressure or forms a volatile oxide, and it is also apparent that for chemical use the 'Tiegel' platinum seems to be quite as satisfactory in quality.

"The foregoing data may be summarized as follows:

	Rate loss per hour in mgs.	
	1200°	1100°
Ordinary ware (0.5 (?) per cent Ir.)	0.85	0.3
'Tiegel' platinum	0.2	0.11
'Thermoelement' platinum	0.17	0.05
American refined ware	0.3	0.1

"These data are not to be taken as rigidly exact, but they are probably fairly indicative. It should be remembered that the crucibles were not polished or wiped between the separate heatings.

"From the above and other tests it may be inferred also that there is a sharp rise in the volatility curve for iridium, and apparently for platinum also between the temperatures 1100° and 1200°. This point it is the intention of the committee to investigate further. It is true, it would seem that for temperatures up to 1100° the volatility loss is of little significance with refined

[1] Ztschr. Instrumentenkunde, 30, 190 (1910).
[2] Bull. 422, U. S. Geol. Survey, p. 122.

ware, but that it may be of some moment with ordinary chemical ware low in iridium and free from volatile base metals. At higher temperatures and with long-continued heating, however, the losses are appreciable even with the purest ware and are very high with commercial ware.

"In this connection it is proper to say that in all probability the maximum temperature of the blast used in the above experiments is above that commonly attained in most laboratories. The gas used was artificial. Attention may be called also to the fact that relatively few substances obtained in chemical analysis require blast ignition and that blasting of an hour's duration is seldom necessary, so that in the majority of cases the volatility loss may be ignored.

"Relative Stiffness and Hardness of Ware.—Pure platinum is soft and lacks stiffness. For these reasons it has been common practice to leave a certain amount of iridium in ware made from it or even to add to the amount already present. This addition is especially pronounced in triangles, which may contain 15 to 20 per cent of iridium. The crucibles of 'Tiegel' platinum made up in this country and also those of American-refined metal showed lack of stiffness in a very objectionable degree. In contrast with them was the crucible of 'Thermoelement' platinum which, though not so stiff as the crucibles of commercial ware, was sufficiently so for all practical purposes. The reason for this difference is not yet apparent, but it may be due to the different shape of the crucibles or to a different thickness of the metal. If so the defect mentioned in the American crucibles tested is one that can be easily remedied by the makers.

"Triangles.—In order that no error might be introduced by the use of triangles differing in composition from the crucibles, whereby iridium or other metal might pass from the former to the latter, the makers were asked to furnish with the crucibles triangles of the same composition, and this they did.

"The refined crucibles and triangles were found to stick together badly while hot, owing to the welding property of pure platinum. They could be separated when cool, but often only by the expenditure of some force and with danger of tearing out metal from the crucibles. It is probable that, in order to help maintain as far as possible the purity of a vessel of highly refined platinum, it should not be used in conjunction with a platinum triangle of different quality. Sagging, to a much greater degree than with ordinary triangles that have been some time in use, was not observed. The sticking defect is serious enough to take into consideration with refined ware. Therefore, experiments were made to test the temperatures obtainable inside a crucible with triangles of different materials and shapes. Without entering into details, it may be said that with a vertical blast flame the differences were far less than had been expected between triangles of platinum, of clay and of quartz, so that except for particular uses platinum triangles seem to have little advantage over those of clay or quartz when used under the conditions of the tests. The clay triangles with projecting points on which the crucibles rest allow as high a temperature to be reached in the upper part of the crucible as those of platinum. Quartz triangles when made in one piece are to be had, but the cheaper ones of nickel or 'nichrome' covered with quartz tubing are probably just as serviceable.

"A word of caution may be added here with regard to the use of 'nichrome' in direct contact with platinum. It has not been shown that there is no contamination from this source, and in view of the cost of platinum ware any additional source of contamination is to be guarded against.

"Blistering.—The blistering of crucibles seems to be far less frequent now than it was some years ago. It is probable that this defect resulted from past methods of manufacture rather than from other causes, and the committee has not given experimental attention to the subject.

"Cracking—One manufacturer attributed cracking not to the faulty nature of the ware but to careless handling of magnesium-ammonium phosphate, etc., and to heating with reducing flames. Another treated the ware mechanically to lessen the tendency to crack.

"Extra Cost of Refined Ware.—The refining of platinum to the extent shown by the 'Tiegel' platinum of Heraeus and by the recent product of one of the American manufacturers necessitates a higher charge than we have been accustomed to pay for commercial ware. In the experience of those who have bought the refined ware in this country the extra cost is in the neighborhood of 30 cents per gram. This is a large relative increase, but not excessive in comparison with the advantage gained from having an article that one knows to be free from all objectionable impurities in significant amounts. If platinum can be refined to the extent of removing all or nearly all iron and other base metals without removing all the iridium, the presence of the latter might be no disadvantage when extreme temperatures are not called for. The matter is important, for stiffness is essential to large vessels, and this quality iridium undoubtedly imparts to platinum ware. That iron can be so removed without removing the iridium the following experience of one of the committee at the Bureau of Standards appears to show. For the sake of completeness data not relevant to the point in question are not included.

"Two crucibles, No. 65, bought in 1905, and No. 117, bought from another firm in 1908, but never used before, were first heated electrically at 1250° for several hours. No. 65 showed then no iron, or at most a trace, and lost weight subsequently over the blast at 1100°-1200° at the rate of 0.64 mg. per hour. Crucible No. 117 yielded 1.4 mg. iron oxide after the electrical heating. After cleaning, subsequent blast ignition caused a loss at the rate of 1 mg. per hour for the first 3 hours and of 0.9 mg. for the next 8 hours; the surface became strongly alkaline and showed more iron oxide. From the stiffness of the crucibles and their high loss in weight it is practically certain that both contained iridium, yet the one was free from iron, the other heavily charged. The original source of crucible No. 65 is not known."

The conclusions and recommendations of the committee are as follows:

"Although it were premature to offer anything final in the way of recommendations, the investigation has brought out certain facts and observations which the committee has deemed it wise to lay before the chemists in the foregoing pages without waiting for completion of the inquiry. It is hoped that further tests on domestic and foreign ware and a closer study of the literature will enable it to present a more finished report later.

"It has been shown that ware of foreign make can be had against which nothing can be brought on the score of iron or other base metal content and in which the loss caused by strong blasting seems to be solely of platinum itself and to be entirely negligible, for all ordinary purposes, up to at least 1100°.

"It appears also that American-refined platinum ware can be had of nearly, if not quite, as good quality, and there does not seem to be any reason to think that its quality cannot be still further improved if there is a call for it to be done.

"In order to obtain such ware it is only necessary to *specify that it must show no marked uneven discoloration on heating and must give no test for iron after prolonged ignition (two hours may be regarded as sufficient) and that the rate of loss per hour at 1100° C, over a period of not less than four hours, and preferably longer, shall not exceed, say, 0.2 mg.* The makers are granted a fair margin of safety in this latter item. Ware which does not meet these conditions should not be accepted if the purchaser is willing to pay the enhanced cost of the better ware.

"These specifications are subject to revision."

The Institute of Industrial Research, of Washington, D. C., of which Dr. Allerton S. Cushman is the director, announces the organization and equipment of a Division of Roads and Pavements under the supervision of Mr. Prevost Hubbard, formerly chief chemist in the Office of Public Roads in the Department of Agriculture.

Flow of Heat Through Bodies.

By Carl Hering.

In electric furnaces the economy of the heat losses is of far greater importance than in fuel furnaces, on account of the greater initial cost of the energy. In fact the cost of the energy is in many cases the criterion, hence a mere reduction of the losses may at times make the difference between commercial success or failure. It, therefore, becomes important in such cases to be able to proportion and design the walls of the furnaces so as to reduce these losses to the least that the particular conditions warrant.

To do this intelligently requires a knowledge of the physical laws and constants pertaining to the flow of heat through bodies and from surfaces. The term flow of heat is here used because it is a general one, which refers to all the heat, whether it travels by conduction, convection or by radiation, or any combinations of these; hence it is not necessary to specify the particular way, thereby avoiding ambiguities and errors, such as the very common one of calling the heat conducted through the walls "radiation" losses, instead of conduction losses, even when this heat is taken up by a water jacket, in which case there is no radiation whatsoever.

Although the chief laws concerning the flow of heat are fairly well understood, at least for conduction and radiation, our knowledge of the physical constants is still deplorably meager. The heat conductivities of many materials have been determined, but generally not for the ranges of temperatures occurring in furnaces, and often not for the very materials for which they are needed most in electric furnaces. Moreover, many of them are of questionable accuracy and they are rarely if ever stated in the most convenient way for furnace calculations, nor in the most convenient units. And as for the physical constants for the emission of energy from surfaces to the air, water, etc., including therefore radiation, convection and true conduction (if any), existing data is still more meager, vague and unsatisfactory.

The purpose of the present article is to give a compilation of such physical constants as the writer has been able to gather from various sources, and to present them in the form in which they are most convenient to use by the electric-furnace engineer. The writer does not vouch for their correctness and in fact doubts the accuracy of many of them; he assumes responsibility only for the reduction to the units here used. They are given here merely as a collection of existing data for the benefit of those who wish to use them as they are, and with the hope that such a table will be of sufficient interest to induce others to contribute other data, corrections or more reliable figures.

From the nature of furnace walls it is far simpler to use resistances and resistivities (specific resistances) in the calculations, instead of the older and more common conductances and conductivities (specific conductances). Hence the physical constants have here all been reduced to resistivities, in which form they are not generally given in books.

The units here used are those proposed and recommended by the writer some time ago, as by far the simplest to use in calculations, namely the watt, the centigrade degree and the thermal ohm. The watt (energy per second) is used for the flow of heat in preference to the calorie per second, because all power and energy calculations of the electrical engineer are preferably made in watts and watt-hours (or kilowats and kw-hours), hence this avoids troublesome reductions; moreover, it is an international unit. The centigrade degree is used because it is the more rational scale, is international, and because most thermal data in tables is given in that scale; moreover, it is, in the opinion of the writer, the moral duty of every progressive engineer to do what he can to discourage the use of that senseless, awkward, irrational and unfortunate inheritance, the Fahrenheit scale, which the more progressive nations have abandoned many years ago, if indeed they ever used it.

Lastly, the thermal ohm is used here (for the unit of thermal resistance), because it greatly reduces the calculations, in fact makes them the simplest possible. This new unit was proposed and recommended by the writer about a year ago.* Briefly described, the thermal ohm is that thermal resistance through which 1 watt of heat flow will pass when the temperature drop is one centigrade degree. Hence, if R is the thermal resistance in thermal ohms, H the flow of heat in watts and T the temperature in centigrade degrees,

$$H = T/R$$

which might be termed the thermal Ohm's law.

Moreover, if r is the specific thermal resistance, (resistivity) in thermal ohms per centimeter cube or inch cube, then

$$R = r\,L/S$$

in which L is the length and S the cross section of a thermal conductor, either centimeters or inches being used consistently throughout. This again is like the similar formula for electric resistance. Thermal resistivities, however, seem to have high temperature coefficients and the temperature ranges are great; the resistivities of refractory materials are said to decrease at the higher temperatures; this should be taken into consideration by using the modified value of r for that range of temperature when that data exists, or to allow for it when it is not known.

It will be seen, therefore, that by using these units no conversion factors are necessary, as all coefficients become unity. For the calculations of the electrical engineer the tabulated values of physical constants are therefore best reduced once for all to thermal ohms.

To reduce a thermal conductivity in gram calories per second to the resistivity in thermal ohms, when both are for 1 cm. cube, or for 1 in. cube, multiply the reciprocal of the conductivity by 0.238882. To reduce units in terms of 1 cm. cube to those for 1 in. cube, multiply by 0.393700 when they are resistivities, and by 2.54001 when they are conductivities. To reduce thermal conductivities given in terms of British thermal units (b.t.u. or pound Fahrenheit units) per hour, per square foot surface, per inch thickness, per degree Fahrenheit, to thermal ohm, inch cube units, multiply the reciprocal of that number by 273.013. To reduce gram calories per second to watts, multiply by 4.18617. To reduce a drop of temperature in Fahrenheit degrees to the drop in centigrade degrees, multiply by 5/9. For further reduction factors see the writer's paper above cited, and his Conversion Tables.

The original data for some of the figures in the accompanying table gave the conductivities relatively to silver, water or air, hence required the absolute values of these three materials to reduce them to thermal ohms. For this purpose the conductivity of silver in gram calories per second, centimeter cube units, at ordinary temperatures was taken at 1.0; that for water at room temperatures as 0.0013; and that for air at 0°C. as 0.0000553 (Winkelmann); those for silver and air being the reduction figures recommended and used in the Landolt & Boernstein tables, and that for water being approximately the one there recommended.

Figures concerning such mobile bodies as water and air are reduced here from those given but without any endorsement of the rationality of such data, because with such mobile fluids it would seem that some transfer of heat by convection (bodily movement of the heated material) must have taken place when the figures were determined; and in gases there must have been some radiation also. Even if these other ways of the transmission of heat had been eliminated during the test, they would be present in the practical apparatus to which these figures are applied. Moreover to the writer's knowledge there may be the equivalent of a relatively very high resistance at the surface of contact of a solid and a gas or liquid, hence unless this was eliminated when the determinations were made the results obtained may be far wrong. Hence, in the writer's opinion, fig-

*"Thermal Resistance and Conductance; the Thermal Ohm and Thermal Mho," this journal, Vol. 9, January, 1911, p. 13.

ures for such mobile materials are at best only very crude, if indeed they have much value at all.

A number of values have been included here merely for the sake of comparisons, and because published values of thermal conductivities are sometimes stated relatively to some other material, and if the absolute value of any one of them is known they can all readily be reduced to their absolute values. The writer has constructed furnaces which are virtually cold on the outside, hence low-temperature insulating materials then become available; but in such cases the designer should be cautioned against the dangers of over-insulation, when the material cannot stand a possible increase of temperature.

Another table giving figures for the flow of heat from surfaces will be published in a subsequent article.

The sources of the original data from which these values were deduced are indicated by the letters in the last column, which refer to the notes following the table.

Although the data in this table are arranged to be in the best from for calculations of electric heat, they can also readily be used for steam heat, refrigeration, etc., by first completing the single calculation in terms of the watts flowing through the insulation and then converting those watts into horse-powers, b. t. u. per hour, calories per hour or second, etc., as desired, by means of a single multiplication. Watts × 0.00134111 = horse-powers. Watts × 0.0568776 = b. t. u. per minute. Watts × 0.0143329 = kg-calories per minute.

TABLE OF THERMAL RESISTIVITIES.

APPROXIMATELY IN ORDER OF RESISTIVITY.

Temperatures in Centigrade Degrees.

LB—Landolt & Boernstein tables. The values here chosen are mostly approximate means of the generally numerous and sometimes greatly differing values given by different observers. For the individual values and for the authorities, see those tables. They also include values for very many other materials.

N—Wilhelm Nusselt. *Zeit. Ver. Deut. Eng.*, June, 1908, p. 906, table p. 1006. Materials were placed between two concentric metallic spheres or cubes. Heat generated electrically in interior. Temperature measured with thermo-couples at numerous depths in the material after several days' heating. As here given they represent the resistivities at the temperatures stated, not the means over a range. Probably the best and most reliable determinations published. His conductivities are here assumed to be in terms of kilogram-calories per hour, centigrade, meter cube, units; although not so stated directly in the original, it is undoubtedly

what is meant. An abstract appeared in the *Eng. Digest*, August, 1908, p. 168, in which the units are reduced to thermal units, feet, inches and Fahrenheit degrees; the formula there given omits to say that it is necessary to multiply by the temperature also.

O—Prof. Ordway. *Trans.* Am. Soc. Mech. Eng. Vol. VI, 1884-5, p. 168. Tested in plates 1 in. thick between two flat iron surfaces, one of them heated by steam, the heat emitted by the other being measured calorimetrically. Extended, carefully made researches; presumably very good values. There is an error in the heading in table VII, square inch should read square meter, as in the others.

P—Peclet. Box "Practical Treatise on Heat." Presumably ordinary weather temperatures.

S—H. G. Stott. Power 1902. Pipe coverings. 200 ft. of 2-in. pipe heated electrically to constant temperature. Coverings were somewhat over 1 in. thick; they are here reduced to 1 in. Heat transmitted to air, hence these resistances include that at the surface.

W—Wolff. *Jour. Frank. Inst.*, 1893. The transmission of heat from the interior to the exterior of buildings through the walls; hence ordinary weather temperatures. Prescribed by law by German Government for heating plants. Said to agree well with good American practice. The value here given is an average of all the individual ones, omitting the first one, which differed greatly from all the others.

WF—Wiedemann & Franz; relative values based on silver. Reduced here on the basis that the conductivity of silver is 1.0 in gram calories per second, centigrade, centimeter cube, units.

WQ—Wologdine, Queneau. This journal, September, 1909, p. 383. The temperatures were about 1000° C.; the materials were those of commerce and do not refer to extra pure nor to inferior grades. The present writer is of the opinion, based on the method used in the tests, that these values are probably too low.

Z—Source lost, but probably fairly good values. See this journal, February, 1909, p. 72.

Temperature Coefficient.—Very little data seems to exist on the changes of the thermal resistivity with the temperature. It is generally recognized, however, that thermal insulators decrease in resistivity quite appreciably with increase of temperature. Nusselt, in the researches above cited, paid especial attention to this and finds from his measurements that as a general rule the thermal conductivity of such thermal insulating materials increases at the rate of 1/273 part for every degree centigrade above 0°C. This is of interest also because if this rate continues below 0°C. it means that the curve goes to the absolute zero, which would mean that such materials become absolute thermal insulators at absolute zero (when heat no longer exists.) On the other hand electrical conductors are believed to conduct without resistance at absolute zero.

Iron and Steel Institute.

In our last issue an account was given of the October meeting of the Iron and Steel Institute in London with abstracts of part of the papers. We herewith give abstracts of those papers which had to be omitted in our last issue on account of limitation of space.

Oxy-acetylene Welding.

A paper by Mr. F. Carnevali is entitled "Autogenous Cutting and Welding of Metals." He deals solely with the oxy-acetylene process. The advantages of this process are pointed out and the most important conditions for securing good results are summed up as follows:

1. The use of the purest acetylene obtainable.

2. The use of a blow-pipe so designed as to insure careful adjustment in the proportions of the mixed gases, and to secure their exit at a velocity capable of maintaining the metal sufficiently fluid without the melting flame being too rigid.

3. The provision of an absolutely neutral zone in the melting flame.

4. The use of a pure conducting material of well-defined composition, similar to that of the metal to be melted, in the form of small rods, of such a size as to be rapidly melted without hindering the simultaneous heating of the adjacent parts.

5. Care should be taken that the edges should be free from impurities, and that, whenever possible, they should be arranged at an angle to each other, so as to allow the neutral zone of the flame to penetrate well into the inside, and so completely melt the two surfaces before the extraneous metal is introduced.

6. The use of deoxidizing and fluxing powders for the purpose of eliminating the oxides present, together with the incidental impurities. In view of the unavoidable oxidation of the metal subjected to the melting process, it is necessary to bear in mind the relation between the temperature of the melting points of the oxides and that of the metal itself.

7. Rapidity in melting, in order to avoid excessive heating, which will not only alter and deteriorate the original structure of the metal, but would even favor the occlusion of gas—particularly hydrogen—and so occasion the formation of blow-holes in the melted zone.

In addition to these conditions, care should be taken to see that no sudden cooling should take place owing to any sudden projection of the flame, while, on the other hand, the conditions must, of course, be modified with regard to the conductivity and specific expansion of material as well as with regard to the thickness, size and shape of the pieces operated upon.

In the author's investigations the precautions sketched above were observed and his investigation extended chiefly to the changes in chemical composition and mechanical properties caused by the welding process and to methods of avoiding such changes.

The first two parts of the paper deal with his experiments on the oxy-acetylene method of welding of mild steel and of steels containing medium and high percentages of carbon. While the mild steels and the higher carbon steels are discussed under separate chapters, the results for both classes of steels are summed up together as follows:

1. The violent heating and the sudden melting undergone by the metal alter profoundly its quality. This alteration becomes specially manifest by an internal strain of the metal, meaning by this word an injurious modification of the metal's mechanical properties, caused by the thermal and mechanical phenomena, owing to the high temperature of the process, as the stress and hardness tests show, although uninfluenced by modifications in the chemical composition of the steel. The absence of deformation in the single structural constituents in stress tests is a further confirmation.

2. The alteration in the mechanical qualities (tenacity and elasticity) cannot be remedied by simple hammering on the molten zone—which often proves to be most injurious to high-carbon steels—but must be coupled by proper thermal treatment, such as annealing, which is so much more efficient when prolonged over a sufficient time (30 or 40 minutes), so that the interior stress can be nearly wholly eliminated. Further, the other thermal processes (quenching, etc.) have the greatest influence on high-carbon steels.

3. A remarkable influence on the mechanical properties (more especially of the later steels) is to be attributed to cooling processes, the slowest cooling being the best and most effective.

4. Apart from the alteration in mechanical properties (the principal of which is the change in the elongation), very important modifications take place in the chemical constitution, especially in high-carbon steels. These changes consist chiefly in the diminution in the percentage of carbon, silicon, and manganese. Such variations, which are proportional to the percentages originally present in the steel, are, it is very easy to understand, caused by the strong oxidizing influence to which the metal is subject during the melting, and become modified by the different methods employed in this process. It is easy to remedy this defect by using as a cementing material a steel of analogous composition to the pieces intended for welding, but containing higher percentages of the more easily oxidized elements.

5. The mechanical properties are, owing to the short duration of the process, only slightly altered when, instead of the fusion process, a simple heating with the flame is substituted, as is easy to foresee. As the metal during the melting is subjected to a strong internal stress, with every increase in the depth of the fused portion, the efficiency of the remedial heat treatment, undergone after the melting, rapidly decreases.

The author then investigated the oxy-acetylene welding method of **pig iron**, the experiments being limited to grey varieties.

The results for pig iron are summed up as follows:

1. The rapid melting and cooling of the pig iron subjected to the oxy-acetylene process cause, as might have been foreseen, a fine compact structure in the zone of fusion.

2. Owing to the high temperature and to the energetic conditions of heating which take place during the process of welding, a composition of the pig iron (and therefore, of its internal structure as well) undergoes considerable modification, chiefly owing to the loss in carbon and silicon (both of which strongly influence the structure of the metal). This loss, of course, varies with the different melting processes employed. An easy method for partly remedying this loss is to employ an appropriate cementing material which will supply the elements eliminated by oxidation.

3. The mechanical properties of the metal are not greatly influenced by oxy-acetylene welding, when properly carried out. The internal stress suffered by the metal confers great hardness on the zone of fusion, as shown by the Brinell tests. The brittleness tests, although they reveal the good quality and homogeneity of the metal, do not appear to be affected by the slight variations due to the melting of the metal.

4. The heat treatment and the cooling conditions, though they exert considerable influence on pig iron subjected to the process, do not appreciably modify the mechanical properties, and are of interest only when it becomes necessary to take into consideration the dilatation of the metal in relation to its low thermo-conductivity in the welding of special engine parts in which the physical properties are of great importance.

Phosphates in Basic Slag.

A paper by Mr. VICTOR ADOLPH KROLL, of Luxemburg, gives a detailed account of the author's extended "Researches on the nature of the phosphates contained in basic slag derived from the Thomas-Gilchrist (basic Bessemer) dephosphorization process." It is a very long paper accompanied by analytical tables and some fine microphotographs.

The annual production of basic slag is about 2,600,000 tons. Th slag contains nearly one-fifth of its weight of phosphoric acid, combined in a peculiar form the exact nature of which has hitherto defied the closest investigations.

After a very complete and careful history of former investigations on this subject, the author gives an account of his own researches. He distinguishes the following phosphates in basic slag.

First, "carnotite," discovered by Carnot, the typical silico-phosphate, in form of flat prisms, probably belonging to the monoclinic system, or in form of prismatic crystals as slender needles; the formula of carnotite is

$$(3\ CaO,\ P_2O_5;\ 2\ CaO,\ SiO_2)_3$$

Second, "hilgenstockite," the tetraphosphate of Hilgenstock, in the form of yellowish flattened prisms, with the formula

$$(3\ CaO,\ P_2O_5;\ CaO)_3$$

Third, "steadite," the silico-phosphate of Stead and Ridsdale with the formula

$$3\ [(CaO)_3,\ P_2O_5]:\ 2\ (CaO),\ 1\ (CaO)_2,\ SiO_2$$

This salt is therefore neither tribasic nor tetrabasic, but intermediate between the basicity of the two, and shows by its constitution that in all these slag phosphates it is not the basicity which counts, but the sum total of the foreign salts and bases linked up with the orthophosphate molecule.

"The silico-phosphate, which only contains tribasic acid, is perfectly equivalent to the tetraphosphate, because it is not the addition of a base, and a base alone, which confers a special constitution on a phosphate, but it is to a much greater extent the addition of a neutral silicate which produces the new and sufficiently stable molecule while preserving absolutely the same nature as the basic salt in which the silicate is found badly enough replaced by lime."

The theoretical part played by the tetraphosphate vanishes before that played by the neutral silico-phosphate, the apparent part played by the higher basicity being nothing more than a mere error of observation.

This composition of steadite assures to it considerably more influence in the liquid slag than its predecessors possessed. As a matter of fact, the slag in practice seldom reaches the percentage of silica and of lime corresponding to the ratio $5CaO, P_2O_5; SiO_2$, which is peculiar to carnotite, nor yet to so small a percentage of silica as to yield simultaneously hilgenstockite in the solution. Artificial enrichment accompanied by synthetical chemical reactions is therefore necessary in order to form these two constituents, and it is the selective crystallographic action occasioned by slow cooling which causes this phenomenon.

On the other hand, the composition of steadite more closely approaches that of the ratios found in the slag, and it is formed preferentially when the percentage of the latter in silica is not sufficient to give rise preferentially to more acid compounds, nor the cooling sufficiently slow to afford the crystallization a choice of selection as to the form it will take on assuming the solid state.

The main object of the author's researches, however, was to find a fourth phosphate in basic slag, intermediate between steadite and carnotite, the presence of which was sought for on the grounds of theoretical deductions. It is called "thomasite" and was found in all the slags collected from different districts.

"Thomasite" is nearly always found in the form of homogeneous cryptocrystalline masses, which may occasion difficulties in its identification. The reason is that it forms the mother-mass of the slag itself, and all the substances previously described are nearly always the products of selective crystalline decomposition, which occurs during slow cooling in the heart of an originally homogeneous mass of thomasite.

As slow cooling is just the condition necessary for obtaining fine crystals, a well-crystallized mother-mass is less frequently encountered than the products of its decomposition, which are always sought toward the center of the blocks of slag, whereas the main phosphoric mass is altogether cryptocrystalline, and is passed over unnoticed by those who are seeking to find crystals.

It is indeed its character of a mother-mass which has led to its escaping the notice of those who are in search of crystals. On a closer search, however, it can be found in all basic slags no matter what their source, and it will then be seen that it forms a very considerable cluster, out of which appear, in favorable localities, little crystals of greenish-blue color.

Thomasite is a silico-phosphate and a double salt of lime and of ferrous oxide. The formula given by the author for thomasite is

$$6\ CaO,\ P_2O_5;\ 2\ FeO,\ SiO_2$$

The phosphate in this is hexabasic, and therefore intermediate between the tetraphosphate and the octobasic salt. The reasons for speaking of hexaphosphates are discussed at considerable length.

Italy.

In view of the original intention of the Institute to hold the meeting at Turin, Italy, and to combine with it visits to the principal centers of the iron and steel industry of Italy, a large number of the papers prepared for the meeting deal with the present status of the Italian iron and steel industry.

A paper by Mr. CATANI, giving an interesting sketch of the present developments in the electrometallurgy of iron and steel in Italy, is published in full elsewhere in this issue.

A paper by D. DOMPE, of Milan, and Mr. F. S. PUCCI, of Milan, deals with "the present state of the metallurgical industry of Italy." The first part, by Mr. Dompe, gives statistical data on the production of pig iron, wrought iron, and steel, and brief descriptions of the principal works and their equipment. The second part, by Mr. Pucci, discusses the further treatment of the iron and steel and its manufacture into various products, a list of the different plants being given in a geographical arrangement according to provinces of Italy.

A paper by Mr. A. Ciampi, of Florence, deals with the iron ore deposits of Central Italy; a page by Prof. G. La Valle, of Rome, with the iron ore deposits of southern Italy and Sicily; a paper by Mr. L. Testa, of Igkesias, with the iron ore deposits of Sardinia, and a paper by Cavalier G. Calvi with the production of iron ores in the Brembana Valley.

Finally a paper by Dr. L. Leigh Fermor, of Calcutta, is to be mentioned which discusses the origin of the iron ores of Swedish Lapland.

A Continuous Carbon Dioxide and Temperature Recorder and Its Application to Combustion Efficiency *

By Ed. A. Uehling.

After the possibility to utilize the pressure of steam as a motive force had become fully recognized, the first problem was to construct a practical machine through which the heat energy stored in steam under pressure could be converted into mechanical motion. In the solution of this problem the plain slide-valve engine was evolved. With the advance of the mechanic arts this type of engine was improved in power and effectiveness.

Meanwhile improvements in the construction of the steam boiler had made higher steam pressures possible. To utilize the greater expansive force thus made available the automatic cut-off was invented, compounding was resorted to, and by adding the condenser the expansive force of steam was utilized to the practical limit. By virtue of these strides in the progress of steam engineering the consumption of steam per horse-power hour was reduced from an average of 35-40 lb. down to 12-15 lb. For a while it seemed much more could not be expected.

Then came the steam turbine. Its rapid development in the direction of high-power units caused a revolution in the application of steam as the motive force in generating electricity, and is making heavy inroads on the domain of the reciprocating steam engine in the propulsion of ships.

Compactness of construction, directness of action, avoidance of all reciprocating strains, absence of large rubbing surfaces, elimination of lubricating oil in contact with the steam, absence of cylinder condensation, are all points of superiority of the steam turbine as a prime mover.

In the direction of economy the turbine is not superior to the highest type of reciprocating engine; it excels, however, in utilizing the lower ranges of the expansive force in steam, and by combining the high-pressure reciprocating engine with the low-pressure turbine a steam consumption of 10 to 12 lb. per horse-power hour is being practically achieved.

Hand in hand with the progress in the engine room went of necessity improvements in the boiler room. In the direction of fuel economy we early find the feed-water heater and later the economizer. Every effort was directed toward increased capacity and higher steam pressure; this necessitated increased strength and resulted in the development of the water-tube boiler.

In the direction of mechanical equipment wonderful strides have been made in the past two decades. Mechanical stokers, forced-draft automatic coal and ash-handling machinery, etc. are now found in the boiler houses of all the larger up-to-date power plants. All these vast improvements in the development of the application of steam power have been accomplished by the mechanical engineer with the aid of the physicist and metallurgist, but without the direct assistance of the chemist.

This is deplorable and accounts for the fact that in utilizing the steam, which is a physical and mechanical problem, an economy of 60 to 70 per cent has been achieved, whereas the generation of the steam, which is a fundamental chemical problem, nothing worth mentioning has been gained in the past generation, 30 to 40 per cent of the heat energy stored in the coal still passing up the chimney, due mostly to lack of control of the process of combustion.

The possibilities in this direction have been shown by the brilliant investigations of Professor Bone; but while we may readily concede that surface combustion may ultimately prevail, we must not for that reason relax in our efforts to improve existing methods, and this can be accomplished only by the aid of the chemist.

I venture to say that in this country to-day, not one in a hundred of the managers, engineers or superintendents of steam-power plants knows the composition of the coal he is burning, not one in ten knows its contents of fixed carbon, volatile matter, ash, and moisture. Not in one plant out of a hundred are the products of combustion systematically sampled and analyzed. Yet in the composition of the flue gas lies the key to fuel economy.

Of the heat generated from the coal burned in the average steam plant less than 70 per cent, and in many cases not even 60 per cent is transmitted to the water in the boiler; the bulk of the balance is carried off by the product's combustion. To reduce this loss to a minimum we must know its cause, and this can be determined only from having a complete knowledge of the chemical composition as well as the physical character of the fuel used, and a continuous control over the process of combustion.

I lay special stress on the continuity of control over the process of combustion, because the conditions are continully changing, not only from day to day, and from hour to hour, but from minute to minute. Changes in atmospheric condition as to pressure, temperature, and humidity; changes in the physical structure of the coal as to preponderance of lumps or fines; changes in the condition of the fire, due to accumulation of ashes, formation of clinker, etc., and, last but not least, changes in the rate of combustion necessary because of variable steam consumption.

The best results are obtained by securing complete combustion with a minimum excess of air, and since there is true relation between the per cent of CO_2 in the flue gas to the excess of air supplied we have in this constituent an index to efficient firing. If, therefore, the per cent of CO_2 be continuously revealed to the fireman it will serve as a guide and enable him to control his fire so as to obtain the most economical results.

If we know the composition of the fuel the loss of sensible heat up the chimney can be readily calculated from the stack temperature and the per cent of CO_2 contained in the flue gas. By basing the calculation on a unit weight of the total carbon contained in the fuel the formula for computing the waste heat from combustion become very simple.

A number of instruments have been devised which automatically sample and analyze the flue gas and record the per cent of CO_2 it contains at short intervals. There is also one which does this continuously and at the same time continuously indicates the per cent of CO_2 at or near the boiler front where the fireman can see it without leaving his post, and I have been honored with the privilege to bring this instrument to your attention to-night. (See the article on p. 681 in this issue.)

Formulæ for Determining the Heat Carried Off by the Flue Gases.

NOTATION.

A = weight of air supplied in burning 1 lb. of carbon.
Ac = " " " required to burn 1 lb. of carbon.
Ah = " " " " " the available hydrogen per pound of carbon.
Ae = weight of air supplied in excess of that required to burn a weight of fuel containing 1 lb. of carbon.
An = weight of dry gas contained in the flue gas per lb. of carbon burned.
Av = weight of water vapor in atmosphere per lb. of air supplied.

* A paper presented at the joint meeting of the New York Sections of the American Chemical Society, the American Electrochemical Society, and the Society of Chemical Industry, on November 10.

Ov = weight of volatile oxygen contained in fuel per lb. of carbon.

Ht = weight of total hydrogen contained in dry fuel per lb. of carbon.

$Ha = Ht - \frac{Ov}{8}$ = weight of available hydrogen in fuel per lb. of carbon.

$Wh = 9/8\ Ov$ = water of hydration in fuel per lb. of carbon.

Wm = weight of water (moisture) in fuel per lb. of carbon.

P = per cent of CO_2 contained in flue gas.

Pc = " " CO " " " "

L = B.t.u. loss due to sensible heat in flue gas per lb. of carbon when burned with dry air.

Lc = B.t.u. loss due to fuel value of CO contained in flue gas per lb. of carbon burned.

Lv = B.t.u. loss due to moisture in air supplied per lb. of carbon burned.

Lh = B.t.u. loss due to water of hydration in fuel per lb. of carbon burned.

Lm = B.t.u. loss due to moisture in fuel per lb. of carbon burned.

T = temperature of flue gas on leaving the boiler.

t = temperature of air in boiler house.

$S = 0.23$ = specific heat of flue gas.

$Sw = 0.48$ = specific heat of water vapor.

Pure air contains	by weight	by volume
Oxygen	23	21
Nitrogen	77	79

One cu. ft. of air at 62 deg. F. weighs .0761 lb.

" " " " nitrogen at 62 deg. F. weighs .0738 lb.

Complete Combustion of Carbon with Theoretical Amount of Air.

One lb. of carbon requires for complete combustion $Ac = 11.6$ lb. of dry air, which measures 152 cu. ft. at 62 deg. F. The products of complete combustion of 1 lb. of carbon, with the theoretically required amount of air, will weigh $Ac + 1 = 12.6$ lb. Hence the loss of heat up the chimney will be:

$$L = 12.6\,(T - t)\,S \qquad (1a)$$

Substituting the value of S

$$L = 2.9\,(T - t) \qquad (1)$$

Complete Combustion of Carbon with an Excess of Air.

Air is composed of 21 per cent of O_2 and 79 per cent of N; hence, according to Avogadro's law, 21 per cent of CO_2 is the maximum obtainable.

When carbon is burned with an excess of air (Ae), which by volume equals $\frac{Ae}{0.0761}$ cu. ft., then

$$P = \frac{152 \times 21}{152 + \frac{Ae}{0.0761}}$$

from which we get $Ae = \frac{21 \times 11.6}{P} - 11.6$

The total weight of air $A = Ac + Ae$. Substituting the values of Ac and Ae we have

$$A = \frac{21 \times 11.6}{P}$$

$$L = (1 + A) \times (T - t)\,S \qquad (2a)$$

Substituting the values for A and S and reducing to the lowest terms we have

$$L = \left(0.23 + \frac{56}{P}\right) \times (T - t)$$

Calculation of Heat Lost in the Flue Gas When Hydrogen Forms an Appreciable Part of the Fuel.

In the chemical reaction which constitutes the combustion of hydrogen, 8 lb. of oxygen and 1 lb. of hydrogen unite to form 9 lb. of water vapor. This requires 34.8 lb. of air and results in 35.8 lb. of combustion product. In commercial flue-gas analyses no account is taken of the moisture, hence only the nitrogen derived from the combustion of hydrogen effects the analytical result. The burning of 1 lb. of hydrogen with the theoretically required volume of air therefore results in 26.8 lb. of N_2 by analyses.

Hence if fuel consisting of carbon and hydrogen is burned with the theoretically required air,

we have $P = \frac{11.6 \times 21}{11.6 + 26.8\,Ha}$

if excess air is used

we have $P = \frac{11.6 \times 21}{11.6 + 26.8\,Ha + Ac}$

from which we get

$$Ac = \frac{11.6 \times 21}{P} - 11.6 - 26.8\,Ha$$

$$An = Ac + 0.77\,Ah + Ac$$

Substituting and reducing

we have $An = \frac{11.6 \times 21}{P}$

$$L = (An + 1) \times (T - t)\,S + 9\,Ha\,(T - t)\,Sw \qquad (3a)$$

Substituting the values of An, S and Sw and reducing

we have $L = \left(\frac{56}{P} + 0.23 + 4.3\,Ha\right) \times T - t \qquad (3)$

Loss Due CO in Products of Combustion.

When the per cent of CO (Pc) is known, the heat loss due to its presence (Lc) is easily determined. The weight of carbon in a molecule of CO_2 is the same as in a molecule of CO_2 and it follows from Avogadro's law that the weight of carbon burned to CO is to that burned to CO_2 as the per cent of CO is to the per cent of CO_2 contained in the combustion products.

Thus, letter X = the weight of carbon burned to CO,

we have $\frac{X}{1 - X} = \frac{Pc}{P}$ from which we get $X = \frac{Pc}{P + Pc}$ = carbon burned to CO per unit of carbon contained in the fuel. Since CO burned to CO_2 per unit of carbon develops 10,150 B. t. u.

we have $Lc = 10{,}150 \times \frac{Pc}{P + Pc} \qquad (4)$

Loss Due to Water Vapor in the Air.

Atmospheric moisture exerts a chilling effect on the fire because of its high specific heat and because at least part of it will be decomposed. But since under normal conditions the hydrogen which was set free by decomposition will reunite with the oxygen from the air in the combustion chamber and will evolve as much heat there as was absorbed in the fuel bed in setting it free, there results no heat loss due to this double reaction. It will be necessary, therefore, to consider only the sensible heat carried off by moisture contained in the air, hence

$$Lv = Av \times (An + 0.23\,Ah)\,Sw \times (T - t) \qquad (5a)$$

Substituting and reducing we have

$$Lv = Av\ \left(\frac{117}{P} + 0.88\,Ha\right) \times (T - t) \qquad (5)$$

All natural solid fuels contain water in two forms; moisture (Wm), i. e. water which can be driven off by drying at about 212 deg.; and water of hydration (Wh), which passes off at much higher temperature with the volatile combustible matter, the estimation of which is ordinarily but wrongly included in the volatile combustable matter.

Loss Due to Water Hydration.

If we know the weight of oxygen contained in a given fuel per lb. of carbon get the water of hydration.

$$W'h = 9/8\ Ov$$

Hence $Lh = 1.125\ Ov \times (T - t)\ Sw$ (6a)

Substituting the value of Sw

we have $Lh = 0.54\ Ov \times (T - t)$ (6)

Loss Due to Moisture.

Moisture in fuel ($W'm$) exists as water, which must first be raised to 212 deg., then evaporated, the vapor passing off at the temperature of the flue gas.

Hence $Lm = W'm\ (212 - t) + 966 + (T - 212)\ Sw$ (7a)

Substituting the value of Sw and reducing

we get $Lm = W'm\ [(0.48\ T) + (1076 - t)]$ (7)

Recapitulation.

(1) Heat in B.t.u. carried off by the products of combustion per lb. of carbon burned when there is no excess of air.

$$L = 2.9\ (T - t) \quad (1)$$

(2) Heat in B.t.u. carried off by the products of combustion per lb. of carbon burned with an excess of dry air.

$$L = \left(\frac{56}{P} + 0.23\right) \times (T - t) \quad (2)$$

(3) Heat in B.t.u. carried off by the products of combustion per lb. of carbon when fuel containing hydrogen is burned with an excess of dry air.

$$L'' = \left(\frac{56}{P} + 0.23 + 4.3\ Ha\right) \times (T - t) \quad (3)$$

(4) Heat value in B.t.u. carried off by the products of combustion containing CO per lb. of carbon burned.

$$Lc = 10150 \frac{Pc}{P + Pc} \quad (4)$$

(5) Heat in B.t.u. carried off by the products of combustion due to water vapor in the air supplied in burning a weight of fuel containing 1 lb. of carbon.

$$Lv = Av' \left(\frac{117}{P} + 0.88\ Ha\right) \times (T - t) \quad (5)$$

(6) Heat in B.t.u. carried off by the products of combustion per lb. of carbon due to water of hydration in the fuel.

$$Lh = 0.54\ Ov \times (T - t) \quad (6)$$

(7) Heat in B.t.u. carried off by the products of combustion due to moisture contained in the fuel, per lb. of carbon.

$$Lm = W'm\ (0.48\ T + 1076 - t) \quad (7)$$

These formulæ show clearly that the heat wasted up the chimney depends on two factors, the per cent of CO_2 and the temperature of the flue gas. The per cent of CO_2 in the flue gas is an index to the efficiency of the boiler as a heat generator and the temperature is an index to its efficiency as a heat absorber.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

The Turin Exhibition.

Your correspondent spent a week in Turin early in September, naturally giving much of the time to the International Exhibition there. There was very much to be seen that was praiseworthy. For one thing the popular sideshows which exasperate the serious visitor were at a minimum.

The general engineering exhibits were decidedly interesting. Of outstanding interest in the frontier between the spheres of engineering and chemistry was the excellent French exhibit of electric furnaces. The American exhibits failed to do justice to American potentialities, and no single section in the United States pavilion was really representative. Metallurgically the British display was worse, and the German display was quite indifferent.

In regard to pure chemistry a special feature of the whole exhibition was the British display, organized by the Board of Trade, of a completely equipped laboratory with apparatus and reagents for both commercial routine testing and for special research. Next to this was a first-class electro-physical laboratory organized by the National Physical Laboratory.

This is not the place to write of the display in such industrial arts as weaving, spinning ceramics or automobiles, where the dispaly was decidedly good. On the electrical side there was a very fine display of heavy generating plant, single-phase railway equipment and extra high-tension overhead material.

The British Industrial Outlook.

Since I wrote my letter at the end of August there has been a decided improvement in the outlook. The Royal Commission on the Railway Strike has reported fully and impartially; the extreme trades union element is, of course, dissatisfied, but the more responsible among their leaders are trying to smooth down the trouble. The South Wales coal area is unsettled, and the neighboring copper works have had trouble. There are, too, still threats of a big coal strike in the north.

Irresponsible socialist extremists are preaching a combined railway and coal strike, which the great mass of the general public, artizan as well as middle-class, will not stand.

The Government efforts to rush through their industrial insurance bill making provision for sickness, and also in certain trades for unemployment, are disturbing to some of their usual supporters. The reason at the root of their action is probably not so much to clear the way for other legislation next year as to discount the force of the Socialist agitation. Disturbed supporters are, however, fearful of the fruits of hurried legislation.

Taking things all round the outlook is better than a month ago, trade conditions are good, and engineering works are now being hampered by that inevitable concomitant of a trade boom, the difficulty of getting the raw materials.

The general confidence is strong, although the European situation still has potentialities of international trouble. Morocco is almost settled, but the Turco-Italian trouble may spread to the Ægean Sea or the Balkans. Assuming the best rather than the worst, economists can then give their attention, and educate an intelligent public attention, to the inter-action of scarcity in food stuffs, heavy gold production and the decreased purchasing power of gold.

Engineering Imports and Exports.

The Board of Trade returns for the nine months ended Sept. 30 give the value of imports of iron and steel including manufactures, as £8,201,274, with exports £31,851,601; showing an increase in imports of £1,692,389, and a decrease in exports of £83,303 as compared with the corresponding period of last year. For other metals, including manufactures, the imports were £20,730,879 and exports £8,024,961, the respective increases being £3,136,716 and £398,697.

Imports of electrical goods reached £1,012,643, and exports £1,990,852—a decrease in imports of £142,936 and a decrease in exports of £1,043,873. Imports of machinery were £4,411,648 and exports £22,535,942; showing increases of £1,068,346 and £1,001,425 respectively. Imports of new ships amounted to £60,916, with exports £4,039,482—an increase in imports of £38,581, and a decline in exports of £3,535,579.

The effect of the recent labor troubles is shown by the fact that the returns for the month of September show considerable decreases in the exports of all these classes of goods except non-ferrous metals which increased by £10,810. The decreases are: Iron and steel, £301,337; electrical goods, £222,357; machinery, £350,799; and ships £186,080. Imports of iron and steel increased by £77,025; non-ferrous metals by £435,176, and machinery by £82,331; but imports of electrical goods were lower by £53,532, and the value of imported ships declined £482.

Market Prices in October, 1911.

Copper has been rather dull. Commencing at £55, it had dropped by the 10th to £54-5-0, and, after a short rise, to £56, again dropped and finished £55-5-0.

Tin has been, on the whole, going up. Commencing at £182.0-0 it rose in two jerks to £188-10-0 by the 10th, dropping again to £183-5-0 by the 12th. It then rose to £192 (20th) and closes at £186-15-0.

Lead has been steadily appreciating, with very slight dip on the 10th. Opened at £15-5-0 and closes at £15-15-0.

Hæmatite opened at 61/6, dropped sharply on the 11th, reaching 60/3 on the 12th, then rose to 61/-, and closes at 60/9.

Scotch Pig has been fairly steady, fluctuating only from 52/- to 52/4½. Closes at 52/3.

Cleveland has been moving slightly in sympathy with Scotch Pig. Opened at 46/-, closes at 46/2.

India-rubber has been rather on the decline, opening at 4/7, holding at 4/5½ in mid-month, dropping to 4/3 by the 25th, and closing at 4/3.

Recent Chemical and Metallurgical Patents

Iron and Steel.

Combined Open-Hearth and Electric Furnace for Steel Refining.—The interest taken by the United States Steel Corporation in electric steel refining is further evidenced by a patent of Mr. WM. R. WALKER and Mr. JAMES H. GRAY. Instead of refining steel first in an open-hearth and then transferring it in molten condition to an electric furnace for further treatment, they carry out the whole operation in one and the same furnace, which is first used as open-hearth and then as electric furnace, thus eliminating any transfer of molten metal. (A furnace of this type was in use a year or so ago in Homestead, but none of the results obtained have so far become available for publication.) The furnace has the form of an ordinary open-hearth furnace and is first used as such, silicon, carbon and phosphorus being eliminated by means of an oxidizing slag. This slag is then removed and a fresh basic slag is supplied, while simultaneously electrodes are introduced into the furnace from the top. The electric-furnace treatment now begins and in its non-oxidizing atmosphere the steel is desulphurized and deoxidized. During this second electrical stage of the process, the regenerative chambers are cut off from the main heating chamber. (1,000,217, Aug. 8, 1911.)

Titanium Treatment of Steel.—A patent of Mr. AUGUSTE J. ROSSI, of the Titanium Alloy Manufacturing Company, refers to the treatment of steel with ferro-titanium, only such a quantity of titanium being used as is required to combine with the undesired compounds and elements, and to secure a final product containing substantially no titanium. The object is to procure a close grained, dense structure, without blowholes or cavities. The method is applicable in the crucible, converter and open-hearth steel processes for castings, and in the production of ferro-alloys. (1,003,805, Sept. 19, 1911.)

Electrolytic Refining of Iron.—For the electrolytic production of pure iron, free from carbon, from impure iron, like cast or wrought iron scrap, cast iron turnings or borings, etc., Mr. ALEXANDER S. RAMAGE, of Buffalo, N. Y., uses the process sketched in Fig. 1. The electrolytic cell 1 is divided by a diaphragm 2 of asbestos cloth into anode and cathode compartments 3 and 4. The anodes 5 are of sheet lead, the cathodes 6 of iron. When a solution of ferrous sulphate is electrolyzed in both compartments, iron is deposited on the cathodes, while ferric sulphate and sulphuric acid are formed at the anode. From the anode compartment the acid liquor is passed into the scrubber 7, where it is subjected to the action of a small proportion of sulphur dioxide. (Only enough sulphur dioxide

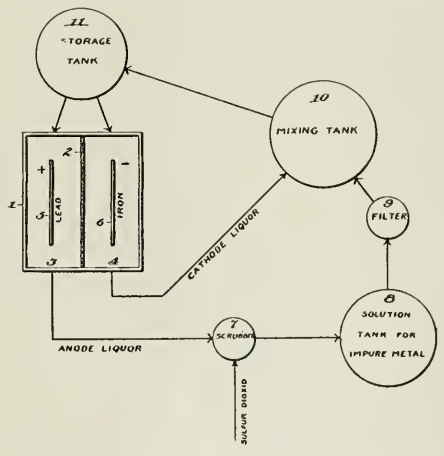

FIG. 1.—ELECTROLYTIC REFINING OF IRON

is used to form sufficient sulphuric acid to replace that lost by leakage, but not so much as to effect the reduction of the ferric sulphate to ferrous sulphate.) The acid liquor then passes to solution tank 8, where it is brought in contact with the impure iron to be refined (scrap, etc.), together with ferrous sulphide, which under the action of the acid liquor generates hydrogen sulphide. Under these conditions there occurs a complete pre-

ciptation of those metals whose sulphides are insoluble in dilute acids. To aid the solution of the iron, heat is employed, and the solution tank is also fitted with an insoluble anode buried in the scrap and with an iron cathode in the liquor above the scrap, so as to aid in the solution of the scrap iron and diffuse the hydrogen throughout the solution. The hydrogen and the sulphuretted hydrogen resulting from the solution of the ferrous sulphide effect the reduction of the ferric sulphate to ferrous sulphate. When the liquor has become practically neutral, it is forced through a filter press 9, flowing thence to a mixing tank 10, where it is mixed with the effluent liquor from the cathode compartments. The mixed liquor flows to a storage tank 11, whence it is distributed to the several anode and cathode compartments of the electrolytic cells, thus completing the cycle of operations. The preferred temperature during electrolysis is 145 deg. Fahr., a suitable current density is 10 amp. per square foot, the voltage approximating 2.5 volts per cell. With revolving cathodes current densities approximating 100 amp. per square foot may be used, with a correspondingly increased voltage. The chief feature of the process is that it avoids the solution of such metals as are liable to contaminate the electro-deposited iron, notably carbon and certain metals, such as arsenic and antimony, whose sulphides are insoluble in dilute acid solutions. (1,007,388, Oct. 31, 1911.)

Steel for Armorplates.—A low-carbon steel for armor plates and gun tubes is patented by Mr. Wm. Beardmore, of Glasgow, Scotland. In addition to the usual ferrite, it contains a percentage of carbon, not exceeding 0.25, and molybdenum and nickel in proportions sufficient to compensate for the deficiency in the strength and toughness of the steel due to the low percentage of carbon. The composition is 0.15 to 0.25 per cent C, 1 to 2 per cent Mo, 5 to 7 per cent Ni, further not over 3 per cent W, and not over 0.7 per cent Mn. This steel does not sufficiently harden by mere quenching when hot. It must be subjected to a process of cementation. By suitably regulating the degree and extent of differential hardening treatment to which the steel plates are subjected, it is possible to secure great hardness in some parts while retaining at other parts a ductile and tough condition. "In the case of armor plates the qualities possessed by the steel enable them after cementation to resist the penetration of modern capped projectiles and at the same time to resist the racking action of the projectiles, particularly in the case of plates of less thickness than the caliber of the guns used in attacking them. In the case of steel for gun tubes, an increased resistance to bursting or cracking of the tube by the shock of discharge is obtained. (1,007,055, Oct. 31, 1911.)

Treatment of Iron and Steel to Prevent Rusting.—Mr. Thomas Watts Coslett, of Birmingham, England, proposes to prevent the rusting of iron or steel by subjecting it to an acid solution of zinc phosphate. A concentrated solution of 6 oz. zinc, 1 pint phosphoric acid and 1 pint water is made up and applied directly to the iron or steel articles for a short time or is diluted with water before the iron or steel articles are immersed in it. For dilution 1 oz. of the concentrated solution is added to each gallon of water. For the purpose of renewing the dilute solution there is added to each gallon thereof ¼ oz. or less of the concentrated solution as and when required. Under certain circumstances it is of advantage to treat the iron with a solution containing both zinc phosphate and iron phosphate; in this case iron filings and granulated zinc are dissolved in phosphoric acid. "The formation of the deposit on the iron or steel surface under treatment may be accelerated by passing an electric current through the dilute solution, which may be either in a hot or a cold condition," with iron anodes. (1,007,160, Oct. 31, 1911.)

Gold and Silver.

Continuous Vacuum Filter.—A novel form of continuous filter for separating cyanide solution from ore pulp has been patented by Mr. Bruce W. Taylor, of New York. As shown in Fig. 2, which is a sectional elevation, the machine consists of a tank in which a chain of filtering pans is mounted, adapted to travel around sprocket wheels, one of which is mounted outside and slightly above the top of the tank, while the other is located in the lower part. The vacuum pans have the usual construction of wire cloth, cocoa matting and filter cloth, and each pan has suitable connections with vacuum and

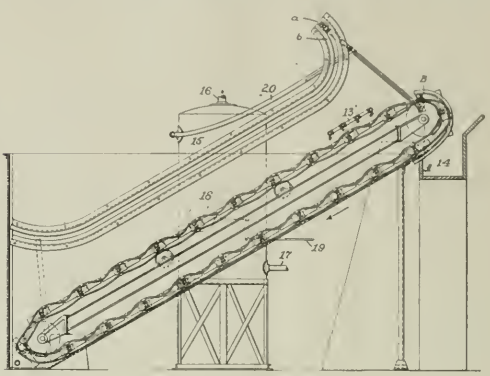

FIG. 2.—CONTINUOUS FILTER

air pressure. The point at which the pans are connected with the vacuum and where the air pressure closes is indicated at *A*, while the point at which vacuum is cut off and air pressure applied is shown at *B*. As the pans descend into the tank which is filled with the pulp to be filtered, they are connected with vacuum and consequently accumulate a cake of slime. As the pans rise out of the tank they first pass under a water spray shown at 13, where they receive a wash. Later the vacuum is broken at *B* and air pressure applied which forces the cake from the pan into a discharge launder 14.

The vacuum tank is indicated at 15, and has dry vacuum connection at 16 and wet vacuum connection at 17. The pump operating the latter is controlled by a float 18, 19, so that it will work fast or slow according to the amount of solution in the tank. There is a continuous vacuum on the hose 20,

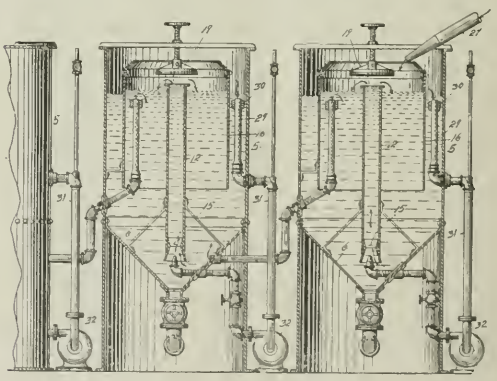

FIG. 3.—CONTINUOUS AGITATOR

and the vacuum on the several pans is controlled by suitable valves. The pipe connection at the end of the hose is provided with a trolley *a* and track *b*, and the pipe travels back and forth as the chain of filter pans revolves, the hose also following the line of travel. (1,000,856, Aug. 15, 1911.)

Pulp Agitator.—The improvement made by continuous agitation of ore pulp in cyanide solution has led to a number

of designs of agitators being patented. One of the latest is that of Mr. WILLIAM C. PATERSON, of Denver, Col. The agitator may be used either singly or in plurality. In the accompanying drawing, Fig. 3, the agitator is shown in plurality for continuous work.

The machine belongs to that class of agitators in which a centrifugal pump is the means of agitating the pulp, and in which means are provided in the tank for permitting only clear solution to go to the pump, thereby avoiding excessive wear due to the abrasive action of the mineral particles. In the drawing the number 5 designates a cylindrical tank having a cone bottom 6, with a central pipe 12, which is slightly reduced in diameter at 15. Surrounding the upper part of the central pipe is a circular partition 16, while immediately above the central pipe is a baffle plate 19, which is movable vertically. Pulp is fed to the system at 27, and the agitation and circulation are accomplished by centrifugal pumps 32. The pump draws practically clear solution from outside the circular partition, through the pipe 31, which terminates in a flexible portion 20, with a float 30.

Similar arrangement is provided on the opposite side of the tank, but within the circular partition, for the purpose of carrying a portion of the pulp from one tank to another. By this arrangement, agitation is accomplished by the circulation of clear solution through the central pipe, and the transfer of pulp through the system is made by continuously drawing off a uniform sample of the pulp as it falls from the top of the central tube. (1,000,689, Aug. 15, 1911.)

Improvement in Zinc Dust Precipitation.—Mr. CHARLES W. MERRILL, of Berkeley, Cal., who had used zinc dust precipitation of cyanide solutions for some years, has recently been granted letters patent for an improvement in the system. He claims that the ordinary zinc fume or dust is rendered less efficient as a precipitant on account of the slight coating caused by oxidation of the zinc. It is further claimed that this inefficiency is more noticeable in treating low grade or weak solutions. Mr. Merrill proposes to add to the usual precipitating system a grinder, such as a small tube or barrel mill, through which the entire mixture of gold-cyanide solution and zinc dust is to be passed. This apparatus will be placed somewhere between the tank containing unprecipitated solution and the filter press which is to separate the solid from the precipitated solution. The grinding operation will remove the deterrent coating from the zinc fume and increase its efficiency as a precipitant. (1,006,865-6, Oct. 24, 1911.)

Copper.

Copper Converter Tuyere.—Another patent has been added to the list of those issued to Mr. ELIAS A. C. SMITH, of Baltimore, Md., in connection with the development by him and Mr. Peirce of the basic copper converter. This latest patent refers to the construction of the converter tuyere, and the only claim reads as follows: "A blast tuyere, provided at its outer end with a Dyblie valve and its casing having a removable cap, the main bore of the casing being in alignment with and of the same diameter as the bore of the tuyere, and said cap having a perforation of but slightly less diameter than that of the tuyere; whereby, during the continuance of the blast, a punch bar may be employed, making a machine fit with said perforation and approximately but loosely fitting the bore of the tuyere, and whereby, on removing the cap during interruption of the blow, a second punch bar may be employed, still more neatly fitting the bore of the tuyeer." (1,007,149, Oct. 31, 1911.)

Treatment of Copper-Zinc Sulphides in a Converter.—With a view to improving the methods used for the treatment of copper and zinc sulphide ores, M. DÉSIRÉ KORDA, of Paris, has invented a procedure which he claims to be more economical than any yet devised. He provides an ordinary converter of the kind used for converting copper and uses a high proportion of coke in its lining. This lining may be formed of an intimate mixture of 60 parts quartz, 20 parts coke and 20 parts refractory clay. The lining around the tuyeres has no coke. After the converter is dried and heated in the usual manner and lined with incandescent coke, covering the tuyeres with combustible material. A few minutes' blowing brings the contents to a white heat, when the ore is then charged until the converter is full. It is preferable to charge the ore in the form of rock. In order to start the operation quickly, the cleanest sulphides are charged first, the less fusible ores following. Finally a charge of coke of nut size is added.

The blast is continued at a moderate pressure until a liquid bath forms in front of the tuyeres, after which the pressure may be increased. At the end of an hour the charge is melted to a homogeneous mass and the maximum blast is obtained. Zinc is reduced and discharged at the mouth of the converter, where it burns to oxide and is conducted to recovery chambers. Copper is converted to matte, and the operation is stopped when the latter approximates 60 per cent copper. Five per cent of pyrite is now added to the converter, having the effect of cleaning the slag of copper. The converter is then skimmed and the matte blown to metal.

The following figures are given by the inventor as showing an actual test of the process: Ore: Cu, 6.77 per cent; Zn, 16.31 per cent; Fe, 24.00 per cent; S, 23.00 per cent; SiO_2, 15.00 per cent. Matte: Cu, 67.22 per cent; Zn, 2.36 per cent. Slag: Cu, 0.54 per cent; Zn, 4.64 per cent. Oxide: Cu, 0.10 per cent; Zn 55.00 per cent. The net recovery is thus 93 per cent of the copper and 78 per cent of the zinc. Owing to slight waste in the recovery of the latter, however, this figure is reduced to 60-70 per cent of the zinc really recovered in the form of oxide. (1,003,051, Sept. 12, 1911.)

Lead and Zinc.

Refining Lead and Lead Alloys.—The removal of impurities from lead and the alloys of lead with antimony and tin is highly desirable from a commercial point of view. Chief among these impurities is arsenic, the presence of which renders lead unfit for certain commercial uses. Mr. LELAND E. WEMPLE, of St. Louis, Mo., proposes to accomplish the removal of arsenic and other impurities by treating the molten lead or lead alloy with an alkaline hydroxide, such as sodium hydroxide, bringing the metal in intimate contact with the solvent for the impurities.

The apparatus used is represented diagrammatically in Fig. 4. It consists of a series of pots adapted to be heated from fire boxes, and having spouts for conducting molten metal from

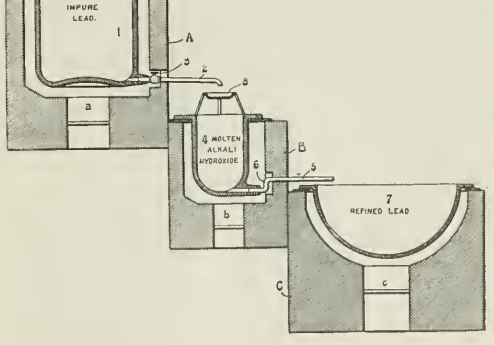

FIG. 4.—LEAD REFINING

one to another. The impure metal is contained in pot 1, and is conducted to the alkali pot by pipe 2, falling first into a perforated pan 8 placed above the alkali pot. This has the effect of disintegrating the molten stream into innumerable globules, exposing a large surface of metal to the action of the alkali. The refined metal falls to the bottom of the alkali pot and passes through the pipe and trap 5, 6, into the pot 7. It will be

inevitable that some of the alkali will also pass into pot 7, and this is removed by treating the molten mass with dry nitre cake, which is forced to the bottom of the pot 7. This quickly unites with any alkali in the mass and rises to the surface, forming a slag which is skimmed off.

If it is desired to refine lead alloys, such as those of tin and antimony with lead, it is necessary to retard the action of the alkali, so that tin and antimony will not be dissolved. This is done by adding a reducing agent such as zinc dust, iron filings or aluminium powder. In case iron scale is used, the inventor prefers to mix 20 parts of iron scale with 100 parts of alkali hydroxide in the reaction pot.

For the purpose of accelerating the removal of some impurities which are not readily acted upon, such as bismuth, tin and antimony, it is well to mix with the alkali hydroxide an oxidizing substance such as the nitrate, chlorate or peroxide of sodium or potassium. (1,006,323, Oct. 17, 1911.)

Extraction and Electrolytic Precipitation of Zinc.—The treatment of low grade zinc ores, containing from 5 to 15 per cent of zinc, with or without other metals, is a problem which attracts a great deal of attention from metallurgists. In a patent recently granted to Messrs. John R. Williams, Henry W. Bradley and Benjamin Bradley, of Sheffield, England, a process is outlined which contemplates the removal of the zinc by dissolution in a weak acid solution of zinc sulphate, and the electrolytic reduction of zinc from this solution.

Sulphide ores must be first roasted, after which they are leached in a suitable tank with a solution containing 6 to 8 per cent neutral zinc sulphate and 0.3 per cent sulphuric acid. These strengths were arrived at by experimentation. It was found that with quantities of zinc sulphate from 5 to 16 per cent the rate of deposition was no greater than at 5 per cent, while below 5 per cent the rate rapidly decreased. Also, with the higher percentages of zinc sulphate in the extracting solution, the loss of solution in the ore was too great. The acid strength is determined by the tendency of the ore to form a gelatinous mass with the acid, and by the effect of the acid on the cathode. With regard to gelatinization, the limit may be 2 per cent, but with regard to the action on the cathode the limit must be as low as 0.5 per cent. If the current density does not exceed 11 amp per square foot of lead anode surface, the anodes may be run for 300 days continuously without renewal. It is preferable to use a current density of about 10 amp per square foot of surface, and to start electrolysis with a neutral solution.

The inventors have a preferred form of cell which they use for electrolysis. It consists really of a number of practically separate cells parallel to one another. The cathodes are made of iron, preferably tempered and galvanized, and the anodes of lead plate. The anodes are placed one on either side of the cathode so that both surfaces of the latter are operative.

Copper ores may be similarly treated with a slightly acid solution of copper sulphate, or mixed copper and zinc ores may be leached out together and recovered separately by electrodeposition under proper electrical conditions. (1,006,330, Oct. 17, 1911.)

Electric Zinc Furnace.—Two patents of Mr. A. L. J. Queneau, of Philadelphia, Pa., refer to an electric zinc furnace which, in its latest construction, is shown in Fig. 5. It is a rotary furnace provided with a molten resistor D of molten iron containing 12 per cent phosphorus (to increase the electric resistivity) or preferably of molten slag. To get high fluidity of the slag, florspar or phosphoretic slag from an open-hearth steel furnace may be added. The furnace has an outer metallic shell *k* of low-carbon steel. At the feed end it is closed by a metallic plate *h*, insulated from the metallic shell *k* and provided with a flange *v* for making contact with one of the brushes *y* of the external electric circuit. The opposite end of the furnace is closed by a plate h^1 which is electrically connected with the metal shell *k*. The other brush *Z* of the external elective circuit makes contact with the shell *k* through the intermediary of the tire ring *d*. The shell *k* is provided with an outer lining of fire brick and an inner lining of magnesite brick or chrome brick. The end courses *C* are made of a conducting mixture of graphite, dead-burned magnesia, and tar. Exterior to these courses *C* are the raphite end linings *n*, adjacent to the end plates *h* and h^1. The electric circuit is, therefore, completed from brush *y* to plate *h*, to grpahite end lining *n* and conducting course *C* to the fluid resistor *D*, thence to the conducting course *C* at the other end of the chamber, the graphite lining *n*, plate h^1, shell *k* and ring *d* to the other brush *Z*.

At the left hand of the diagram the condenser is shown, with the shell k^1 lined with graphite compounded with clay Within the condenser are arranged the baffle dip partitions *L*, provided with apertures *o*. The construction may best be seen from the separate diagram *A* shown at the top left corner of

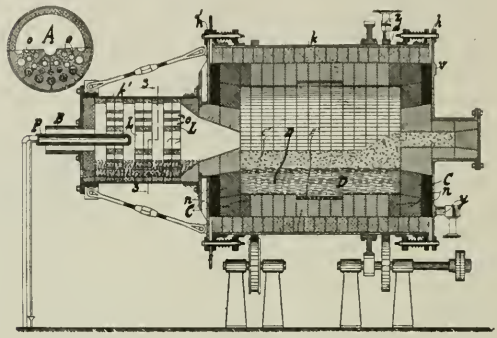

FIG. 5.—ELECTRIC ZINC FURNACE

the illustration, which gives a cross section of the condenser along the lines 33 in the main diagram. The combustible gases, such as carbon monoxide, escape from the condenser through the prolong *B*. To regulate the temperature in the condenser, the pipe *P* is provided through which cooling water is passed.

The charge consists of a mixture of zinc ore and coke, wherein the coke is but slightly in excess of that theoretically required for reduction of the ore. The charge is preheated to as high a temperature as the coke will stand without ignition, say 500° C, within a rotary furnace of the muffled type, heated from the outside and containing a number of steel balls so as to serve as a ball mill. The preheated charge is then supplied to the electric furnace. (1,006,876 and 1,006,877, Oct. 24, 1911.)

Nickel.

Treatment of Nickel-Copper Ores.—An improvement in the treatment of the nickel-copper ores of Sudbury, Ontario, Canada, is made the basis of a patent granted to Franklin R. Carpenter, deceased, and Arthur H. Carpenter, his son, of Denver, Col. The process has to do with the removal of the copper and sulphur from the ore, leaving the iron and nickel as a roasted product suitable for reduction to ferro-nickel alloy. The inventors first give the ore a dead roast, leaving the iron, copper and nickel practically as oxides. They then add a suitable amount of raw pyrite or pyrrhotite, together with the necessary salt, and give a chloridizing roast. Owing to the greater ease with which copper is chloridized, the process can be controlled in this respect, so that when the resulting mass is lixiviated only copper will be leached and nickel will remain with the iron. The nickel iron residue can then be smelted directly or with other iron ores for the production of ferro-nickel alloys, thereby saving the cost of separating the nickel and giving complete utilization of the iron. (1,006,355, Oct. 17, 1911.)

Alloys.

Ferrochromium Made in Continuous Resistance Furnace.—Instead of a discontinuously operating arc furnace, Mr.

EDGAR F. PRICE, of the Electro Metallurgical Company, proposes to use a continuous resistance furnace for the production of ferrochromium. A body of molten metal occupies the lower portion of the furnace. Above this rests a deep body of molten slag, and on the top of it is placed the charge mixture of chromite, coke, lime, etc. The body of slag is heated by a current passed through it between electrodes suspended from the top into the charge mixture and into the layer of molten slag. As reduction proceeds, the iron and chromium alloy and the alloy settle through the slag into the layer of metal beneath. The slag produced combines with the slag resistor and the excess slag and metal are removed from time to time through tap-holes, additions being made to the charge as required. The reduced metals thus quickly separate from and are maintained out of contact with the free carbon in the charge. The resulting alloy is, therefore, low in carbon. (995.-481, June 20, 1911.)

Nickel Titanium.—To produce a binary alloy of nickel and titanium, Mr. AUGUSTE J. ROSSI, of the Titanium Alloy Manufacturing Company, mixes nickel, nickel oxide and titanic acid with sufficient aluminium for the reduction of the oxides. The mixture is then heated in an electric furnace and the reduced titanium *in statu nascendi* alloys with the nickel. The reactions during the reductions are

$$3\ TiO_2 + 4\ Al + Ni = 2\ Al_2O_3 + Ni + 3\ Ti$$

and

$$3\ NiO + 2\ Al = Al_2O_3 + 3\ Ni$$

Instead of aluminium, carbon may be used as a reducing agent, but a higher temperature is then essential. (1,003,806, Sept. 19, 1911.)

Aluminium Bronze.—Mr. P. H. G. DURVILLE, of Paris, France, patents the use of manganese as a purifier for copper-aluminium alloys. He uses the following composition: 86 to 95 per cent copper, 0.05 to 5 per cent manganese and 6 to 11 per cent aluminium. The metals can be melted in the order indicated, but a portion at least of the manganese must be added in the form of an alloy with copper or with aluminium at the time of casting. Manganese in small proportions plays the part of a purifier as regards impurities other than oxides, which are not removed from the alloy by aluminium. The greatest proportion of manganese, up to 5 per cent, increases the hardness and the malleability of the alloy. These alloys have all the qualities of binary aluminium bronzes (consisting of copper and aluminium only), that is, great strength, good color and resistance to chemical agents, while being very easy to work. They are characterized moreover by the advantage that very sound ingots are obtained which can be easily forged, stamped, rolled or drawn. (1,007,548, Oct. 31, 1911.)

Pyrophoric Metal Alloy.

An improvement in pyrophoric bodies is claimed in a patent granted to GEORG F. HOFMANN, of Munich, Germany. It consists in adding metallic cerium to an alloy of manganese and antimony. Pyrophoric bodies of antimony and manganese are known, but their properties are not such as adapt them for use in ignition appliances, for the reason that they are not easily abraded by files or other frictional means. The inventor claims that the addition of about 5 per cent metallic cerium renders the antimony manganese alloy soft enough to be easily filed or abraded by friction so that particles fly from the body in a stat of incandescence. This alloy is different from that in which cerium is the main source of the pyrophoric property, where about 70 per cent cerium and 30 per cent iron are combined. (1,006,840, Oct. 24, 1911.)

Chemical Engineering.

Generating Steam from Molten Slag.—In Figs. 6 and 7 are shown two recent methods of generating steam from molten slag. Fig. 6 shows the arrangement designed by WALTER L. JOHNSON, of Middlesbrough, England. The main points in his invention comprise means for eliminating objectionable gases from the steam before use. Referring to the figure, *a* represents a slag spout which delivers hot slag from a furnace to the boiler *c*. A stirrer *d* may be used if desired. The boiler contains water and milk of lime for the absorption of sulphurous gases. The granulated slag is removed by elevators as shown, while the steam passes through the tower *h* to the tower *i* where it encounters a falling spray of hot caustic soda contained in the tank *k*. This is designed to neutralize any acid

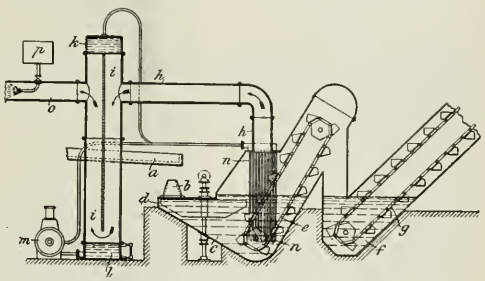

FIG. 6.—GENERATING STEAM FROM SLAG

gases, but a further neutralization is provided for by an ammonia spray *p* in the pipe *o*. The caustic solution is circulated by the pump *m* through coils *n* in the boiler, so that it is kept at a temperature of about 212 deg. Fahr. The ammonia may be recovered by condensing the engine exhaust. (1,005,711, Oct. 10, 1911.)

Fig. 7 represents the design of WILLIAM E. MCKEE, of Bisbee, Ariz. It compries a boiler and elongated leg in which is a bucket elevator for the removal of the granulated slag. The molten slag is first received in a hopper placed above the boiler. Between the hopper and boiler is a specially designed valve which can be closed to shut off the flow of slag and prevent the escape of steam. An opening for the escape of steam to the

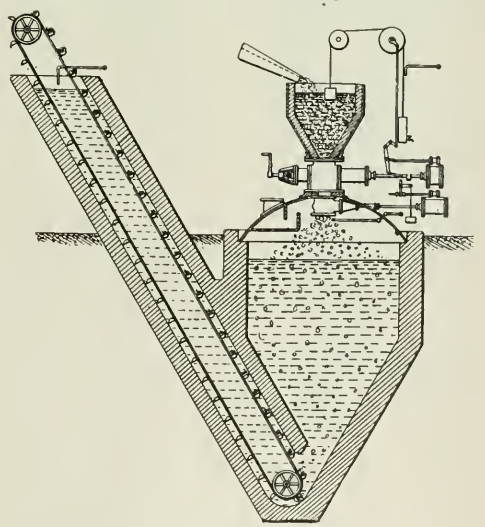

FIG. 7.—GENERATING STEAM FROM SLAG

point of utilization is shown in the boiler head. It will be noticed that provision is made for a difference in head of the water in the boiler proper and in the leg. This difference amounts to 2 ft. head for every pound of steam pressure in the generator. Feed water is introduced through the leg so that practically all the heat of the slag is utilized before its discharge. (1,001,290, Aug. 22, 1911.)

Electric Furnace Designs.

Electric Resistance Furnace.—In electric resistance furnaces with an electrode at the top and an electrode in the bottom, the upper electrode is kept in good contact with the upper part of the charge. When the charge sinks down in the furnace, this contact is liable to be broken and an arc is formed. This increases the resistance and reduces the power supply to the furnace and causes other disadvantages, like greater electrode consumption, concentration of the heat on the top, etc. To prevent this, Mr. Albert Petersson, of Odda, Norway, arranges the feeding device in such a way that the fresh charge is fed in a horizontal direction toward the upper electrode pressing against it and preventing the formation of arcs. Quite a number of such arrangements are described, of which one is shown in Fig. 8 (1,002,444, Sept. 5, 1911).

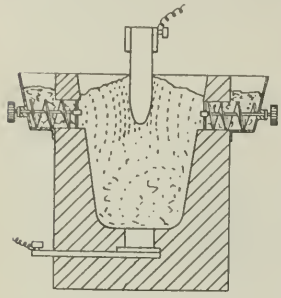

FIG. 8.—ELECTRIC RESISTANCE FURNACE

Electric Furnace with Conducting Hearth.—Mr. Georges Massip, of Paris, France, patents an electric furnace with an upper movable electrode, while the hearth itself acts as the lower electrode. The hearth is made of a material, like magnesia, which is a non-conductor of electricity when cold, but becomes a conductor when heated. To heat it, there are embedded within the hearth (but removed from the inner surface of the hearth) metallic heating resistors, suitably connected, like the upper electrode, to an electric circuit. (1,005,725, Oct. 10, 1911.)

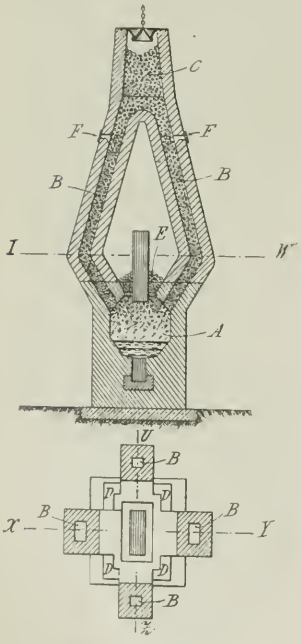

FIG. 9.—ELECTRIC REDUCTION FURNACE

Electric Reduction Furnace.—Mr. Hans Bie Loventzen, of Notodden, Norway, has patented the furnace shown in vertical and horizontal cross-section in Fig. 9 for operation with single-phase current by means of an upper and a lower electrode. Surrounding the upper electrode are a series of vertical channels *B* which terminate in a common charging shaft *C*. By means of a fan, the gaseous products of reaction are withdrawn through the channels. Through the valves *F* air may be blown into the channels, if desired. The furnace construction is such as to permit separate feeding of ore and carbon, namely, the ore *C* through the channels *B* and the coke *E* around the upper electrode. (996,492, June 27, 1911.)

Electric Furnace.—An electric-furnace construction of Mr. Alvois Helfenstein, of Vienna, Austria, is shown in Fig. 10, in vertical and horizontal cross-section, the two diagrams not being drawn to the same scale. The two side walls *A* and *B* are connected by means of the end walls *g* and *h*. On the top of the furnace two parallel supports d_1 and d_2 are arranged in the form of water-cooled girders, resting on the end walls of *g* and *h*. The two girders are spaced apart so as to form a charge opening, which extends the whole length of the furnace chamber, and a superposed receptacle *b* is provided to confine the charge. The lateral arched coverings of the furnace chamber a_1 and a_2 are likewise supported by those girders. An upper vertical electrode *i*, longitudinally arranged, is disposed in the charge opening and extends nearly the whole length of the furnace chamber. Horizontally arranged in the bottom *C* of the furnace is the bottom electrode *k*, also extending nearly the whole length of the furnace chamber. The openings *o* are provided for inspection and manipulation of the charge. As will be seen, on both sides of the furnace, above the charge, separate chambers e_1 and e_2 are formed into which the reduction gases can escape, being subsequently withdrawn through the outlets f_1 and f_2. (1,000,805, August 15, 1911.)

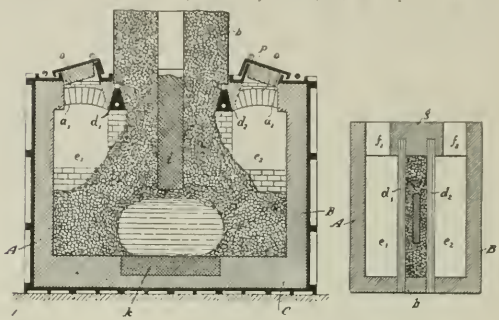

FIG. 10.—ELECTRIC REDUCTION FURNACE

In another patent of Mr. Helfenstein a slightly modified furnace construction is shown. The top of the charging shaft is closed and the whole arrangement is again such that free spaces are formed on the sides above the charge, into which the gases evolved during the reaction can escape. If they are combustible it is proposed to utilize their calorific effect within the furnace. For this purpose air is blown into these spaces and the gases are burnt, thus preheating the ore before it enters the melting zone. (1,002,988, Sept. 12, 1911.)

A third patent of Mr. Helfenstein refers to the construction of a battery of electric furnaces, all with one single common bottom electrode. That is, a single massive body serves as a common bottom to all of the furnaces and serves as bottom electrode for all of them. Upon this bottom various furnace shafts are constructed, whereby each single shaft may be used as an independent working hearth so that it is possible to conduct melting operations of different character in the different furnaces. (1,002,843, Sept. 12, 1911.)

Two-Phase Electric Furnace.—A patent of Mr. Axel R. Lindblad, of Ludvika, Sweden, refers to a two-phase furnace, which has already been the subject of an article by Mr. T. D. Robertson in our November issue (p. 573). The essential electrical connections are shown in Fig. 11. 1 and 2 are the

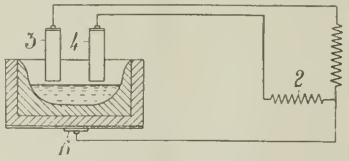

FIG. 11.—TWO-PHASE FURNACE

two phases of a two-phase system, each being connected with one of the upper electrodes 3 and 4, while the neutral point is connected with the contact 6 in the bottom of the furnace. As the two circuits have a phase difference of 90 deg. relatively to each other, the current which passes through the smelting bath and contact 6 is V_2 times the current passing through each of the electrodes 3 and 4. The tension between both electrodes is also V_2 times the tension consumed in each arc. If the current supply is three-phase, it is changed to two-phase by the well-known Scott transformation. (1,002,286, Sept. 5, 1911.)

Electric Furnace.—Mr. LARS YNGSTRÖM, of the Stova Kopparbergs Bergslage Aktiebolaz, of Falun, Sweden, patents the furnace shown in Fig. 12. A crucible 1 forms the working or melting chamber, and above it is provided a stack 2 for feeding the charge downward. But between the walls of the stack and the crucible there is a ring-shaped space 4 through which more charge is introduced into the furnace, while it also serves for the introduction of the electrodes 3, which are thus surrounded by charge material. (Bottom electrodes may also be provided.) A vault or roof for the crucible which would be liable to destruction is thereby avoided. 6 is the tapping hole. Two modifications of this furnace design are also described. (1,001,915, Aug. 29, 1911.)

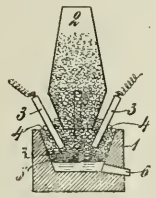

FIG. 12—ELECTRIC REDUCTION FURNACE.

Furnace Electrodes.

Dimensioning of Furnace Electrodes.—Mr. CARL HERING'S well-known laws of electrode losses are the basis of a recent patent granted to him for dimensioning electrodes. He proposes to dimension them in such a way that no heat passes through the hot electrode end (within the furnace) in either direction. No heat flows, therefore, from the furnace interior through the electrode to the outside. Only the heat generated within the electrode from electrical energy (the C^2R heat) passes out of the cold electrode and to the outside. The first claim reads as follows: "In an electric furnace, an electrode having a resistance such that the C^2R heat developed therein by current transmitted therethrough to said furnace shall be substantially equal to twice the heat conduction loss when no current flows." (990,719, Aug. 1, 1911.)

A second patent of Mr. Hering relates to this dimensioning of electrodes in combination with other features. It will suffice to give here the first claim: "In an electric furnace, molten conducting material serving as a furnace resistor, and an electrode in electrical communication with said resistor for communicating heating current to said resistor, the length and cross-section of said electrode being so related that the resistor heating current passed through said electrode raises said electrode to a temperature preventing heat conduction through said electrode from said molten material." (990,720, Aug. 1, 1911.)

Protective Coating for Carbon Electrodes.—To protect carbon electrodes against oxidizing influences, Mr. JOS. L. K. SNYDER, of the National Carbon Company, of Cleveland, Ohio, provides a protective coating to the electrode surface, while in a green (unbaked) and therefore plastic condition. During baking or later in the electric furnace this coating is automatically changed by the heat into a protective and very firmly adhesive slag. If the carbon mix, of which the green electrode is formed, contains acid impurities, like silicious material, sodium carbonate with a binder may be used for the coating. Under the influence of heat this will combine with the silicious material and form a slag-producing glazer. Or, if the carbon mix contains basic impurities, like ferric oxide, potassium bisulphate or borax with a binder may be used for the protective coating. Or calcium chloride may be used for the coating, as it will form with the carbon calcium carbide. Pitch and tar are suitable binders. (1,000,761, Aug. 15, 1911.)

Large Electrode.—The construction of an electrode for very large currents, like 25,000 amp., for calcium carbide furnaces is the subject of a patent of Messrs. WM. T. GIBBS and R. A. WITHERSPOON, of the Shawinigan Carbide Company. The head of the electrode (Fig. 13) consists of a casting of circular shallow horizontal box form *b* with a diametrical hollow flange *c* upon its top. The electrode head is water-cooled, *i* and *j* being the feed and discharge pipes for the box and *k* and *l* for the flange. The flange *c* acts as a terminal and also as a means for connecting the electrode with a crane. The horizontal box position *b* has a central opening encircled by a series of similar openings, all provided with screw-threaded sockets. A series of short graphite plugs *m* are screwed into the sockets in the head, and into their lower ends (as at *o*) are threaded amorphous carbon rods *p*. Thus these electrode pencils consist in their upper parts of graphite and in their lower parts of amorphous carbon. A sheet-iron shell encloses the pencils and a filler *s*, consisting of 100 parts by weight of ground coke, 27½ parts redistilled tar and 27½ parts pitch, is packed around and between the pencils, and is preferably molded and baked before the shell is set in place. The reason for using a graphite electrode in the water-cooled head is that amorphous carbon, when used in such water-cooled heads, is liable to break, while graphite does not break. For the lower parts of the pencils amorphous carbon is used on account of its cheapness. The electrode is shown in the illustration applied to a calcium carbide furnace, supported on a wheel truck 4 and having a carbon base 2 and limestone walls 3. (1,003,354, Sept. 12, 1911.)

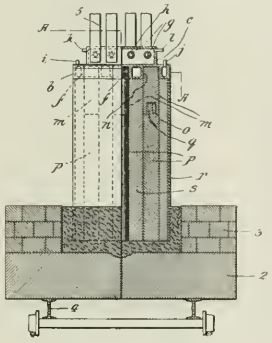

FIG. 13—LARGE ELECTRODE OF GRAPHITE AND CARBON.

Various Electric Furnace Processes.

(See also above under the headings for the different metals.)

Electrically Heating Carbon.—In electrically heating carbon, for the production of electrode compositions, battery fillers, etc., a close adjustment of time and temperature is required to convert the given raw material into a product of the desired character. While in practice the intermittently operated furnace is always employed, Mr. WILLIAM ACHESON SMITH, of the International Acheson Graphite Company, has devised a continuously operating furnace in which the charge is progressively advanced in a direction parallel to the lines of flow of the electric current. In this way the charge may be subjected for any desired period (depending upon the rate of advance of the charge) to uniform temperature conditions. Two slightly different designs of the furnace are shown in Fig. 14. In the left-hand drawing the furnace charge 8 serves as the resistor interposed between the upper and lower electrodes 6 and 7. The lower electrode is supported by a hollow water-cooled metal bar or casing 9 carried by the furnace walls. In the furnace walls adjacent the heating zone a hollow space 4 is provided which communicates by inclined apertures 4*a* both with the heating chamber and the external air so that the furnace gases may readily escape from the heating zone and a mantle of such gases may be burned within the furnace wall to economize heat. Water pipes 5 are provided between the heating zone and the discharge hopper. The latter is provided with a slightly coned disk, rotated by a worm gear, so that the material is discharged over the periphery of this disk only while it is rotating. In the right-hand diagram the upper and lower terminals 6 and 7 are connected together by a carbon or graphite rod 14, which is particularly useful when the charge,

in the cold state, is a poor conductor of electricity. There are also some other small differences in design in the two furnaces, which can be seen in the illustration. (Process patent 1,004,923; furnace patent 1,004,924, both of Oct. 3, 1911.)

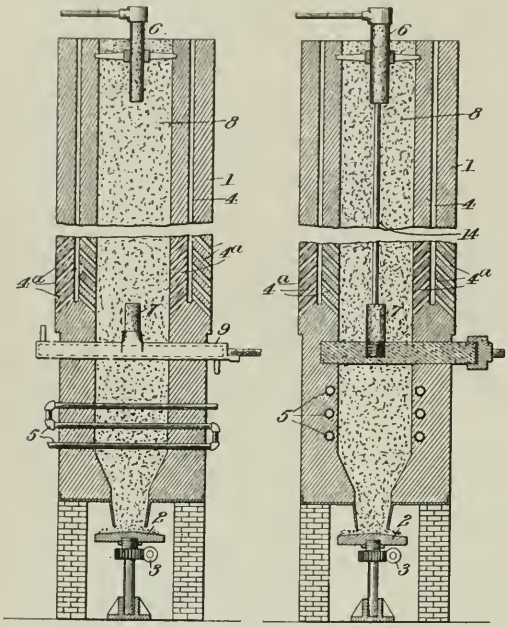

FIG. 14.—CONTINUOUS FURNACE FOR HEAT TREATMENT OF CARBON.

Bulk Graphite.—In the conversion of carbon into graphite in electric furnaces it is necessary to shield the carbon from the direct action of the air, but to permit the free escape of the distillation gases. For this purpose the carbon is surrounded by a granular mass of carborundum, white crust, etc. Under usual operating conditions it is impossible to maintain a sharply defined demarcation plane between the carbon and the surrounding material, especially near the upper and lower surfaces of the charge. It is, therefore, usually necessary, in unloading each furnace charge, to discard a considerable mass of graphite, by reason of the admixed carborundum, etc. Mr. Alfred L. Robinson, of the International Acheson Graphite Company, overcomes this difficulty by the furnace construction shown in Fig. 15. The crushed petroleum coke or gas coke 2,

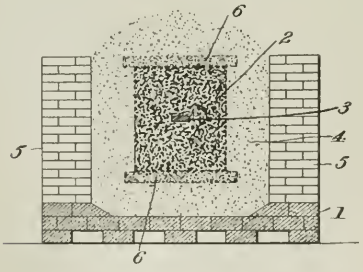

FIG. 15.—GRAPHITE FURNACE

which is to be changed into graphite, is placed between two lower and upper layers 6 of a mixture which during the furnace treatment cakes into a strong solid mass (for instance, a mixture of 25 parts of bituminous coal, 50 ground coke and 25 ground furnace crust, consisting of carborundum, siloxicon, etc.). 3 is a starting core of carbon, used when the initial conductivity of the charge is low; 4 is the embedding material supported by the walls 5 of loosely assembled firebrick. In charging the furnace admixture of the coke with the embedding material is avoided by the use of vertical separating walls of paper. At the close of the operation it is easy to take the furnace to pieces. (1,004,469, Sept. 26, 1911.)

Abrasive and Refractory Material of Alumina and Magnesia.—Research work carried out by the Carborundum Company, of Niagara Falls, has resulted in the production of several interesting new products, for abrasive and refractory purposes, which are disclosed in some patents of Mr. Thomas B. Allen. All of them have alumina as chief constituent. The first product consists essentially of alumina and magnesia, with not over 25 per cent magnesia. Bauxite is used as source of alumina and magnesite as source of magnesia. They are calcined to remove the water from the bauxite and the carbon dioxide and water from the magnesite and the calcined materials are then mixed together with a sufficient amount of carbon to reduce the major portion of the oxide of iron and oxide of silicon. For example, a mixture of 100 parts of calcined bauxite, 15 calcined magnesite, and 6 carbon, treated in an electric furnace, yields a product consisting of 14 parts MgO and 84 $Al_2 O_3$, the remainder consisting of oxide of titanium, iron and silicon. By keeping the temperature of the electric furnace relatively low, the oxide of iron and silicon can be reduced without affecting the oxides of aluminium and magnesium. The resulting ferrosilicon can be separated. The content of magnesia in the finished product affects its toughness. It should not be more than 25 per cent, and by varying it a series of products of varying hardness and toughness can be prepared. (1,001,497 Aug. 22, 1911.)

Abrasive and Refractory Material of Alumina, Magnesia and Boric Oxide.—In a second patent of Mr. Allen boric oxide is added to the alumina-magnesia product. Boric acid is mixed with calcined magnesia, for instance, in the proportion of 35 to 65, and heated in a fuel-fired furnace to about 1300 deg. The product is crushed and 25 parts of it are mixed with 100 parts of calcined bauxite and 8 parts coke and this mixture treated in an electric arc furnace. The product contains 12 per cent magnesia, 6 per cent boric oxide, and 79 per cent alumina, and is a dark colored crystalline material of great hardness and very brittle. Addition of boric oxide increases the brittleness and hardness. (1,001,570, Aug. 22, 1911.)

Abrasive and Refractory Material of Alumina and Beryllia.—A material consisting of alumina and less than 18 per cent of beryllia (that is, less than represented by the formula Be O $Al_2 O_3$) is the subject of a third patent of Mr. Allen. He treats in an electric furnace a mixture of 100 parts by weight of calcined bauxite, 75 parts of beryl, 12 parts of coke (to reduce the oxides of silicon and iron) and 50 parts of oxide of iron (to remove more readily the reduced silicon and titanium). The product contains 7½ per cent of beryllia and 89 of alumina. The content of beryllia gives to the product an improved crystallization, while the toughness decreases with increase of beryllia and the hardness increases with increase of beryllia. (1,001,571, Aug. 22, 1911.)

Purification of Abrasive and Refractory Materials.—In a fourth patent of Mr. Allen a method is described for removing aluminium carbide and ferrosilicon, which are the chief impurities in abrasives produced in an electric furnace. Sodium chloride under the action of heat is used as the purifying agent. The crushed abrasive material is mixed with sodium chloride and heated to a temperature of from 800 to 1200 deg. C. This is followed by washing with water or a dilute solution of a mineral acid, in order to remove any excess of sodium chloride or products of the reaction. Two to five per cent by weight of sodium chloride added to the fused alumina are sufficient for purification. The reactions which eliminate the ferrosilicon and aluminium carbide are given as follows:

$$Fe_4\ Si + 16\ Na\ Cl = 4\ Fe\ Cl_3 + Si\ Cl_4 + 16\ Na$$

and

$$Al_4\ C_3 + 12\ Na\ Cl = 4\ Al\ Cl_3 + 3\ C + 12\ Na$$

These reactions are reversible, going from left to right at high temperatures. If they are carried out at a sufficiently high temperature in an oxidizing atmosphere, then, in spite of their reversibility, these reactions can be carried through to a finish, because the Fe Cl_3, the Si Cl_4, etc., are volatilized as soon as formed and the Na and C are oxidized, thus removing all newly formed compounds (those given on the right hand of the equation) from the sphere of action, and permitting the above reactions to go on continuously without stopping at some intermediate equilibrium. (1,001,572, Aug. 22, 1911.)

Purification of Emery Ore.—Emery ore consists principally of alumina, but is always associated with impurities such as iron oxide and usually silica and often small quantities of titanium oxide, etc. To remove these impurities, Mr. FRANK J. TONE, of the Carborundum Company, of Niagara Falls, employs an electric-furnace process, the impurities being reduced by means of carbon. It is important not to reduce any alumina, since in this case an entirely different, easily friable product would be obtained. For this reason only sufficient carbon is used to reduce the impurities. Further, the temperature is maintained above the reduction temperature of silica, but below that of alumina. As this would be impossible with an arc furnace, a resistance furnace is used. The mass of emery ore and carbon is placed between the electrode terminals of a furnace and current is passed through it. As the heating of the mass progresses and it becomes partially fused, its conductivity increases, and when it reaches a well-fused condition the charge becomes a good conductor of electricity. The furnace now acts as a simple resistance furnace. The purified fused alumina collects at the bottom with the impure alumina resting on it on top. The lower layer of pure fused alumina is a poor conductor of electricity, so that the distribution of the current is self-adjusting, the current confining itself practically to the layer of impure alumina on the top. The electrodes are accordingly raised from time to time. (1,002,608, Sept. 5, 1911.)

Boron.—A number of patents of Dr. E. WEINTRAUB, of the General Electric Company, deal with an elaborate method in producing pure boron. The usual method for producing boron includes the reduction of boric anhydride with magnesium, the general process being to heat a mixture of magnesium with an excess of boric anhydride. This reaction is accompanied by the production of magnesium borate and by the formation of other compounds. The resultant product, therefore, contains a relatively high percentage of material other than boron. The usual washing with water and hydrochloric acid decreases the percentage of impurity, but does not yield a product which could be termed, in the chemical sense, "pure boron." This impure product can be greatly improved, however, by "fractional decantation," consisting in grinding the product with water or hydrochloric acid and then decanting off the top of the liquid before complete precipitation has occurred. Boron has a greater specific gravity than the impurities, such as magnesium boride. By repeating this treatment, the proportion of impurities can be reduced several per cent.

The resulting product, in form of a brown powder, is compressed into the form of a stick or rod, say 6 cm long and 5 mm in diameter. The stick is then highly heated in an electric vacuum furnace to dissociate and drive off various of the impurities, like magnesium boride and boron hydride. This treatment may be continued for several hours at a temperature of say 1200 deg. C. without any danger of contaminating the boron by the carbon of the resistance heater. As a result of this treatment, an important physical change takes place, since the boron stick which before the treatment was a non-conductor becomes a relatively good conductor of electricity.

The next step in this process consists in melting down this conductive boron by heating it as anode in a vacuum arc. For this purpose an electric vacuum furnace is used in form of a hermetically closed glass vessel, with some mercury as cathode and the boron stick as anode. Hydrogen gas is introduced into the vessel and a pressure of the hydrogen of from 2½ to 15 cm of mercury is maintained. This hydrogen gas is chemically inert, but serves to concentrate the arc on the lower end of the boron stick.

While chemical text-books describe boron as being a non-conductive material which vaporizes at high temperatures without melting, the boron produced by the above process is a relatively good conductor of electricity, is a dense and solid body and undergoes complete fusion without apparent vaporization. Such pure conductive boron may be used for a variety of purposes and may be shaped into rods or glow bodies for use in incandescent lamps and furnaces. (997,879; 997,880; 997,881; all of July 11, 1911.)

Vacuum Furnace for Treatment of Refractory Materials.—The same principle of melting a refractory material as anode in a vacuum mercury arc may be applied to the treatment of refractory materials other than boron. For instance, for the fusion and purification of tungsten, thorium, osmium, etc., in form of rods pressed from the powdered metal. Several vacuum furnaces for this purpose are described by Dr. Weintraub. The principle is the same in all. (997,882 and 997,883, July 11, 1911.)

Distillation Process for Antimony and Arsenic.—Distillation at reduced pressure is one of the features of a process for treating ores containing antimony and arsenic, devised by Dr. COLIN G. FINK, of the General Electric Company. It may be applied, for instance, to electrolytic slimes containing antimony, and a very pure antimony can be obtained from a slime containing 35 per cent of antimony, the yield being almost 95 per cent. At atmospheric pressure the vaporization point of antimony is between 1500 and 1700 deg. C. At a pressure of 5 to 6 mm mercury it is only 735 deg. C. At a pressure of 40 mm mercury, as used in the author's process, it is between 1200 and 1300 deg. C. For the treatment of stibnite, $Sb_2\ S_3$, using an ore containing 62 per cent of antimony, 11.3 parts of stibnite, 12 parts of limestone, 2½ parts of coke and 6 parts of fluorspar are ground to 20 mesh and charged into an air-tight electric resistance furnace, the charge serving as resistor. The temperature is raised to 600 or 700 deg. C. and maintained there for one and a half hours to let the following reaction proceed:

$$Sb_2\ S_3 + 3\ Ca\ CO_3 + 6\ C = 2\ Sb + 3\ CaS + 9\ CO$$

A vacuum of 40 mm mercury is maintained by constant operation of the air pump. Then the temperature is raised to 1300 deg. C. and maintained there for about one hour, while the antimony is distilled off and condensed in a water-cooled condenser which is in communication with the furnace chamber.

The reduction of the stibnite may also be accomplished by heating the powdered ore with finely divided iron. Two parts by weight of stibnite are mixed with one of iron. The temperature of the charge is raised to 700 deg. C. for 20 minutes, to reduce the stibnite:

$$Sb_2\ S_3 + 3\ Fe = 3\ Fe\ S + 2\ Sb.$$

The temperature is then raised to 1200 or 1300 deg. C. for an hour and the antimony distilled and condensed. Instead of metallic iron, an oxide ore, as hematite or magnetite, may be used, the oxygen of the hematite serving partly to unite with the sulphur of the stibnite to form sulphur dioxide, SO_2, and the remaining sulphur combining with the reduced iron to form sulphide of iron. From two to three parts by weight of powdered carbon to one part of ore are added to the charge, to increase its conductivity and to permit the carbon monoxide formed to keep the charge porous.

Instead of an iron ore, a chrome iron ore, like chromite, may be used, $Fe\ O\ Cr_2\ O_3$. For example, about four parts of finely ground stibnite are mixed with two parts of finely ground chrome iron ore. One part of powdered coke or charcoal is added for the purposes mentioned. The finely ground mixture is heated to 900 deg. for one or two hours, to reduce the antimony and chromium:

$$3\ Fe\ Cr_2\ O_4 + Sb_2\ S_3 + 12\ C = 3\ Fe\ S + 12\ CO + 2\ Sb + 6\ Cr$$
$$2\ Fe\ Cr_2\ O_4 + Sb_2\ S_3 + 6\ C = 2\ Fe\ S + SO_2 + 6\ CO + 2\ Sb + 4\ Cr.$$

The temperature is then raised to 1500 deg. C. for one or two hours to distil and condense the antimony. (996,474, June 27, 1911.)

Silica Glass.—Mr. H. A. Kent, of the Silica Syndicate, of London, England, patents a process of making silica glass (fused silica), the first claim reading as follows: "The manufacture of silica glass by causing grains or particles of silica to fall or be projected separately through a heated zone and onto a movable heated body in a chamber, said particles being subjected to a temperature sufficient to sinter them by this single operation into a homogeneous mass of silica glass." One method of making a silica rod or tube is shown in Fig. 16.

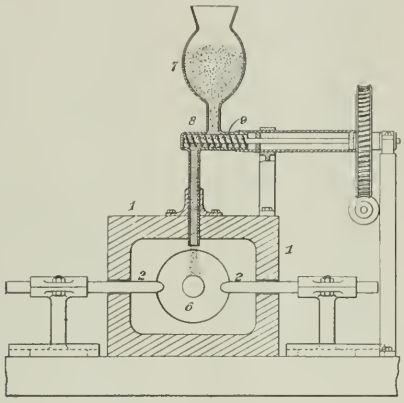

FIG. 16.—MANUFACTURE OF SILICA GLASS.

The electric furnace 1 is provided with adjustable electrodes 2. The ground silica grains are carried from the container 7 through the tube 8 with the revolving worm 9 and drop down onto the heated cylinder 6 of silica-glass upon which they form a homogeneous mass of further silica glass. (1,003,271, Sept. 12, 1911.)

Burning Cement with Electric Heat.—Methods have been proposed for burning cement by the direct heat of the ordinary short arc, but for practical reasons the scheme has not been adopted. Mr. Carleton Ellis, of Montclair, N. J., has recently patented a process for the utilization of a long arc in cement burning. An alternating current of from 4000 to 6000 volts is used, and this for commercial reasons may be a three-phase system. Three or more arcs may be arranged to work on the three phases of such a system, with the kiln connecting with the neutral junction. With a kiln about 20 ft. long and about 20 in. in diameter, a current of from 200 to 300 amp and at 4000 to 6000 volts may be used. The length of the kiln determines the voltage necessary to strike the arc, while the amperage is adjusted in accordance with the heating effect required.

In order to prevent the arc "blowing out," the inventor injects a spiral current of air moving tangentially around the arc, as by this means he is enabled to project arcs of great length without loss of stability. In order to protect the lining of the kiln as much as possible, the kiln may be rotated at high speed so as to carry the load well up on the side of the kiln, and by the application of the electrode magnet the arc may be deflected at one or more points into close contact with the material to be clinkered, and away from the opposite and unprotected side of the kiln. (999,494, Aug. 1, 1911.)

Gas Reactions.

Nitric Acid from Air.—The Pauling process for the fixation of atmospheric nitrogen by the electric arc has come into considerable prominence by the two commercial plants in Austria and France employing it on a large scale (this journal, Vol VII, p. 430; Vol. VIII, p. 102, 196) and also by the decision to use it in a plant in course of erection in the South. In the existing Pauling plants the arrangement is very similar to that of the horn lightning arrester, as described in the articles referred to. It appears, however, from two recent patents of Mr. Harry Pauling that he is also paying attention to quite different designs, using a long vertical arc. But the arrangement is very different, for instance, from the long arc of the Badische Company's furnace. While in the latter the air passes in spiral form along the whole vertical arc from the bottom to the top, Pauling provides gas inlets and outlets alternately all along the arc. The furnace has a central vertical open shaft within which the arc plays. The walls contain gas outlets alternately from the bottom to the top. When the air enters through one of the inlets it travels only a comparatively short distance along the arc, during which time the nitrogen combines with the oxygen, and the gas mixture formed is then withdrawn. The principal advantage claimed for the arrangement is that it is possible to reduce the velocity of the air current to a value which obviates all risk of blowing out the arc. (999,586, Aug. 1, 1911.)

A second patent of Mr. Pauling refers to the difficulty experienced with a long arc in a comparatively narrow shaft on account of the fact that the walls of the shaft being heated to a high temperature may become conductors and carry some of the current. This is prevented by subdividing the surface of the furnace walls facing the flame into a number of areas or elements, each of which is separated from the surrounding elements by gas passages which penetrate into the wall to such a depth as to obviate any risk of the wall acting as a conductor when it becomes hot. (999,587, Aug. 1, 1911.)

The long vertical arc of the Schoenherr furnace of the Badische Company was originally caused to play between a solid iron core as lower electrodes (where the air enters) and a hollow cooled upper electrode (where the gas mixture leaves). In their latest construction Dr. Otto Schoenherr and Mr. J. Hessberger employ a hollow cooled electrode also at the lower entrance end of the furnace, arranged in such a way that the starting point of the arc at this lower electrode moves about on its surface, while the arc as whole remains stable and stationary. (1,003,299, Sept. 12, 1911.)

In a patent of Mr. Johan Jetmund Thoresen, of Kristiania, and Mr. Filip Tharaldsen, of Meraker, Norway, the method is patented for treating air by means of an arc made to rotate by a rotary magnetic field. The process is described by reference to the induction motor in which the primary pole pieces produce a rotary magnetic field and this rotating field causes the secondary (the rotor or the armature) to rotate. "The electro-dynamic action between the electrically rotatory primary field and the current induced in the induction coils produces a torque, which causes the secondary core to rotate along with the said field. By preventing the secondary core as well as the coils from rotating and by making a rupture in the said coils and placing the ends of the rupture (electrodes) in the field perpendicular to the direction of the latter, an electric arc or series of electric discharges will be produced in the space between the cores, and the current will pass through said arcs perpendicularly to the field. The electro-dynamic force produced by the combined action of the current in the arcs and rotary field will cause the arcs to be deviated to one side and in the direction in which the field rotates. As the direction of the lines of force of the rotary field is determined by the shape of the field cores and the path of the arc being always perpendicular to the field, it is evident that by giving the field cores a cylindrical or other shape and moving the field accordingly the arcs will assume a cylindrical or other shape. By making the cores cylindrical and causing the field to rotate, the elec-

trodes being placed at suitable intervals, we obtain a continuous row of arcs, each forming a part of a cylindrical surface, and all the said arcs together constitute a complete cylindrical surface. The arc may be supplied with current from a separate single, two or three-phase transformer or from a source of direct current instead of supplying the same with current from the secondary coils. It may be necessary to have in series with the arcs a certain amount of self-induction in order to impede the flow of current. We can also connect the electrodes in series with the coils that produce the magnetic field." (996,951, July 4, 1911.)

Mr. CARLETON ELLIS, of Montclair, N. J., uses a long arc and causes it to revolve about its normal axis in the path of the current of air and at a slightly lower speed than the current of air. The extinguishing effect of the air blast is minimized by the almost equal speeds of arc and air, while "the aureola contact is greatly reduced over methods which involve the travel of the air longitudinally with the arc. The process therefore yields a large output with simplicity of furnace construction, small number of units and therefore reduced labor cost and maximum electrical efficiency." (1,002,249, Sept. 5, 1911.)

Ozone Generators.—The details of construction of an ozonizer, invented by Mr. LOUIS GOLDBURG, of Indianapolis, Ind., are well described in his third claim: "An ozonator, comprising a casing having a contracted inlet opening at one end, a block fitting within said casing adjacent to said inlet and having therethrough a plurality of distributed air passages communicating with said inlet, a cylindrical shoulder formed on said block, a tubular dielectric fitting said shoulder and adapted to be supported thereby in said casing, an outer electrode disposed around said dielectric tube, an inner electrode having screw-threaded connection with said block and located concentrically within said tube, said electrodes being formed to provide opposed projections distributed throughout the contiguous areas of said electrodes, the projections on one of said electrodes being uniformly spaced away from those on the other, the end of said casing which is opposite said contracted air inlet being arranged to permit said block, dielectric tube and electrodes to be readily withdrawn therethrough, and means for connecting said electrodes with a suitable source of electromotive force." (995,958, June 20, 1911.)

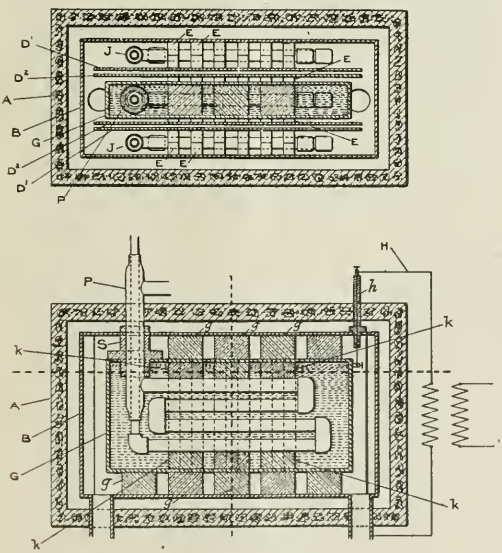

FIG. 17.—OZONIZER.

In an ozonizer of Mr. JAN STEYNIS, the chief feature is the elimination of some of the heavy insulation usually required. This object is obtained by grounding one side of the high-tension circuit and also grounding the cooling apparatus. Fig. 17 shows a plan and a central longitudinal vertical section of the ozonizer. *A* is the external casing, *B* is a box of thin metal connected to the grounded side of the circuit. On each of the longer sides of box *B* and on the inside thereof are a series of vertical metallic bars *E*, *E*, etc., which constitute the discharge points of the electrode. The bars *E* are perforated at intervals in a direction parallel to the longer side of the box, and through these perforations extend a series of metallic pipes forming a cooling coil *J* for receiving a gasified liquid, or in some cases cold water or brine. Since the said box *B* is grounded, the pipe coil need not be insulated as heretofore. Against the faces of the discharge bars *E* is placed a thin sheet of glass or micanite D^1 which is separated a slight distance from a parallel sheet of like material resting against the faces of similar discharge bars on the outside of the central electrode. Between these sheets passes the air to be ozonized.

The central electrode consists of an internal metallic box *G* with the vertical discharge bars *E*, *E*, etc., on its outer sides. The box is insulated from the surrounding box by blocks, *g*, *g*, etc., and is connected to one side of the circuit by a wire *H*, passing through and insulating tube *h* in the top side of the box *B*. Within the central metallic box *G* is a cooling coil *P*, like the coils *J*. It is, however, insulated by oil or other liquid insulator from the box *G* in which it is contained, being supported in the box by insulating blocks *k*, *k*, etc., and where it passes through the top side of the box the outgoing end is enlarged to receive within it the incoming end, and thereby call for only one insulating bushing *S*. The coil *P* will be connected to the coils *J* and to ground, so that the only insulation required in the apparatus is that for the central electrode. (997,339, July 11, 1911.)

Electrolytic Furnaces.

Partition for Electrolytic Furnaces.—In electrolytic furnaces partitions are sometimes required, for instance, for separating the anode gases from the metal deposited on the cathode. It has been proposed to form such non-conductive partitions by chilling a layer of the molten electrolyte itself against a water-cooled metallic curtain. However, it is not possible to maintain such layer of chilled electrolyte of sufficient thickness and at a sufficiently low temperature to avoid its conducting a portion of the current from the molten electrolyte to the curtain. Messrs. GEORGE O. SEWARD, of East Orange, N. J., and FRANZ VON KÜGELGEN, of Holcombs Rock, Va., in a patent assigned to the Virginia Laboratory Company, overcome this difficulty by using two curtains, side by side but insulated from each other,

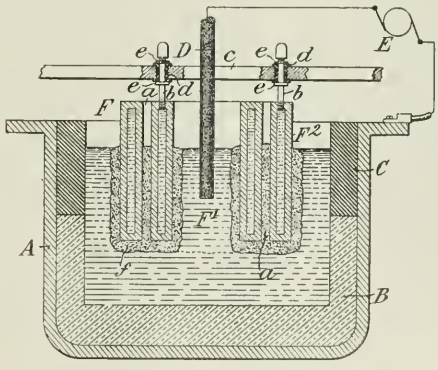

FIG. 18.—PARTITIONS FOR ELECTROLYTIC FURNACES.

instead of a single one. In Fig. 18 *A* is the circular electrolytic vessel or furnace with an insulating lining *B* in its lower part and a conductive carbon lining *C* at its upper part, which serves as anode. In the center of the furnace is the cathode *D*. Between anode and cathode is provided the non-conductive partition *F* which consists of two tubular concentrical cylindrical water-cooled curtains F^1 and F^2, between which is an annular

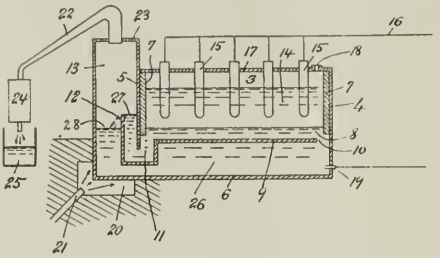

FIG. 19.—PRODUCTION OF METALLIC SODIUM FROM FUSED SODIUM CHLORIDE.

space *a*, which is kept filled with congealed salt or packed with insulating material, such as fire-clay or asbestos. (13,277, July 25, 1911.)

Metallic Sodium by Electrolysis of Fused Sodium Chloride.—In the electrolysis of fused sodium chloride with a cathode of molten lead the sodium set free at the cathode alloys with the lead and it is necessary to remove the sodium-lead alloy from contact with the molten electrolyte for two purposes: First to provide a fresh molten lead cathode surface ready to alloy with sodium, and second to recover the sodium from the sodium-lead alloy in the form in which it may be desired, for instance, as metallic sodium. For this removal of the lead-sodium alloy from the electrolytic cell, Mr. Robert J. McNitt, of Niagara Falls, N. Y., in a patent assigned to the Roessler & Hasslacher Chemical Company, makes use of differences of specific gravity to provide the circulation of the molten electrode material. Pure molten lead has a higher specific gravity than a molten alloy of lead and sodium. If, therefore, in Fig. 19 the channel 26 is first filled with molten pure lead and the compartment 8 (just above the partition 9) and the seal 11 with a molten alloy of lead and sodium on which rests the molten electrolyte 14 of sodium chloride, there will be a difference between the hydrostatic levels at the points 27 and 28. When a direct current is then passed from the anodes 15 through the sodium chloride 14 to the lead cathode 8 (electrical connection being made at 19 to the external circuit), the sodium chloride is decomposed, the sodium alloying with the molten lead 8. More sodium chloride is now fed into the cell, etc. Meanwhile, of course, a portion of the cathode alloy is forced down through seal 11 under wall 5, over wall 12 into the outside furnace chamber 13. In this chamber 13 the temperature is maintained high enough so that some or all of the sodium in the lead-sodium alloy is driven off by distillation and is condensed in 24. There remains back in 26 a weak alloy which returns through opening 10 into the electrolytic chamber 3. The difference of specific gravity is, therefore, utilized to maintain a difference of levels at 27 and 28 and therefore provide an overflow from 27 to 28. (995,476, June 20, 1911.)

Electrolytic Processes.

Mercury Cathode Cell.—A patent of Mr. Meyer Wildermann, of Ealings, London, England, refers to improvements in his mercury cathode cell, in which the mercury is contained in superimposed troughs (see our vol. I, page 589). The details of improvement are indicated in the first claims: "In electrolytic cells for the electrolysis of alkaline salts provided with a mercury cathode contained in superimposed troughs, with division ribs dipping into the mercury, with stirrers for mixing the mercury and amalgam on the anode side, with carbons floating on the mercury on the cathode side, the provisions of means for preventing the carbons from rising over a certain height in the troughs. (998,063, July 18, 1911.)

White Lead.—A process differing in various respects from his former white-lead process is the subject of a patent of Dr. Carl Luckow, of Cologne, Germany. While the specification

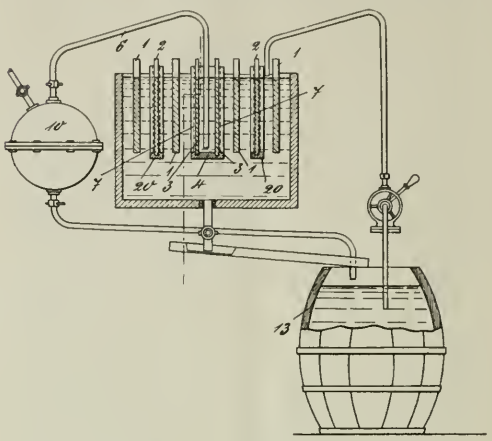

FIG. 20.—ELECTROLYTIC PRODUCTION OF WHITE LEAD.

relates in general to the electrolytic manufacture of difficultly soluble salts of heavy metals and gives data on the production of chrome yellow, Prussian blue and Paris blue and white lead, only the white-lead process will here be described. The anodes 1 of Fig. 20 consist of soft lead. The cathodes 2 are skeletons of soft lead or hard lead with active fillings of spongy lead oxide. To prevent enrichment of the electrolyte with caustic alkalies, the dilute solution caustic, as it is being formed during electrolysis, is constantly withdrawn by means of what is called "filtering cathodes" 3, 4. All the cathodes 2, including the filtering cathodes 3, 4, are inclosed with wooden frames 20 and filtering cloths 7. The electrolyte is a diluted solution containing from 1 to 2 per cent of a mixture of from 90 to 95 parts by weight of sodium chlorate and 10 to 5 parts of sodium carbonate calculated free from water. During electrolysis the carbonate and water are always added as they are consumed, while the soda-lye is always extracted, as it is

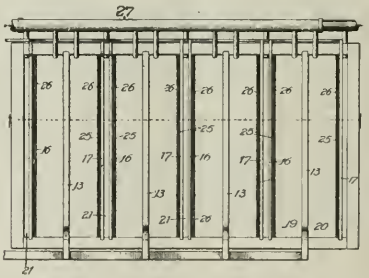

FIG. 21.—ELECTROLYTIC TREATMENT OF WASTE LIQUORS.

produced, from the filtering cathodes 3, 4, by means of a syphon 6 and passed through a receptacle 10 for carbonic acid into the tank 13, from whence it is fed back into the cell. (1,006,389, Oct. 17.)

Electrolytic Recovery of Waste Liquor.—In a patent assigned to the National Tube Company, Mr. Fred. F. Farnham, of McKeesport, Pa., recovers iron and sulphuric acid

from solutions of ferrous sulphate resulting from cleaning steel by means of sulphuric acid. He uses a diaphragm cell, in which diaphragms of asbestos 25 with an outer layer of burlap 26 (see Fig. 21) are fastened to the perforated lead anodes 16 and 17. The iron sheets 13 are the cathodes. Between each cathode 13 and the adjacent anodes 16 and 17 are formed the cathode chambers 19 and 20, while between adjacent anodes 16 and 17 the anode chambers 21 are formed. During electrolysis sulphuric acid accumulates at the anodes and iron is deposited on the cathode. The ferrous sulphate solution is fed from the inlet pipe 27 into the cathode compartments. It gradually seeps or filters through the diaphragms and the associated anodes into the anode compartments. While the solution is in contact with the anodes, sulphur dioxide is formed with the consequent formation of sulphurous acid, which is immediately oxidized to sulphuric acid, the reactions being $SO_2 + H_2O = H_2SO_3$ and $2\,H_2SO_3 + O_2 = 2\,H_2SO_4$. This sulphuric acid is withdrawn from the anode chamber through the outlet pipe. (1,006,836, Oct. 24, 1911.)

Synopsis of Metallurgical and Chemical Literature

Gold and Silver.

Melting Zinc-Box Precipitate.—Some interesting points bearing on the production of high-grade bullion from zinc-box precipitate is given in the August, 1911, issue of the *Monthly Journal* of the Chamber of Mines of Western Australia, by Messrs. J. B. AARONS and HERBERT BLACK. The authors were confronted with conditions which gave them low-grade bullion, and experimented with a view to raising the grade and thereby reducing refining and banking charges.

Their present procedure is as follows: All the precipitate and short zinc are sent to the acid vat, and only the well-washed long zinc is returned to the boxes. No scrubbing or screening of short zinc is attempted. After acid treatment the precipitate is filter-pressed, washed three or four times with hot water, dried with air and dropped into cast-iron trays, weighed and placed in a cast-iron muffle, where it is subjected to a roast at dull red heat, or merely dried. The dried or roasted precipitate is not screened, but is directly fluxed with borax and sand, and in some cases with nitre. A typical charge is 100 parts precipitate, 50 parts borax, 20 parts sand, and when nitre is used, 7 to 10 parts nitre. The charge is smelted in clay liners in plumbago pots and poured into conical molds. The bullion thus obtained is subsequently melted in plumbago pots and cast in bars of 500 oz.

The authors believe that it is easier to produce high-grade bullion direct from the precipitate than to produce low-grade bullion direct from the precipitate and afterward refine it; moreover, there is less chance of loss when the refining is carried out through the medium of the flux than in the refining of the metal. They further believe that if the acid treatment and subsequent washing are carried out thoroughly, roasting to dull red heat is unnecessary, and that drying at 100 degrees Centigrade is sufficient. The production of high-grade bullion is mainly a question of thorough acid treatment, careful washing, and the selection of the proper fluxes in the fusion. The use of fire-clay liners in the plumbago pots is a strong factor in the production of high-grade bullion, whether nitre is used or not, as it guards against the reduction of zinc from the zinc sulphate or silicate present.

Tables of figures are given to show that the use of nitre is not attended with the baneful effects usually attributed to that flux. Equal quantities of precipitate, one fluxed with nitre and the other without, gave results favorable to the use of nitre. Further evidence is offered in tables showing a comparison between the gold called for by assays of the precipitate and the gold recovered in bullion, showing practically no loss of gold.

A comparison between smelting in plumbago pots and clay liners in plumbago pots gives results very favorable to the latter, showing a higher grade and fineness of bullion. The use of nitre, however, is found to be unnecessary when clay liners are used.

As regards roasting to a red heat versus drying of the precipitate, the authors believe that the latter is all that is necessary unless the acid treatment is poorly done, or in the case of coatings of base salts on the zinc. In the latter cases roasting is necessary or else treatment with nitre in clay pots. With regard to the elimination of the base metals, zinc, copper and lead, thorough acid treatment and washing, with reduction in clay pots, should eliminate the zinc; nitre flux and the use of clay liners should remove the copper, and similar treatment should take care of the lead, although manganese dioxide may be added to facilitate operations.

The following deductions are made as a result of the authors' work: No screening of short zinc is necessary, the cost of extra acid being more than compensated for by the reduction of refining and banking charges. Acid treatment should be as complete as possible. Washing in the press is by no means sufficient and leaves much to be desired. Roasting at red heat is unnecessary except as noted heretofore; drying is all that is necessary. Clay liners to plumbago pots are essential to the production of high-grade bullion unless all the zinc salts can be washed out of the precipitate. The use of thees liners gives slags of lower value; more quiet fusion; the absence of obnoxious fumes and lower bullion realization costs.

Losses in Cyanidation.—Under this caption Mr. H. FORBES JULIAN discusses the relative merits of filtering devices, and some errors in their operation, in the October, 1911, *Mining Magazine*. Leaving out of consideration the losses which occur before filtering commences, the author assumes the preparation of a slime pulp of a consistency ranging from 1½ tons to 3 tons of liquid for one ton of solid, although this may be thickened to a consistency of 1 : 1.

Cake Formation and Thickness.—When filtering slime containing much amorphous matter it is well to apply a low suction, about one-quarter of the maximum, until the cake is about ⅛ in. thick, and then apply the maximum. Operators as a rule pay too little attention to this variation in vacuum, but keep it constant throughout cake formation. The thickness to which a cake is allowed to build up is a matter that must be determined by experiment, for it may be only ½ in. in the case of a gelatinous slime, or 2 in. when crystalline material is filtered. The rate at which the filtrate is drawn may be utilized to determine the best thickness.

The porosity of a cake is affected by the pressure of formation. Thus a cake deposited by vacuum contains 40 to 65 lb. dry ore per cu. ft., according to the specific gravity and fineness of the material, while the same material filter-pressed in a cake contains 70 to 110 lb. dry ore per cu. ft. This explains why high-pressure filters give thin, sloppy cakes from which the valuable solution has not been fully pressed, when filtering amorphous material, whereas the vacuum filter working on the same material forms thick, porous dry cakes.

Characteristics of Filter Cakes.—Vacuum filters will produce a thicker cake from so-called natural slime, and one that is more uniform in its porosity; but on crystalline material a pressure filter will produce a heavier cake in given time, but not heavier in proportion to the power expended, and not uniform. The cake formed on a vacuum filter is more uniform, being made up of a number of layers, whereas in the pressure filter, segregation is unavoidable. This makes washing more uniform in the vacuum filter. Moreover, in washing vacuum filter cake a turbid wash solution can be used which will soon adjust the porosity of the cake if there is any tendency to uneven flow.

Care of the Cake.—During the time the cake is exposed to air it must be handled with extreme care. If too high a vacuum is held it has a tendency to disturb the grain of the cake and disturb its even porosity. If suction is cut off entirely there is danger of portions of the cake falling off the filter. Vibrations also must be reduced to a minimum, as these disturb the integrity of the cake.

Washing the Cake.—When the cake is ready for washing

it contains 30 per cent to 35 per cent of its weight of valuable liquor, together with undissolved metallic gold and silver particles and compounds. The liquor may be washed out by water, but if the latter values are to be recovered they have to be removed by a solution wash. The solid gold and silver remaining in the pulp may be still in its natural state, or it may have been reprecipitated during the agitation process. In any event these solid particles dissolve slowly, the latter more so than the former, and therefore the rate of solution washing must be slow enough to give the necessary time for contact between the solution and the particles.

It is well known that in the dissolving and agitating process, a point is reached beyond which the cyanide solution will not dissolve any more gold. This is due to reaching a point of equilibrium due to the presence of various salts in solution. If it were possible to bring fresh, potent solution in contact with the pulp at that time, further solution could take place. This is exactly what is possible in washing a filter cake with barren solution, but sufficient attention is not paid to it.

Reprecipitation and Resolution.—Reprecipitated metal does not dissolve with the same readiness that is noted in the natural state. Reprecipitation is due to local action of physical and chemical forces. Graphite, tellurides, sulphides, arsenides, charcoal, grease, oils, and even silica or alumina in a finely divided state, precipitate gold and silver from working cyanide solutions, and this precipitate shows little tendency to again dissolve in the same solution. In fact, it is difficultly soluble in fresh solutions. Hence in washing a cake with solution for the purpose of removing as much as possible of the undissolved or reprecipitated gold time should be allowed for contact. A cake ¼ in. thick requires about as much time to be solution-washed as does one 2 in. thick.

Preparation and Application of the Wash Solution.—If it is not already aerated it should be treated to give it maximum oxidizing power, and if not already turbid it should have some slime added. It should be made stronger in cyanide than that originally used in the treatment tanks, and some free alkali should be added. In applying this solution it is necessary only to give it such a rate of flow as would prevent backward diffusion, but in practice this time cannot be allowed. Nevertheless, the time allowed should be as great as possible, and not as absurdly low as in some instances.

Water Wash.—The object of the water wash is to remove cyanide solution remaining in the pulp from the solution wash. This would appear to be a simple matter, but in practice it is found that a great deal more water must be drawn through the cake than that indicated by a simple calculation. A low vacuum throughout the whole wash is desirable for a maximum strength of filtrate, but a high vacuum at the start would save time if maintained no longer than is necessary to just withdraw the stronger portion of the filtrate. But even then some cyanide will be held by absorption, requiring time of contact to diffuse into the water wash. The more porous the cake the lower should be the vacuum, and the finer and more amorphous the material the longer should be the time of contact.

Washing by Filtration and Decantation.—The simplest of all methods of washing is by decantation, but in practice there are serious objections to it. The unavoidable loss of dissolved metal remaining in the pulp is the greatest. In filtering, the amount of dissolved metal left in the cake has no relation to the original richness of the solution. In decanting, the metal contents are removed by two to four washes or dilutions, while in filtering this is done by an infinite number of washes. If the total quantity of liquor used in the decantation process be made the same as in the filter process, say 3 : 1, the theoretical separation of dissolved metal by three decantations would be only 78.4 per cent. In practice 75 per cent would be considered fair work. In the filtration process with this same proportion of liquor there is no difficulty in removing 99 per cent of dissolved metal. But in order to get 99 per cent of dissolved metal by the decantation process it would require a total of 12 tons of wash liquor to 1 ton of solid. Wash waters generally contain small quantities of dissolved metal, and the solution in the residue pulp generally contains this metal in proportion to the amount of moisture retained, which for filtration is about 1 of solution to 2 of solid, and for decantation 1 : 1. Hence this loss in decantation is twice what it is in filtration. Again the wide difference in the quantity of wash water used in the two processes affects the cost per ton of ore. In filtration the amount of wash liquor used seldom exceeds twice the weight of the solid, while in decantation it is common to use five of wash liquor to one of solid. Finally reprecipitation and absorption are greater in decantation than in filtration, as the very dilution with water in the decantation process is sufficient to cause silica and alumina to precipitate and carry down gold and silver and cyanide.

The Brakpan Mill, Transvaal.—One of the newer cyanide mills on the Rand is that known as the Brakpan, in which are installed such modern features as zinc dust precipitation, agitation of slime in Pachuca tanks, and filtration in Butters vacuum filters. A complete description is given in the *South African Mining Journal* for Aug. 12, 1911.

The ore is first separated into coarse and fine portions, sorted, and the coarse portion crushed. The battery bins have a capacity of 6,000 tons of fine ore. Stamps of 2,004 lb. weight are used; at present there are 160 installed and provision is made for 40 more. The stamp heads are 42 in. long, 9½ in. in diameter and weigh 788 lb. Stems weigh 696 lb., and are 14 ft. 6 in. long and 4½ in. diameter. Tappets weigh 232 lb., and a shoe weighs 288 lb., and is 14 in. long and 9¼ in. diameter. Ten stamps are driven by one motor.

The stamped ore is distributed to the tube mill cones, which are of the Caldecott diaphragm type. There are six tubes, 5 ft. 6 in. by 22 ft., and provision is made for the installation of four more. The feed contains 35 per cent moisture. Following each tube is a set of five stationary amalgamation plates, 12 by 5 ft., with a grade of 18 per cent. The amalgamated pulp is classified in cones, the overflow going to the cyanide plant, while the underflow is returned to two of the tubes for further grinding.

The cyanide work is divided into separate treatment for sand by percolation, and slime by agitation. The pulp delivered to the cyanide plant is, therefore, classified into sand and slime by means of cones. The sand is delivered to the collection tanks with 30 per cent moisture, but additional water is added, so that clean sand is delivered to the 60-ft. collectors. The overflow of the collectors is again cone-classified to remove the last traces of sand from the slime. From the collectors the sand is conveyed by belts to a Blaisdell distributor which serves the treatment tanks. After treatment the sand is removed by a Bleichert system of aerial haulage running from beneath the tanks to a cantilever tower where it is dumped. This system was installed with a guarantee to dump tailings at a cost not to exceed three cents per ton.

The slime overflow of the classifying cones passes to slime collectors where it is allowed to settle. It is treated in six Pachuca tanks, 15 ft. by 45 ft., where four hours agitation is given. Stock tanks are placed between the Pachucas and the Butters Vacuum filter, the latter consisting of two boxes and a total of 330 leaves. The filtered solution is clarified in two sand filters, used alternatively, and passes to gold solution storage tanks. Precipitation is made by zinc dust in Merrill presses. The zinc emulsion is made in emulsifying cones in which the zinc dust is agitated with weak solution before being added to the gold solution. The solution from sand and slime treatment, together with the zinc emulsion, is pumped to the Merrill presses by three plunger pumps driven by 10-hp motors.

Electric power is used throughout the plant, the aggregate power of motors installed being 10,000 hp for mine and mill. In the mill the distribution of motors is as follows: Stamp battery and tube mills, 1950 hp; reductions works pumping plant, 1000 hp. The power supply is delivered through underground cables, paper insulated and lead covered. These cables are laid

on a ring system, so that supply can be maintained to any point through an alternative part of the system in the event of a break in any particular cable.

Zinc.

Electric Zinc Smelting in Sweden and Norway.—For several years extensive experiments have been carried out on the use of the electric furnace in zinc metallurgy in Sweden and Norway, as has been described repeatedly in this journal, but details have been maintained secret with great care. However, now information regarding the process has become available for the first time, owing to the controllers of the works seeking English and German capital for the purpose of continuing the trials and enlarging the plant. According to the October issue of the *Mining Magazine*, of London, an English company has been formed for the purpose of acquiring two electric smelting works, one at Sarpsborg, Norway, and one at Trollhättan, Sweden, and also the rights in connection with the construction of another at Tysse, near Odde, in Norway. The process and furnace used at these works are intended for the treatment of complex sulphide ores and other material, such as Broken Hill slime and the intimately mixed sulphides of lead, zinc, copper and iron that occur in large quantities in various parts of the world, at present of little or no commercial value. Reports have been made by J. C. Moulden for the Sulphide Corporation and by F. W. Harbord, the latter of whom made thorough tests of the plants at Sarpsborg and Trollhättan. The information here given is called from the reports of these experts:

"The electric furnace employed has carbon electrodes and the heating and melting of the charge is effected by resistance with a current of low voltage. One electrode is in the bed and the upper one is removable through the roof. The cross-section of the upper electrode measures approximately 2¼ sq. ft. In the first furnace the charge was introduced through the roof, but more recently the door is placed in the side and the operation is thus made more continuous. The capacity is 3 tons, and 2.8 tons of roasted ore can be treated per 24 hours. The horsepower per furnace is 350, and at Trollhättan the cost of power supplied by the hydroelectric company is 30s. 3d. ($7.56) per horse-power year. At Mr. Harbord's tests on roasted Broken Hill slime the energy used per ton of ore was 2078 kw-hours. There are 11 furnaces in Trollhättan. The roasted ore, coke or anthracite dust and flux are charged into the furnace, and most of the zinc and some of the lead is volatilized. The greater proportion of this is condensed as a crude spelter with high lead content, but much of it is precipitated as metallic fume and oxide, and has to be returned to the furnace in subsequent charges. The lead that is not volatilized is reduced as liquid metal, and it contains a considerable proportion of the silver. Matte is formed of the iron, copper and sulphur, if present in the ore, and some of the lead, zinc and silver passes into it. Some lead also escapes with the slag. The crude zinc is refined in other electric furnaces and the final zinc product is exceptionally pure, averaging 99.9 per cent and commanding a premium price in the market."

"At the time Mr. Harbord made his examination the furnaces were built of porous material, apparently similar to that used in old-fashioned zinc distilling retorts, and some of the lead and silver percolated through and had to be caught underneath; this he calls 'leakage' lead. He found also that the lead that exuded in this way during his experiments did not necessarily come from the charges under his observation and was partly produced during the treatment of other ore at an earlier period. Thus the silver contents of the lead did not at all coincide with that of the ore treated by him. The general results of his trials were by no means ideal, and he makes many suggestions for improvements; but his conclusions are that the process may easily be developed into one of prime importance, especially at the new plant proposed at Tysse, where the estimated cost of a horse-power-year is only 14s. ($3.50).

"During his experiments at Trollhätten seven furnaces treated during 27½ days, 518 tons of roasted Broken Hill slime, 19 tons of calamine, 22½ tons of zinc-lead powder produced previously, and produced 160.8 tons of crude zinc which by refining yielded 112.4 tons of pure zinc and 24.7 tons of lead, together with 36 tons of powder, in addition to which 41 tons of lead were tapped containing 141 oz. silver per ton and 'leak' lead amounting to 17 tons was recovered assaying 27 oz. silver per ton; also 9 tons of skimmings containing zinc, lead and silver. The recovery from these various sources was 64 per cent of the zinc, 74 per cent of the lead and 40 per cent of the silver, not reckoning the metals recovered in the powder form. Mr. Harbord goes into details as to many points where increased extraction and lower costs may be obtained."

"Mr. Moulden is of opinion that, by means of improvements already indicated, the extraction should eventually be 75 per cent of the zinc, 80 per cent of the lead and 80 per cent of the silver, and on this basis he figures the profit obtainable on slime bought from the Sulphide Corporation and shipped to Sweden. The slime is taken to average 32 per cent zinc, 23 per cent lead and 25 oz. silver, and on the current basis of payment would cost £2 16s. 8d. per ton at Broken Hill. The freight to Trollhättan would be £2 5s. 3d., making the total cost per ton at the smelter £5 8s. 5d. The value of the recovered metals on the percentage figured by Mr. Moulden would be £9 9s. 11d. The cost of treatment he estimates at £3 os. 7d., so that the margin of profit would be £1 9s. ($7.25) per ton of slime. It is unnecessary to say that the process is in its infancy and that already many improvements are obvious; also that everything depends on the cost of electric heat. Enough is shown, however, in these reports to make it clear that the process and method of metallurgy deserve close attention."

The subject is discussed by the *Mining Magazine* in an editorial which gives figures on the capitalization of the companies and contains the remark that "the present cost of electrodes is staggering, amounting to £204 ($1020) during the treatment of the 550 tons of material" in Mr. Harbord's tests. Attention is drawn to the fact that a great many other electrometallurgists are experimenting on the same lines and that "theoretically their furnaces both in principle and in method of construction are practically identical with those at Trollhättan, so the relative skill of manipulation, attention to detail, and cost of power will decide the actual success of any of these rival processes." It is further pointed out that "the practice in zinc metallurgy in retorts had been so much improved during the last year or two that the lead content is no longer a drawback; in fact, the buyers desire to have at least 5 per cent lead, for this is found useful in collecting the silver, and the leady residue left in the retorts is sent to the lead furnace." It had recently been said that the slime from Broken Hill, if concentrated by flotation and judiciously mixed with the zinc product, is profitably marketable. It appears, however, that, in negotiations with German and Belgian firms, all sorts of difficulties are raised, and when the sale of concentrated slime without admixture with zinc material is proposed the terms and conditions become impossible. Thus the Broken Hill producers are desirous of trying some alternative process for the purpose of realizing the great accumulations of slime. The Sulphide Corporation is the only Australian producer that is selling slime concentrate to the newly formed firm, operating in Sweden and Norway, the others apparently waiting for the Imbert process (see, for instance, our May issue, p. 259) to become established. This is under option in London to a Broken Hill group that had previously backed the Swedish-Norwegian venture.

Chemical Engineers.

Firing Boilers with Producer-Gas.—*Stahl und Eisen* of Oct. 26, 1911, p. 1771, contains some interesting tests on firing boilers with producer gas, made by the Compagnie des Mines d' Anthrazite de la Mure (Isère) a la Motte d'Aveillans (France). The boiler house contains three boilers with a total heating surface of 4521 sq. ft. Two of these boilers were

double cylindrical with fire tubes of 1615 sq. ft. each and the other was a double cylindrical boiler with water tubes above and of 1202 sq. ft. One fire-tube and one water-tube boiler were used for the test with a total heating surface of 2907 sq. ft. and heated by producer-gas which was generated in a Kerpely producer of 6.9 ft. inside diameter. Fuel was a slaty anthracite, obtained as a waste product from the mines, the size of the coal ranging from 4/5 in. to 2 2 5 in. Two coal analyses may be given:

	I.	II.
H_2O	3.31	2.9
Ash	23.35	22.7
Carbon	71.76	69.4
Vol. Matter	1.58	5.0

Ash analysis:

SiO_2	76.54 per cent
Fe_2O_3	8.84 per cent
Al_2O_3	4.30 per cent
CaO	4.42 per cent
Alcalis	5.90 per cent

Both boilers were filled up to a mark on the gauge glass when started, the test lasted 10 hours and the boilers were then filled up again to the same level. The feed-water temperature was 151 deg. F., and had been used before as cooling water in the water-jacket of the producer. The water was measured in a tank, the steam pressure was kept constant at 80.9 lb. per square inch. The arrangement had already worked for 10 days before the test without any trouble. The total evaporation during the ten hours of the test was 73,193 lb. of water, the coal consumption 11,850 lb., therefore evaporation 6.18 lb. H_2O per pound coal for feed water temperature of 151 deg. F. or 5.5 for water of 32 deg. F. This was very satisfactory since by direct firing this coal evaporated only 2.5 lb. of water per pound of coal. This was due to incomplete combustion on grates, due to its high content of slate. To gasify this coal is advantageous because it permits making use of this coal, of which only the better grades could be sold at all; moreover, the expenses for boiler firing are thereby considerably reduced. One man for a battery of boilers is enough to regulate the gas and air inlet at the burners. Having automatic coal feeders and ash removers, one man can handle two producers with a capacity of 88,184 lb. coal per day. It may be remarked that during the first four hours of the test the producer ran on cool gas with 4 5 per cent CO_2 (Period I). During the following six hours the producer was run somewhat hotter (Period II), causing a poorer gas with 7-8.5 per cent CO_2, but despite this fact the evaporation was higher than before. In the latter case the gas contained more sensible heat. From previous tests it is estimated that the temperature varied between 302 and 482 deg. F. (200 and 250 deg. C.).

During the first period of 4 hours 26,455 lb. water were evaporated, by 4060 lb. coal, which equals 5.3 lb. H_2O per pound coal; during the second period of 6 hours 46,738 lb. water by 6834 lb. coal, or 6.8 lb. water per pound coal. In other tests similar results were obtained on a slaty hard coal with 35-40 per cent ash, giving an evaporation of 6.5, the producer being run like Period II. In this case the gas main should be as short as possible to reduce radiation losses. For illustration, another example may be cited where a Kerpely producer was directly connected with a heating furnace, the coal was from the Saar district (Germany). In the beginning the producer was operated in the normal way, but since a few years the producer has been run on hotter gas, (but with more CO_2) and it was found that the furnace works better and with a lower coal consumption per ton of production.

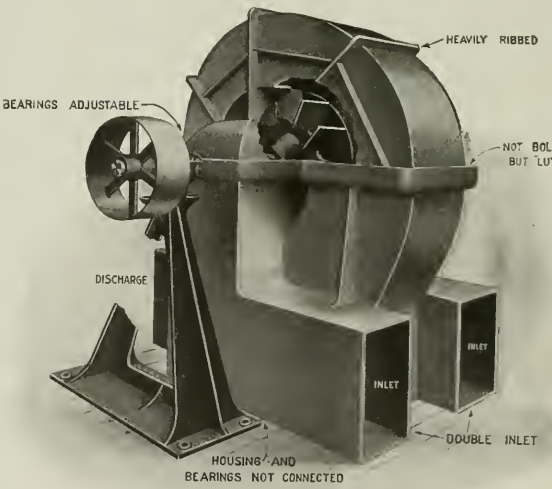
Induced Draft for Sulphuric Acid Chambers.

The advantages of fans for producing induced draft in the manufacture of sulphuric acid by the chamber process have long been known to acid manufacturers, but more or less difficulty has been experienced in designing and manufacturing a fan that would meet the requirements.

The principal advantages to be derived from induced draft are:



ACID FAN.

(1) Greater production per cubic foot of chamber volume

(2) Reduced cost of nitre per pound of acid so produced.

(3) Concentration of a greater amount of chamber stock to acid of 60 deg. Baumé in the Glover tower.

(4) Better absorption of nitre in the Gay Lussac towers on account of the proper excess of oxygen in the chamber process.

(5) Even draft on the sulphur burners.

(6) Successful use of intermediate towers, which are not successfully used where natural draft is used, except in rare instances.

Poor design and construction of fans have been one of the drawbacks to their successful use in induced draft. It would seem to be a simple matter to use a fan for this purpose, but on account of the limiting conditions there have been many

failures. The only material of which a fan for this purpose can be constructed is lead, for the gases are hot and corrosive; but, on the other hand, the great weight of lead and its tendency to distortion have been the cause of failure.

Various designs have been suggested. Some make use of a rigid metal such as iron, covered with lead, but in these the lead has a tendency to become separated from the iron and render the fan inoperative.

More designs have used overhung blast wheels where, on account of the necessary thickness and weight of the lead, the wheel has to be balanced perfectly and the journal boxes adjusted to a fine point. If these conditions are not observed, the blast wheel, projecting beyond the bearings into the fan housing, would revolve eccentrically; the great weight would bend the shaft, and the blades striking the housing would be broken; or the metal in the blades would become crystallized from vibrations and break. Considering the speed at which these fans must be operated, the possibility of breaking the blades becomes a source of danger as well as trouble and expense. Fans of this type also become unbalanced due to corrosion.

In order to overcome these difficulties and objections in acid fans, a design shown in the accompanying illustration has been made by Mr. N. L. Heinz and Mr. L. B. Skinner, who are practically engaged in acid manufacture. The machine is made and marketed by the Stearns-Roger Manufacturing Company, Denver, Col. It probably is more expensive to manufacture than other designs, but, when its service is considered, the increased cost is more than counterbalanced by continuous operation without constant attention and frequent repairs.

The lead alloy of which the fan and housing are made is of the proper mixture to resist acid corrosion, and the tensile strength of the metal is not impaired by improper handling. The blades are of the right number and shape to give the highest efficiency, fitting closely to the housing. The latter is heavily ribbed to give stability, and avoid the necessity of constant adjustment due to warping. The bearings of the fan are separate from the lead housing, thus reducing the possibility of tearing the latter by vibration. Accessibility is provided by luting the cover of the housing to the base, instead of bolting the two parts together.

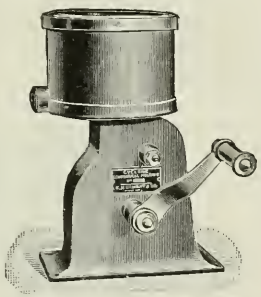


FIG. 1.—HAND-DRIVEN 5-IN. CENTRIFUGAL.

The general construction of this machine is such as to make the high rate of speed of the fan absolutely safe as far as possibility of accident is concerned. It operates at 475 r.p.m., and will furnish the gas necessary for the operation of a chamber set of 300,000 cu. ft. with intermediate towers. The approximate shipping weight of the machine is 7500 lb.

Centrifugals for Laboratory Work.

One of the quickest and most efficient methods to remove crystals and precipitates from mother-liquors and solutions is undoubtedly to use centrifugal force.

This fact is amply demonstrated by the enormous amount of large centrifugals in use in many industries. In the laboratories of chemical and pharmaceutical factories, sugar works, dye-houses, technical schools and metallurgical industries, the only difficulty which has heretofore prevented the use of smaller centrifugals has been their relatively high price and bulkiness as they were generally the reduced models of the big machines.

In the accompanying illustrations, however, is shown a centrifugal which, on account of its compactness and extreme simplicity, can be produced at a much lower cost than has heretofore been possible.

The Chavant "cyclone" laboratory centrifugal has been on the market for many years. It was formerly made in Jersey

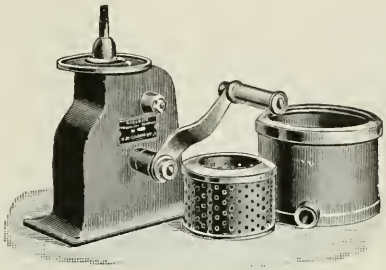

FIG. 2.—BASKET AND CASING REMOVED.

City, N. J., but the works were recently moved to Fontenay-sous-Bois, France, where a larger plant and better manufacturing facilities were to be had with the enormous European field near at hand.

The design and construction of the "cyclone" centrifugal have been improved in many respects. The new model, known as

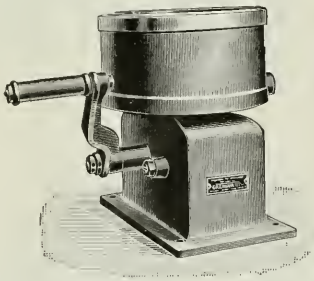

FIG. 3.—HAND-DRIVEN 8-IN. CENTRIFUGAL.

Type "F," is made in three sizes: 4½, 5 and 8 in., and is furnished with a crank for hand-drive or a pulley for power-drive. The machine, mounted on ball-bearings, is exceptionally light-running and can be operated at high speed without any perceptible vibration.

Fig. 1 shows type F, 4½ and 5-in., hand-driven. In Fig. 2

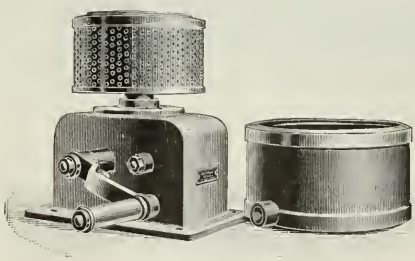

FIG. 4.—CASING REMOVED.

basket and casing are removed. Fig. 3 shows type B, 8-in., hand-driven, while Fig. 4 shows the same with casing removed.

There are no pulleys or belts in the internal mechanism, which consists of machine-cut gears, made with the greatest accuracy by special machinery in order to insure long wear and easy running.

The gears, lubrified by outside oilers, are encased in the base casting fully protected from dust, but can be easily reached for cleaning as no part has to be unscrewed.

The basket and also its casing are detached by simply lifting them off the machine and they can be replaced instantly.

The basket is made of bronze and brass and is perfectly balanced. For acid products it is tinned and its casing lined with porcelain. A hard rubber basket can be supplied too.

For all "cyclone" centrifugals the manufacturer guarantees that with a maximum of 70 revolutions of the crank or of the pulley per minute they will give all the results which shall be expected from a first-class laboratory centrifugal.

The general sales agent of the company is Mr. Victor J. Boulin, with offices at 123 Liberty Street, New York City.

Repair of a Large Rock-Crusher Shaft.

A repair of exceptional size was recently executed for the North River Stone Company, of Kingston, N. Y., on one of its rock-crusher shafts. The shaft in question was 18 ft. long and ranged from 12 in. to 22 in. in diameter. It was 14 in. in diameter at the point of fracture.

It was decided to make the repair by the thermit process, but owing to the fact that there were not adequate facilities at Kingston for aligning the pieces accurately, they were sent to the Jersey City shops of the Goldschmidt Thermit Company, where they could be placed in V blocks, mounted on a perfectly level bed plate and so lined up accurately, previous to welding them together.

There is no necessity to describe here again the well known thermit reaction of Dr. Hans Goldschmidt between aluminium and iron oxide, yielding a slag of alumina and as chief product a molten highly superheated low-carbon steel, available for welding. By mixing steel punchings with the thermit the carbon content of the thermit steel is increased, and the quality of the steel is also improved by the addition of other materials such as manganese, nickel or chromium.

The temperature attained by the reaction is approximately

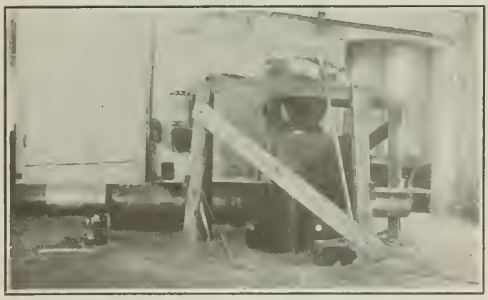

FIG. 1.—PREHEATING SHAFT PREVIOUS TO WELDING BOX AND CRUCIBLE IN POSITION.

5400 deg. Fahr. and it will readily be seen that by pouring this superheated steel into a mold surrounding the ends of the sections to be welded together it will dissolve the metal with which it comes in contact and amalgamate with it to form a single homogeneous mass when cool.

In welding the large shaft for the North River Stone Company a space of 2½ in. was provided between the ends of the sections to be united by cutting away the broken faces to this extent, after which a pattern of yellow wax was formed about the sections in the shape of a collar 14 in. wide and 2 in. thick at the middle point. In cross-section this collar resembled in shape a segment of a circle. A sheet-iron mold box was then placed in position and rammed with special molding material, consisting of a mixture of one-third fire clay, one-third ground fire brick and one-third fire sand. Ordinary molding material would not be sufficiently refractory to withstand the high temperature of the thermit steel.

Wooden patterns were used for two pouring gates, a riser directly over the top of the weld, and a small preheating opening at the bottom. The flame of a powerful gasoline compressed air torch was then directed into the preheating hole and melted out the wax, thus leaving the mold ready for pouring.

The preheating, however, was continued for a period of ten

FIG. 2.—VIEW AFTER WELD IS FINISHED, BUT BEFORE CUTTING OFF METAL LEFT IN POURING GATES AND RISERS.

hours so as to thoroughly bake the mold and bring the sections to be welded together to a bright red heat, at which time the torch was withdrawn, the preheating hole closed up and the thermit charge, held in two crucibles suspended over the pouring gates of the mold, ignited.

The thermit charge for this repair consisted of 1100 lb. of thermit, 275 lb. of steel punchings, 11 lb. pure carbonless manganese and 11 lb. of chromium thermit. These were all thoroughly mixed with the thermit in the crucibles.

The thermit reaction required about 35 seconds for completion, but the charge was held in the crucibles a few seconds longer so as to allow time for the slag to thoroughly separate from the steel. The slag, being lighter than the steel, floats to the top of the crucibles, while the steel sinks to the bottom. The crucibles are tapped from the bottom, so that the steel flows into the mold first, being led to the lowest point of the mold, then up between and around the sections to be welded into the riser. The slag does not enter the mold at all, but merely overflows.

It is important that the metal in the weld be allowed to cool slowly and in the case of this 14-ft. shaft the mold was left undisturbed for a period of 45 hours, after which it was broken up and the steel left in the riser and pouring gates removed by means of a cutting flame of oxygen and illuminating gas.

The entire repair was carried out in less than a week, including the time required for towing the shaft on a barge from Kingston to New York and back again. This alone took over two days.

The thermit steel collar or reinforcement was not machined off, as it did not interfere with the operation of the shaft and added considerably to the strength of the repair.

If the thermit process had not been available for this work, the owners would have been forced to wait several weeks for a new shaft, while the cost of a new shaft alone would have amounted to several times the cost of the weld.

Mr. Paul O. Abbé announces the opening of an office at room 1201, Johnston Building, 30 Broad Street, New York City, as a builder of jar and pebble mills in all styles and sizes and as agent for the sale of mixers, sifters, vacuum pumps, pressure blowers, and bolting cloth of various makes.

Frictionless Ink-Type Recording Instrument.

An illustrated description of Bristol's patented semi-transparent smoked chart recorder was printed in our issue of January, 1908 (Vol. VI, p. 35). Although these recorders are fundamentally simple in their construction and hundreds are in daily service, there has been a call for a recorder in which the record is made with ink. To meet the demand for a frictionless ink-type recording instrument which would parallel

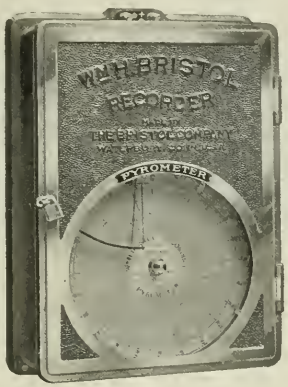

FIG. 1.—OUTSIDE VIEW OF RECORDER.

the smoked-chart recorder as nearly as possible in intrinsic simplicity, and accurately record fractions of millivolts and be adapted for use as a recording electric pyrometer, the instrument illustrated herewith has been developed and placed upon the market by the Bristol Company, of Waterbury, Conn.

These instruments have been thoroughly tested out in practical service for two years past, and are the result of several years of study and experience with an original design patented

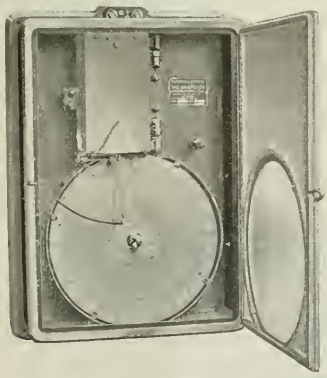

FIG. 2.—INTERIOR VIEW.

by Prof. Wm. H. Bristol on April 13, 1909, of a frictionless ink recorder using a hinged electrical movement carrying a retaining receptacle for marking fluid which extends over the path of the recording tip, and is provided with means for periodically making contact with the source of marking fluid and the chart.

Fig. 1 shows the recorder ready for operating.

Fig. 2 is an interior view showing the galvanometer movement case hinged to the back of the instrument and carrying the inking pad in front of the recording arm.

Fig. 3 shows the sensitive electrical movement swung to one side for convenience in removing the record and inserting a fresh chart. The capillary gold tube open at both ends is carried at the end of the recording arm at right angles to the surface of the chart. The inking pad is suspended from the case of the electrical movement and is curved to correspond with the arc covered by the motion of the end of the recording arm.

When the movement is swung back into its operating position, as shown in Fig. 2, the recording arm can swing free, accommodating itself to the position corresponding to the delicate current which is to be measured. The clock which revolves the chart at the desired speed also automatically presses the inking pad toward the chart every 10 seconds, bring-

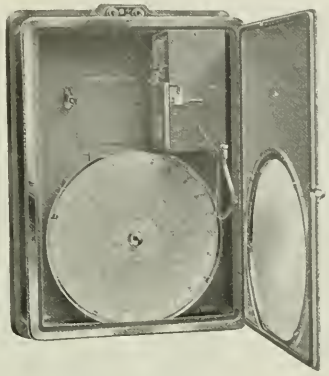

FIG. 3.—INTERIOR VIEW.

ing one end of the capillary tube into contact with the chart and the opposite end simultaneously into contact with the inking pad. A fine dot of ink is left on the chart and the capillary tube is replenished with ink from the pad. The recording arm thus carries a constant supply of ink, and its perfect balance, which is very important, is always maintained. The electrical movements used in these recorders are made especially for this purpose by the Weston Electrical Instrument Company.

Although the most important applications of these recording instruments have been for pyrometers, they have also been used for electrolytic research, recording voltmeters and recording shunt ammeters.

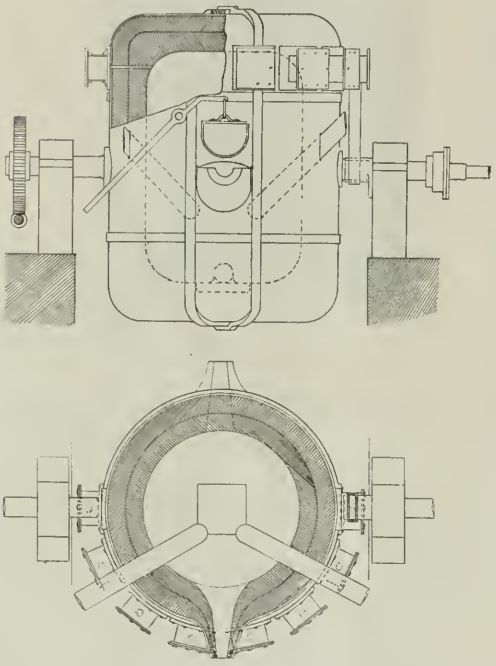
In the determination of sulphur in ores difficulty is frequently encountered in getting all the sulphur in solution before it separates out and collects in a globule of elementary sulphur. When this condition occurs it necessitates longer treatment to dissolve the sulphur. In order to overcome this obstacle, E. H. Westling proceeds as follows: The solvent used is nitric acid of 1.35 sp. gr. with a little dissolved potassium chlorate, at a temperature of about 60°C. The boiling point of this mixture is below the melting point of sulphur, and if the ore pulp is added gradually to the solution sulphur will not separate out but will be dissolved without difficulty. Rapid and complete decomposition is claimed for this procedure.

The Blum Zinc Oxide Process, which is protected by U. S. patent 993,019, consists in heating a charge made up of alternate layers of fuel and mixed zinc ore and fuel. It has been customary to carry out this process on a perforated grate, after the manner of the Wetherill process. Mr. Blum, however, proposes to use a pot like those used in the Huntington-Heberlein roasting system. The layers of alternate ore and fuel are 10 cm thick. The fuel is anthracite fine, both for mixing with the ore layer and for the fuel layer. The advantage claimed is large capacity as compared with Wetherill grates.

Electro-Bessemer Furnace.

In this issue, in the department of Recent Metallurgical and Chemical Patents, an interesting patent of Messrs. Walker and Gray, of the U. S. Steel Corporation, is mentioned, describing a steel refining furnace, which is first operated as an open-hearth and then as an electric furnace, thus obviating the necessity of transfer of the molten metal from one furnace to another.

The analogous idea for Bessemer converter practice is incorporated in the Electro-Bessemer furnace, designed by Messrs. Verdon Cutts & Hoult, 43 Edge Hill Road, Sheffield, England. This furnace was recently described in a paper by Mr. Verdon O. Cutts before the Staffordshire Iron and Steel Institute. After reviewing the different types of electric furnaces in general and those for iron ore reduction and steel refining in particular, Mr. Cutts described the Electro-Bessemer furnace as follows:



ELECTRO-BESSEMER FURNACE.

"The primary object which we had in view in designing this furnace was the reduction of working costs. We recognized the fact that the cost of electrical energy very considerably affects the cost of steel manufacture in the electric furnace. Our experience in important steel works both in this country and on the Continent has revealed a very high cost of generating electrical energy, and, in my opinion, this has proved sufficient at least to delay the adoption of the electric furnace in many steel works. It was, therefore, our object to produce a furnace in which electrical energy is only used where it offers unique advantages over other methods. A careful analysis of the subject shows that the value of the electrical process lies not so much in the making of the steel as in the finishing of the same. This has also been recognized by Héroult, Girod, and others, and accounts for their furnaces being now largely employed for the treatment of steel made in the ordinary Bessemer converter or open-hearth furnace. By our process the steel is made by the usual Bessemer method and finished electrically without it being necessary to pour the molten metal from one vessel to another during the refining operation. The loss of heat and expenditure of labor which are inseparably connected with the duplex process above referred to are thus avoided in the Electro-Bessemer furnace, resulting in a comparatively very high efficiency.

"Further, the Electro-Bessemer furnace is less dependent upon skilled manipulation than is the alternative combination of separate Bessemer and electric furnaces. . . .

"The many complicated designs which have been originated during the past few years have proved conclusively that the safest and shortest way to practical success is the utmost simplicity in construction, and the incorporation of old, well-known and successful methods with new processes. This we have kept well in mind, and the Electro-Bessemer process, as already suggested, combines in principle the ordinary Bessemer furnace and the electrical refining process. The result is that steel is produced cheaply and quickly as in the Bessemer furnace, and the disadvantage of lack of uniformity in steel so produced is entirely overcome by applying the electrical process of final refining.

"The Electro-Bessemer furnace is a closed vessel, having an opening in one side, through which the charge may be introduced and slags added and withdrawn. It is mounted on bearings, and is capable of being tilted within an angle of rather more than 180 degrees. One end of the furnace is fitted with blast tuyeres for blowing. At the other end of the vessel electrodes are arranged, entering through the furnace wall and being adjustable by any of the ordinary independent methods, either electrical or mechanical. A tapping hole is provided at this end of the furnace, which may be used for the removal of the finished product, if desired. Samplings may be taken from the charging opening, which opening might also be used, if desired, for pouring molten metal. The electrodes are fitted with cooling jackets of cold air or water.

"The process is simple in the extreme, being briefly as follows. The furnace is preheated in the ordinary way, and is then charged with molten metal direct from the cupola or blast-furnace mixer, the furnace being tilted into a horizontal position. It is then brought into a vertical position, the "Bessemer" portion containing the charge. The blast comes into action automatically as this position is gained, and the process of conversion proceeds as in the ordinary Bessemer converter. Meantime the "electric" portion of the furnace is heated by the hot gases, etc., resulting from the process, and for the ultimate removal of which gases ample provision is made. On the completion of this part of the process the furnace is tilted and the metal transferred to that end which is provided with electrodes. Current is switched on, and the refining operation continued to any desired extent. Both arc and resistance heating are obtained in the furnace.

"The Electro-Bessemer furnace may be either basic or acid lined; if it is basic lined it is possible to start with impure basic Bessemer pig-iron and to produce finished steel or better analysis than the best acid open-hearth steel. If the furnace has an acid lining, chemical refining of the blown metal does not take place, but the killing of the metal by heating in the 'electric' end of the furnace results in the production of particularly sound castings and ingots free from blow-holes.

"The utilization of the flame from the Bessemer blowing for the heating of the 'electric' hearth results in a considerable saving of electrical energy during the second stage.

"Having poured away the slag containing the bulk of the impurities at the end of the Bessemer blow (assuming a basic lining), new, clean, purifying slags can be added.

"Assuming that the phosphorus content is already low when the electrical operation commences, the energy consumption is less than 100 kw. hours per ton of steel produced. If, however, both desulphurization and dephosphorization are included, about 190 kw. hours are consumed."

Automatic Controllers for Motor-Driven Machinery.

The Electric Controller & Manufacturing Company, of Cleveland, O., has recently placed on the market a line of automatic controllers designed for the specific purpose of giving the utmost convenience in the control of motor-driven machinery.

It has been estimated that the output of many machines can

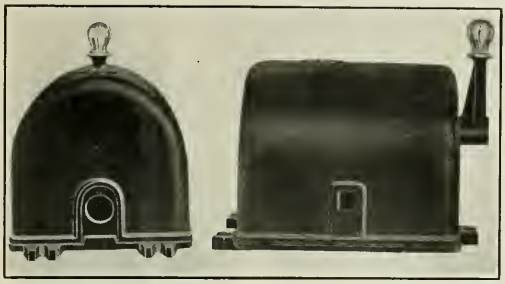


FIG. 1.—FRONT VIEW AND SIDE VIEW OF OPERATOR'S SWITCH.

be increased 20 per cent by the central grouping and convenient arrangement of all the operating levers. "Handiness of control" is recognized as being very important in securing the utmost production from a machine, and the automatic controllers described in this article were designed to provide this "handiness of control" for starting, stopping or reversing the motor and machine.

FIG. 2.—ACCELERATING UNIT.

The controller consists of a small operator's switch, shown in Fig. 1, and an accelerating unit which automatically accelerates the motor during starting and retards it during stopping. This accelerating unit is built in four different types, two of which are shown in Figs. 2 and 3.

The controllers are built in three types to secure: First, non-reversing and electric braking; second, reversing without electric braking; third, reversing and electric braking. In each type a variety of four different forms of accelerating units are

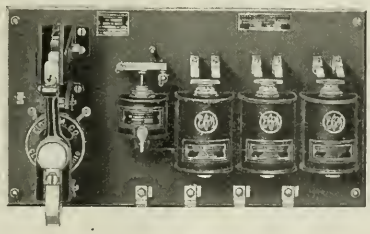

FIG. 3.—ACCELERATING UNIT.

offered. These accelerating units vary in their design from a simple train of accelerating switches up to a unit having a fused service switch, a train of accelerating switches, and complete circuit-breaker features.

The accelerating unit automatically accelerates or retards the motor through the action of series-wound accelerating switches which possess the remarkable characteristic of acting, not only as switches, but as current limit relays as well. When the current in the winding of one of these switches exceeds a predetermined value the switch locks open and cannot close until the current is reduced to the proper value.

When the operator's switch is thrown to the running position, current flows through the motor, through all of the starting resistance, and through the coil of the first series wound accelerating switch. As the motor accelerates the current drops, and when it reaches the correct value the first accelerating switch closes, cutting out a portion of the starting resistance. The succeeding accelerating switches operate similarly, ultimately cutting out all of the starting resistance and putting the motor across the line. By throwing the operator's switch to its original position, the motor is disconnected from the line and consequently stops. Different positions of the handle of

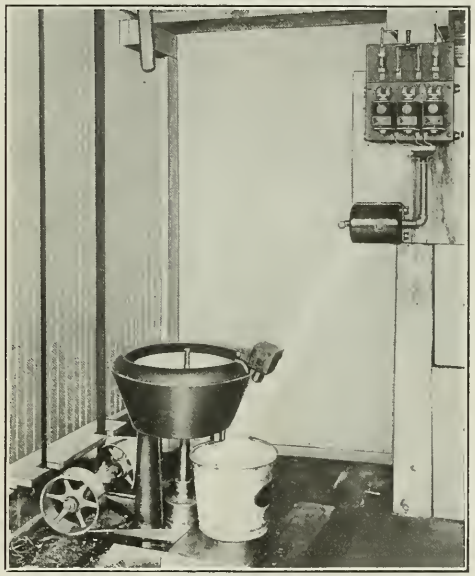

FIG. 4.—MOTOR-DRIVEN CENTRIFUGAL OIL EXTRACTOR EQUIPPED WITH AUTOMATIC CONTROLLER.

the different types of operator's switch provide for drifting, reversing, or rapid stopping by dynamic braking.

Electric braking is secured by a change of connections, accomplished by the operator's switch, which first inserts all the starting resistance in series with the armature. The motor is then quickly and evenly brought to rest by automatic electric braking, the accelerating switches, in this case, acting as retarding switches by cutting out, step by step, the resistance as the current, generated by the motor, decreases due to the slowing down of the motor.

The manufacturers claim the following important advantages for this automatic controller:

It limits the acceleration and retardation current at all times to a safe value.

It accelerates and retards the motor in the minimum safe amount of time, and automatically varies the time of acceleration and retardation, depending upon the load which the motor has to start and stop.

It provides the best conditions for good commutation.

By limiting the current, both in starting and stopping, it limits all mechanical strains on the motor and driven machinery.

It obviates the necessity of mechanical clutches on many motor-driven machine tools.

It adds very materially to the safety of an installation, since in case of accident the motor may be quickly stopped.

It inherently provides no-voltage protection, for if the voltage fails the switches drop open, and upon the return of volt-

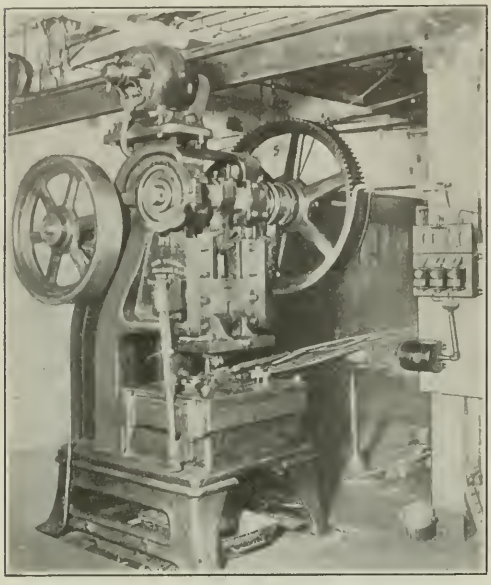

FIG. 5.—MOTOR DRIVEN PUNCH PRESS EQUIPPED WITH A TYPE H. N. B. FORM A. K. AUTOMATIC CONTROLLER.

age they automatically close in their regular method and sequence, again accelerating the motor to full speed.

Fig. 4 shows a motor-driven centrifugal oil extractor equipped with a type H N B, from A K automatic controller, Fig. 5 a motor-driven punch press equipped with the same type of controller. In both illustrations the automatic controller can be clearly seen on the right of the picture, the operator's switch being placed right below the accelerating units.

Census Report on Sulphuric, Nitric and Mixed Acids.

A preliminary statement of the general results of the thirteenth census of establishments engaged in the manufacture of sulphuric, nitric and mixed acids has just been issued by Director Durand, of the Bureau of the Census in the Department of Commerce and Labor. It was prepared under the direction of William M. Steuart, chief statistician for manufactures, Bureau of the Census. The figures are subject to such revision as may be necessary after a further examination of the original reports.

There were 42 establishments engaged in this industry in 1909 and 32 in 1904, an increase of 31 per cent.

The capital invested as reported in 1909 was $18,726,000, a gain of $5,964,000, or 47 per cent, over $12,762,000 in 1904. The average capital per establishment was approximately $446,000 in 1909 and $399,000 in 1904

The value of products was $9,884,000 in 1909 and $9,053,000 in 1904, an increase of $831,000, or 9 per cent. The average per establishment was approximately $235,000 in 1909 and $283,000 in 1904, a decrease of 6 per cent.

The cost of materials used was $5,386,000 in 1909, as against $4,973,000 in 1904, an increase of $413,000, or 8 per cent. In addition to the component materials which enter into the products of the establishment for the census year there are included fuel, rent of power and heat, and mill supplies.

The value added by manufacture was $4,498,000 in 1909 and $4,080,000 in 1904, an increase of $418,000, or 10 per cent. This item formed 46 per cent. of the total value of products in 1909 and 45 per cent. in 1904. The value added by manufacture represents the difference between the cost of materials used and the value of products after the manufacturing processes have been expended upon them. It is the best measure of the relative importance of industries

The miscellaneous expenses amounted to $916,000 in 1909 and $713,000 in 1904, an increase of $203,000, or 28 per cent. Miscellaneous expenses include rent of factory or works, taxes and amount paid for contract work, as well as such office and other expenses as cannot be elsewhere classified.

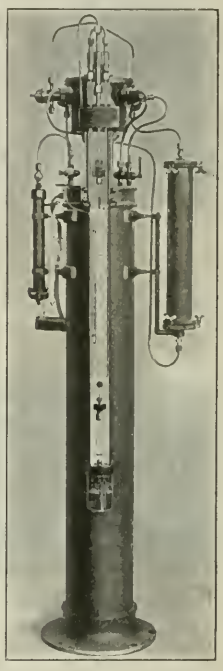

FIG. 1.—CONTINUOUS CARBON DIOXIDE AND TEMPERATURE RECORDER.

The salaries and wages amounted to $2,046,000 in 1909 and $2,062,000 in 1904, a decrease of $16,000, or 1 per cent.

The number of salaried officials and clerks was 330 in 1909 and 308 in 1904, an increase of 7 per cent; their salaries decreased from $556,000 in 1904 to $551,000 in 1909, or 1 per cent. The average yearly salary per official or clerk, therefore, decreased from $1,805 in 1904 to $1,670 in 1909.

The average number of wage earners employed during the year was 2252 in 1909 and 2447 in 1904, a decrease of 8 per cent; their wages decreased from $1,506,000 in 1904 to $1,495,000 in 1909, or 1 per cent. The average yearly wages per man, therefore, increased from $615 in 1904 to $664 in 1909.

The primary horse-power was 6494 in 1909 and 5416 in 1904, an increase of 20 per cent.

The average horse-power per establishment, considering all establishments, was approximately 155 horse-power in 1909 and 169 in 1904.

The total production of sulphuric acid, reduced to 50 deg. Baume, was 2,797,723 tons in 1909 and 1,869,446 in 1904, an increase of 50 per cent. Of this total 933,848 tons were reported in 1909 and 467,614 in 1904 by establishments making it as a chief product, an increase of 100 per cent.; 621,801 tons in 1909 and 433,377 in 1904 by establishments engaged primarily in the manufacture of other products, and 1,242,074 tons in 1909 and 968,455 in 1904 were made and consumed in establishments where manufactured.

The total production of nitric acid was 138,086,565 pounds in 1909 and 108,380,387 in 1904, an increase of 27 per cent. Of this total 8,396,326 pounds were reported in 1909 and 30,306,555 in 1904 by establishments making it as a chief product, a decrease of 72 per cent.; 18,929,620 pounds in 1909 and 15,927,526 in 1904 by establishment engaged primarily in the manufacture of other products; and 110,760,619 pounds in 1909 and 62,146,306 in 1904 were made and consumed in establishments where manufactured.

The total quantity of mixed acid manufactured in 1909 cannot

be shown because the amount made and consumed in establishments where manufactured was not reported; but the quantity manufactured by establishments making it as a chief product and by those reporting it as a by-product was 57,182,168 pounds in 1909, compared with 65,331,327 in 1904, a decrease of 12 per cent.

The production of establishments making mixed acid as a chief product was 45,361,626 pounds in 1909 and 42,812,894 in 1904, an increase of 6 per cent.

A comparative summary follows, giving the general statistics for the industry in 1904 and 1909:

SULPHURIC, NITRIC AND MIXED ACIDS—GENERAL SUMMARY, 1909 AND 1904.

	—Census.—		Per cent. of increase,
	1909	1904.	1904-1909.
Number of establishments	42	32	+ 31
Capital	$18,726,000	$12,762,000	+ 47
Cost of materials	5,386,000	4,973,000	+ 8
Salaries and wages	2,046,000	2,062,000	— 1
Salaries	551,000	556,000	— 1
Wages	1,495,000	1,506,000	— 1
Miscellaneous expenses	916,000	713,000	+ 28
Value of products	9,884,000	9,053,000	+ 9
Value added by manufacture (products less cost of materials)	4,498,000	4,080,000	+ 10
Employees:			
Number of salaried officials and clerks	330	308	+ 7
Average number of wage earners employed during the year	2,252	2,447	— 8
Primary horse-power	6,494	5,416	+ 20

Continuous Carbon Dioxide and Temperature Recorder.

In connection with the paper of Mr. Edward A. Uehling, printed elsewhere in this issue, a description of the Uehling continuous carbon-dioxide and temperature recorder should be of particular interest. It is made by the Uehling Instrument Company, of Passaic, N. J., and consists of a carbon dioxide and temperature measuring machine as shown in Fig. 1, to which are connected by small copper tubing standard type M Uehling pressure and vacuum recorders, properly calibrated for CO_2 or temperature.

Indicators of the standard type Z construction, which are based on the elementary U-tube principle may of course be connected to the machine in addition to the recorders. Thus, for instance, a standard equipment for a boiler plant would consist of the carbon dioxide and temperature machine shown in Fig. 1, which has at the front a CO_2 and a temperature indicator, and in addition to this machine an additional indicator located at the boiler front, and two type M recorders located in the engineer's office, one calibrated for CO_2, and the other for temperature.

Another style machine is shown in Fig. 2. This is a double combined machine, making two measurements of CO_2 and two measurements of temperature. It will be noted that at the front of the machine there are two indicators for temperature and two for CO_2. The full equipment comprises two other indicators placed at the front of the boilers, for the CO_2, and four standard recorders, two calibrated for temperature and two calibrated for carbon dioxide.

The two styles of machines illustrated and the two equipments above described are typical of the numerous arrangements which are possible when a continuous carbon dioxide and temperature machine of this type is used. Standard-style machines include those giving four measurements of CO_2 and no temperature measurements, or again, three measurements of CO_2 and one of temperature, or two measurements of CO_2, or else simply one measurement of CO_2. In every case the equipment can consist of as many recorders and indicators as desired, although the standard equipment comprises extra indicators at the boiler front for CO_2 and one standard recorder for each measurement of CO_2 and temperature.

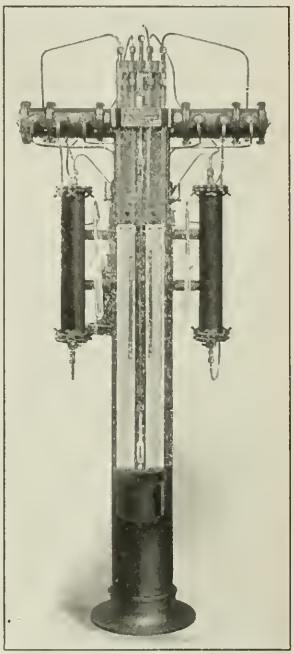

FIG. 2.—DOUBLE CO_2 AND TEMPERATURE RECORDER

This flexibility of equipment as also the ability to use standard recorders and indicators, and to obtain continuous measurement, all follow from the fact that the Uehling continuous carbon dioxide temperature machine operates on the pneumatic principle. By suction apparatus in the machines, a constant vacuum is maintained which draws the gas to be analyzed for CO_2 through two apertures Between the two apertures, the CO_2 contents of the gas are removed by caustic potash. The more CO_2 contained in the gas, the more is removed and the less gas has to pass through the last aperture, and therefore the higher will be the vacuum between the two apertures, so that the vacuum or suction in this chamber becomes a measure of the amount of CO_2 contained in the sample of gas drawn from the boiler. A vacuum indicator and recorder connected to this chamber will measure the per cent CO_2, and readings can be obtained if the CO_2 chart is properly calibrated.

The same principle is applied to measuring the temperature. Here, however, the two apertures through which the gas, or air, as it is in this case, passes, are not kept at the same temperature. In applying the pneumatic principle to the measurement of temperature, one aperture is located in a nickel tube which is placed in the hot gas whose temperature is to be measured, while the other aperture is kept at a constant lower temperature. As the air has a higher temperature when passing through the first aperture than through the second, the suction or vacuum in the chamber between these apertures will increase with increase of temperature, because the volume of air varies directly with the temperature (absolute). Therefore, the vacuum between the apertures needs only to be transmitted to the indicators or recorders by small copper tubing, in order to obtain any number of accurate and reliable measurements.

Water Power Withdrawals.—Over a million and a half acres of public land now stand withdrawn by the Government as being valuable for the possible development of water power. During October the United States Geological Survey recommended the withdrawal of 54,422 acres as having power possibilities and the restoral of 2600 acres in Montana and Wyoming because field examination by the Survey showed them not to be valuable for that purpose.

Welding.

At a meeting of the American Society of Mechanical Engineers held in New York, on Nov. 14, the general subject of autogenous welding was discussed in great detail. Mr. H. R. Cobleigh presented an introductory paper dealing with the general aspects of the subject, in which were described the origin and principles of each process and the apparatus used in each. He outlined the features of electric resistance welding, electric arc welding, thermit welding, oxy-acetylene welding and oxy-hydrogen welding. By means of numerous lantern slides the mechanical details of the apparatus employed in each system of welding were described. It was stated that each method possesses certain advantages and certain disadvantages, so that each system may be considered most advantageous for certain particular services. The oxy-acetylene flame produces a higher temperature than oxy-hydrogen, but operates under the disadvantage of a marked tendency to flash back. This tendency has been overcome by the use of special forms of torches, which require the gases to pass through porous material before being ignited. The oxy-hydrogen apparatus has a less tendency to flash back, but the temperature is not so high. The oxygen and hydrogen for the oxy-hydrogen apparatus can conveniently be produced by electrolytic dissociation of water. The acetylene used in the oxy-acetylene torch is produced from calcium carbide, according to the methods employed with illuminating acetylene. The acetylene is produced by dropping water upon the carbide, or by dropping the carbide into water, the latter method having certain advantages. The oxygen used in the oxy-acetylene flame can be produced either by chemical or electrolytic processes. In any event, it is most advantageous to convey the gases in highly compressed form.

Mr. G. E. Pelissier described the Goldschmidt thermit process of welding, which depends upon the chemical combination of aluminium with oxide of iron, and the resultant products being oxide of aluminium and iron. By the use of motion pictures the thermit welding of rails was shown in a striking and most interesting manner. This process has found numerous applications in heavy engineering, such as that in connection with locomotive and ship machinery repairing.

Mr. C. B. Auel gave much interesting information relating to the Bernardos, Slavianoff and Zerener processes of electric welding. These processes differ according to the material used for electrodes. In the first-named process one electrode is formed by the metal to be welded, and the other electrode is of copper. In the second process the two metallic parts to be joined form the electrodes, while in the third process there are two carbon electrodes, with the metal forming an intermediate contact between these two electrodes. Much attention was devoted by the author to the Bernardos process, which he considered to be the most universally applicable. However, the Slavianoff process produces a stronger joint. In this process use is made of an arc of a length of about ¼ in., an emf force of 25 volts and a current of 150 amp. In the Bernardos process the length of the arc would be about 1 in., the current from 160 to 700 amp and the emf from 45 to 50 volts at the arc.

Mr. W. H. Brown described a welder acting according to the Zerener process, which he has found highly advantageous on account of the economy in operation, the consumption being 18 kw as compared with 50 kw by other electrical processes.

The subject was discussed by Messrs. W. H. Spire, J. D. Mooney, Henry Cave, W. R. Noxon, W. H. Lavin, W. J. Fritz, J. F. Springer, E. B. Katte and Dr. Lieber.

Mr. Noxon called attention to the stoppage of leaks by means of oxy-acetylene welding in a pipe line in central Colorado, which carries water under a head of 1875 ft. The cost of welding this pipe line was only a small fraction of the cost which would have been involved in replacing the pipe line.

Mr. Lavin stated that the oxy-hydrogen process has been widely adopted for regular use in industrial establishments for welding purposes. He claimed as an advantageous feature the fact that the oxygen and hydrogen gases for the flame can be obtained in a high degree of purity by the electrolytic method.

Mr. Fritz showed numerous illustrations of the oxy-acetylene flame, which is now being employed for dismantling the ill-fated battleship Maine in the Havana harbor.

Mr. Springer attributed the high temperature of the oxy-acetylene flame to the concentration of heat units in the small space.

Dr. Lieber stated that the Blau gas which is being used in welding is compressed and liquified until it occupies only 1/400 part of its original volume. As compared with acetylene having 1500 heat units per cu. ft., the Blau gas has 1853 heat units.

New Detinning Works.

The Goldschmidt Detinning Company, of New York City, is erecting a new detinning plant in East Chicago, Ind., with a capacity of about 40,000 tons of tin scrap per year. This plant will have several novel and very interesting features.

Instead of using exclusively tin scrap, the company is making all preparations also for the use of old cans, provided they are obtainable in sufficient quantity and at sufficiently low cost. Further the process to be used will be entirely different from the one now employed by the company at their Chrome, N. J., plant. Instead of making anhydrous tetrochloride of tin as is done in Chrome, they will make pig tin in East Chicago.

The buildings for the plant will be completed within a few weeks and it is expected that the plant will be in operation in the Spring of 1912.

Fixation of Atmospheric Nitrogen in Norway.

Arrangements have recently been made, according to *Tidens Tegn*, Kristiania, Norway, between the Badische Anilin and Soda Fabrik and the Norsk Hydroelektrisk Kvaelstofaktieselskab, to the effect that the management of the large airsalpeter developments in Norway will be laid in the hands of the Norwegians, while it has up till now been in charge of the German company. Mr. Sam Eyde, joint inventor with Professor Birkeland of the nitric acid process bearing their name, is to be at the head of the undertaking.

The greater part of the capital interested in the new and old developments is French. The Germans have about one and one-third million dollars, and the Canadians two and two-third million dollars. Swedish as well as Norwegian capital is also quite heavily interested.

The paid-up capital is sufficient to finish the large developments of water power at Rjukan, which is going to be used exclusively in the airsalpeter industry.

NOTES

Unveiling of Bust of Wolcott Gibbs at Chemists' Club.—On the evening of Saturday, Nov. 25, the bust of the late Professor Wolcott Gibbs will be unveiled with appropriate exercises at the Chemists' Club in New York. The bust will be presented on behalf of the Gibbs family by Mr. Geo. Gibbs and will be accepted by Dr. Moore as president of the club. Prof. Charles E. Munroe will deliver the main address. There will be a reception afterwards and a fine musical program has been arranged. The ladies of the club members have been specially invited.

The American Platinum Works of Newark, N. J., have acquired the business of the Croselmire & Ackor Co.

The **Standard Silver Co., Ltd.**, of Toronto, Canada, are building a new five-story factory for the manufacture of silver-plated hollow ware (on Britannia metal, brass, German silver and copper).

The **Geary Water-Tube Boiler** is the subject of a neat and well illustrated little pamphlet of the manufacturers, the Oil City Boiler Works, of Oil City, Pa.

The Care of the Balance.—Messrs. Voland & Sons, makers of precision balances and weights in New Rochelle, N. Y., have just issued a neat little pamphlet on the "use and care of precision balances." It contains elementary but important instructions on the setting up of a balance, when received from the factory, how to place the parts in position, how to obtain the equilibrium, how to clean it, how to release the beam, where to put the balance, how to lubricate, when this should be necessary, etc. There are also some tables on weights and measures and decimal equivalents.

Dredging for Gold is the title of an interesting pamphlet distributed at the recent California meeting of the American Institute of Mining Engineers and containing a well illustrated description of the two newest gold dredges installed by the Natomas Consolidated, of San Francisco and Sacramento. They are of the California endless chain type, having digging buckets of 15 cubic feet capacity. They dig to a depth of 55 feet below the water line of the pond in which they float. They have a maximum theoretical capacity of about 650 cubic yards per hour and have, under favorable conditions, handled 500 cubic yards per hour of running time in continuous operations in formation extremely difficult to handle.

Experiments in slime filtration carried on by George J. Young at the Mackay School of Mines, Reno, Nev., lead him to believe, as stated in a paper presented to the American Institute of Mining Engineers, that: the vacuum filter is best adapted to the treatment of slime containing a large proportion of clayey material; the pressure filter does its best work on slime which contains much coarse and fine sand; while for material containing a small proportion of fine clayey material and much fine sand, either vacuum or pressure filters could be used with perhaps equally good results. Of the vacuum filters, the thin-cake continuous filters are a decided improvement over the thick-cake filters.

Electrolytic Production of Iron.—A recent British patent (28,226, Oct. 19, 1911) of Mr. S. O. Cowper-Coles is mentioned in London *Electrical Engineering*. It relates to an electrolytic process, in which the cathodes consist of thin sheets of electrolytic iron, and the anodes of bars of pig iron of any kind. The electrolyte can be sulphuric or hydrochloric acids, or a mixture of both, or a ferrous ammonium sulphate. Any thickness of iron may be deposited on the cathode, which can be removed from the cell and the iron taken off. To prevent the anodes becoming coated with carbon, graphite or other impurities, brushes are mounted on a spindle, and attached to the cathode. These revolve and keep the anode surface free.

Seger Cones.—In last year's report of the German Reichsanstalt numerous tests of Seger cones in ceramic kilns in practice are mentioned, which were accompanied by thermo-electric measurements. It was found that the Seger cones broke down in the ceramic kilns at considerably lower temperatures than in the electric furnaces of the Reichsanstalt. This may be due to the long time of heating (60 hours), and perhaps also to a chemical effect of the furnace gases. At any rate, this fact must be taken into consideration in using Seger cones for determining temperatures.

Asbestos is most widely used as a fireproof cloth for theater curtains. Other important uses are the making of firemen's clothing, and insulating materials for both steam and electric power plants.

Sealing Wires in Glass Globes.—A method of sealing wires into glass, which, while primarily intended for mercury-vapor lamps, may have wider use, is described in a recent British patent (No. 1880 of Oct. 12) of Mr. G. B. Burnside. As noted in London *Electrical Engineering*, the wire is placed through a small aperture in the glass or other vitreous substance and heated by a blowpipe flame until perfect cohesion between the two takes place. The seal is then removed from the flame, and when at a dull red heat it is cooled by gradually increasing immersions, of about two or three seconds' duration, in some sperm or similar oil or in wax. For currents above 15 amp. round tubular conductors, plugged with a conducting material, are employed. This form is very useful for mercury-vapor lamps or rectifiers, as the tubular shell is made of a substance that does not form an amalgam, and thus protects the copper from the mercury.

Personal

Mr. **Jacques Abady**, a director of the English firm of Alexander Wright & Co., was recently in this country on a two weeks' visit to their American branch, the Precision Instrument Company of Detroit, Mich. In addition to his business activities Mr. Abady is a barrister, the author of Abady's Gas Analyst's Manual, and other works on combustion, and one of the inventors of the Simmance-Abady combustion recorder and the Simmance-Abady vacuum and pressure gauges. His visit had to do with several new inventions which have passed the experimental stage and which will be shortly on the market for general use in steam and gas plants.

Mr. H. Standish Ball, late of McGill University, Montreal, has left for South Africa, where he will accept a position. His address is P. O. Box 2536, Johannesburg, Transvaal, South Africa.

Mr. R. B. Carnahan, Jr., Vice-President of the American Rolling Mill Company of Middletown, Ohio, has returned from a six months' business trip through Europe in the interest of their well-known American ingot iron.

Mr. Arthur H. Carpenter has returned to Denver after an extended stay in Nevada on professional work.

Mr. C. W. Carpenter, of New York, secretary of the Colorado Vanadium Company, recently made a trip of inspection to the company's mines in southwestern Colorado. He was accompanied by Mr. W. F. Bleecker, metallurgist of the company, and Mr. Kirby Thomas, consulting mining engineer.

Mr. J. V. N. Dorr, metallurgist, of Denver, has been appointed general manager of the Mogul Mining Company, Pluma, S. D., for which he has been consulting engineer for some time.

Mr. Arthur Lakes, Jr., of Denver, has gone to Ymir, B. C., to take charge of the mines and mill of the Ymir-Wilcox Development Company.

Mr. James C. Lawrence has resigned his position as chemical engineer in the U. S. Forest Service, to take up the practice of his profession, and has accepted the position as consulting engineer in charge of the operations of the Forest Products Chemical Company of Memphis, Tenn.

Mr. Warren B. Lippincott, who has been identified with the zinc industry for a number of years, has left the Colorado field and gone to Missouri. His partnership with J. M. McClave, of Denver, has been dissolved and his office will be at Joplin, Mo.

Mr. J. B. McIntosh, formerly of Salt Lake City, has removed his office to Los Angeles. He will have charge of the construction of the new copper smelter to be built for the United Verde Copper Company at Jerome, Ariz.

Mr. C. H. Repath, consulting engineer, of Los Angeles, Cal., has charge of the designing of the new copper smelter for the United Verde Copper Company at Jerome, Ariz.

Mr. B. F. Rice, vice-president and general manager of the McKesson Concentrator Company, of Colorado Springs, has opened an office in the Ideal Building, Denver.

Mr. Etienne A. Ritter, of Colorado Springs, has been examining the carnotite deposits in Utah.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Ore Treatment (*Continued*).

495,637, April 18, 1893, Johannes Pfleger, of Frankfort-on-the-Maine, Germany.

Zinc. Electrodeposits zinc from solutions, or extracts pure zinc from zinc ore, hard zinc, zinc alloys, etc., by use of basic zinc salts obtained by dissolving oxide of zinc in concentrated solutions of sulphates or chlorides of zinc. When used as an electrolyte, all dissolved impurities, such as copper, are precipitated. Like impurities from soluble anodes cannot be dissolved, as basic copper chloride or sulphate is insoluble in the basic zinc solution. The basic zinc salt may be added to neutral solutions; or, with oxide of zinc in suspension, to acid salts. When used as electrolyte, formation of a spongy zinc deposit is prevented. To the solution of basic zinc salt may be added a good conducting neutral salt, such as chloride of sodium or magnesium, of sulphate of potash, and the solution circulated through the electrolytic bath. If necessary zinc oxide may be intermittently or continuously added.

495,715, April 18, 1893, Samuel R. Whitall, of Salt Lake City, Utah.

Gold and silver. Treats chloride, sulphide or arsenide ores containing, besides gold and silver, copper, iron and other impurities, by crushing to pass 16 to 40 mesh screen, then pouring over the dry ore a solution containing ½% to 1½% (of quantity of ore) potassium cyanide, with about 1/3 this quantity of sodium hyposulphite. Water is added in quantity sufficient to cover the ore and allowed to stand until precious metals are dissolved. Gold and silver are then precipitated by zinc or by electrolysis, platinum or carbon anodes being used and a cathode of wires or strips of metal, preferably iron, arranged in parallel lines on copper wires. Gold and silver will be deposited on wires as fine powder, which is collected, dried and melted into bars. Barium, calcium or sodium cyanides may be used instead of potassium cyanide.

If the ore is siliceous, it is first treated with caustic soda and steam under pressure to form a soluble silicate, thereby freeing the precious metals from their combinations with base metals. If the ore is sulphide, it is first given a chlorinating roast with salt and lixiviated with water. Copper or lead contained in the wash water is precipitated by any well-known means.

497,014, May 9, 1893, Frederick W. Cleghorn, of Salt Lake City, Utah, Assignor to Charles G. Brown, of same place.

Gold and silver. The ore is pulverized and screened through a No. 10 screen and saturated in a tank with solution of hyposulphite of soda and sulphuric acid while heated by steam. The sulphuric acid neutralizes impurities of solution. The gold and silver are precipitated as sulphides by calcium or sodium sulphide dried, roasted and cupelled.

The ore remaining in the tank is saturated with sulphuric acid, or muriatic acid, and salt. The gold and silver are precipitated from the solution as chlorides by metallic iron and passing an electric current through the solution. The remaining solutions may be used again.

501,997, July 25, 1893, Stephen H. Emmens, of London, England.

Iron, copper, etc. The apparatus comprises a shallow rectangular vat of paraffined wood. The sides and bottom of the vat are lined with carbon, which forms the anode. An inner rectangular wall of paraffined wood is placed on the carbon floor, leaving a space about four inches wide between it and the carbon side lining on all four sides. The space between the inner wall and the sides of the vat is filled with the ore or other material and a layer of such material about six inches deep is placed on the carbon floor. The electrolyte (such as an aqueous solution of ammonium sulphate or chloride) is poured into the vat until there is a depth of about four inches above the ore, but within the inner rectangular wall. The cathodes consist of a series of rectangular perforated plates suspended parallel with the floor and connected to cross bars extending across the vat, the cathodes being hung about two inches from the layer of ore. The electrolyte can pass underneath the inner wall and saturate the material between the inner wall and the wall of the vat, this arrangement preventing the short-circuiting between the cathode and the ore. The acid constituent of the electrolyte unites with the metal or metallic oxide to form a solution which is in turn decomposed, the metal being deposited and the acid set free to take up a fresh charge of metal from the ore. The perforations in the cathodes facilitate the escape of hydrogen and circulation of the fluid in the upper portion of the vat. When iron ore or scrap iron is being treated for the production of malleable iron, paraffin oil may be poured on the surface of the electrolyte to prevent oxidation. A screen of coarse canvas impregnated with paraffin oil may be supported beneath the cathodes to collect material falling from the cathodes. The apparatus is also applicable to reduction of copper ores, treatment of jewellers' sweepings, sulphides, and other metalliferous substances.

BOOK REVIEWS.

Die Metallurgie des Wolframs.—Praktisches Handbuch von Dr. **Hans Mennicke.** 416 pages, 39 illus. Price 15 Marks in paper cover, 17 Marks bound in cloth. Berlin: M. Krayn.

This book is intended primarily as a reference book. To many it will seem almost incredible that the metallurgy of tungsten requires so bulky a volume, yet the information contained in these pages is for the most part very concise. Although but a few decades ago tungsten was classed as a rare metal, it has in recent years taken a very prominent place among the useful metals. The author has covered every article and patent pertaining to tungsten that have appeared in the last twenty years.

Among the chapter headings are: Ores, Reduction Methods, By-products including scandium, titanium, tantalum and niobium, Manufacture of Sodium Tungstate, Tungstic Acid, Alloys and Compounds, Tungsten Filaments, Fire-proofing Cotton and other Fabrics, and Analytical Methods. Although the chapters on tungsten steel and on tungsten-filament manufacture are comparatively brief and the information based largely on patent literature, the chapters on the production of tungsten powder are particularly well treated, the author having had considerable experience in this line. The book will be welcomed not only by research students but also by steel metallurgists and incandescent-lamp manufacturers.

The Soil Solution. By **Frank K. Cameron.** 125 pages. Price $1.25. Easton, Pa.: The Chemical Publishing Company.

This is an interesting elementary chemical text-book on the nutrient medium for the growth of plants in soil, written from the physico-chemical standpoint. As a rule, books on this subject are either intensely technical and difficult, or they are popular in character so as to aid the practising farmer or horticulturist in raising crops for the market.

This book occupies a middle position. It is neither so technical as to appeal only to specialists, on the one hand, nor so popular and practical as to appeal solely to business men on the other. The book will interest the scientific student of agriculture, the student of applied chemistry and the scientifically minded members of the public at large.

Its thirteen chapters deal with the following topics: The soil, soil management, soil analysis, plant-food theory, dynamic soil phenomena, film water, mineral constituents, absorption by soils, plant growth and concentration, supply and removal of mineral nutrients, organic constituents, fertilizers and alkali.
